For large nha values and arbitrary angles ϑ, with $nh\Delta \ll 1$, the minimum root of the determinant is

$$p=-\frac{2\chi^2}{a\Delta}nl\sqrt{1+\frac{l^2}{h^2a^2}}.\qquad(1.18)$$

Expression (1.18) implies that the minimum root increases with the harmonic number and hence the duration of the transient decreases.

Let us consider the steady-state process for a current that varies harmonically:

$$j_n(t)=j_{n0}\sin\omega t\qquad(1.19)$$

with frequency ω and amplitude j_{n0}.

The Fourier components $\tilde f_n(r,\ t)$, $\tilde g_n(r,t)$, and $\tilde q_n(r,\ t)$ that describe the steady-state process can be written in the following form in accordance with (1.19):

$$\left.\begin{array}{r}\tilde f_n^{(i)}(r,\ t)\\ \tilde q_n^{(i)}(r,\ t)=-\frac{hr}{l}\tilde g_n^{(i)}(r,\ t)\end{array}\right\}$$
$$=-\frac{4\pi}{c}j_{n0}nhaF_n^{(i)}\sin(\omega t-\Phi_n^{(i)})K'_{nl}(nha)\begin{array}{l}iI'_{nl}(nha),\\ I_{nl}(nha),\end{array}\qquad(1.20)$$

$$\left.\begin{array}{r}\tilde f_n^{(e)}(r,\ t),\\ \tilde q_n^{(e)}(r,\ t)=-\frac{hr}{l}\tilde g_n^{(e)}(r,\ t)\end{array}\right\}$$
$$=-\frac{4\pi}{c}j_{n0}nhaF_n^{(e)}\sin(\omega t-\Phi_n^{(e)})I'_{nl}(nha)\begin{array}{l}iK'_{nl}(nha),\\ K_{nl}(nha),\end{array}\qquad(1.21)$$

where the quantities $F_n^{(i)}$, $F_n^{(e)}$, $\Phi_n^{(i)}$, $\Phi_n^{(e)}$ that characterize the changes in the amplitudes and the phase shifts of the field introduced by the conducting medium are determined by the expressions

$$F_n^{(i)}=|G_n^{(i)}(i\omega)|\,|D_n^{-1}(i\omega)|^{-1},\quad \Phi_n^{(i)}=\arg[D_n(i\omega)G_n^{(i)-1}(i\omega)],\qquad(1.22)$$

$$F_n^{(e)}=|G_n^{(e)}(i\omega)|\,|D_n(i\omega)|^{-1},\quad \Phi_n^{(e)}=\arg[D_n(i\omega)G_n^{(e)-1}(i\omega)].\qquad(1.23)$$

Expressions (1.20) and (1.21) for the Fourier coefficients of the magnetic field become much simpler for thin walls; when $nh\Delta \ll 1$ the ratio of the wall thickness to the skin depth δ is much less than unity.

Using expression (1.13) for the determinant and the expansion of the functions $G_n^{(i)}$ and $G_n^{(e)}$ from the general equation (1.19), we find

$$\left.\begin{array}{c} f_n^{(i)}(r,t), \\ q_n^{(i)}(r,t) = -\frac{hr}{l} g_n^{(i)}(r,t) \end{array}\right\} = -\frac{4\pi}{c} j_{n0} nha \Psi_n(\omega, t) K'_{nl}(nha) \begin{array}{c} iI'_{nl}(nhr) \\ I_{nl}(nhr), \end{array} \tag{1.24}$$

$$\left.\begin{array}{c} f_n^{(e)}(r,t), \\ q_n^{(e)}(r,t) = -\frac{hr}{l} g_n^{(e)}(r,t) \end{array}\right\} = -\frac{4\pi}{c} j_{n0} nha \Psi_n(\omega, t) I'_{nl}(nha) \begin{array}{c} iK'_{nl}(nhr) \\ K_{nl}(nhr), \end{array} \tag{1.25}$$

where

$$\Psi_n(\omega, t) = [\sin(\omega t - \Phi_n) + e^{-t/\tau_n} \sin \Phi_n] \cos \Phi_n, \tag{1.26}$$

and the phase is determined from the equation

$$\operatorname{tg} \Phi_n = \omega\tau_n = -\frac{2a\Delta}{\delta^2} \frac{h^2a^2}{l^2 + h^2a^2} I'_{nl}(nha) K'_{nl}(nha). \tag{1.27}$$

It turns out that $\Psi_n(\omega, t)$ is a universal function that describes the penetration of spatially periodic fields into a cavity for which the thickness of the conducting walls is much less than the skin depth and spatial period of the field. This conclusion will evidently hold for any cavity. As a result, to determine the magnetic field as a function of time when there is a conducting chamber, it suffices to know the solutions for the field components in a vacuum (without conducting walls) and to replace $\sin \omega t$ by the function $\Psi_n(\omega, t)$ in them. This function is determined by the duration of the transient τ_n, which depends on the geometry of the cavity and the current distribution.

In the other limiting case, in which $\Delta/\delta = \xi \gg 1$ and $n^2h^2\delta^2 \ll 1$, the functions (1.22) and (1.23) are given by

$$F_n^{(i)} = -\sqrt{2} e^{-\zeta} \frac{\delta}{\sqrt{ab}} \left(1 + \frac{l^2}{h^2a^2}\right) \frac{1}{I'_{nl}(nha) K'_{nl}(nha)}, \quad \Phi_n^{(i)} = \zeta + \frac{\pi}{4}, \tag{1.28}$$

$$F_n^{(e)} = -\sqrt{2} \frac{\delta}{a} \left(1 + \frac{l^2}{h^2a^2}\right) \frac{1}{I'_{nl}(nha) K'_{nl}(nha)}, \quad \Phi_n^{(e)} = \frac{\pi}{4}. \tag{1.29}$$

The field amplitude in the chamber is exponentially small in this case, while the phase is arbitrary.

2. PENETRATION OF A HELICAL FIELD INTO A SOLID CONDUCTING CYLINDER

Let us consider the diffusion of a helical field into a solid conducting cylinder.

The Fourier coefficients for the Laplace transformations of the field components are described by expressions (1.4) and (1.5), as before, in which we must set the coefficients $C_n^{(i)}$, B_{in}, and B_{2n} equal to zero. The nonzero coefficients are

$$\left.\begin{aligned} C_n^{(e)} &= -\frac{4\pi}{c} J_n nha G_n(p) D_n^{-1}(p) I'_{nl}(nha), \\ A_{1n,2n} &= -\frac{4\pi i}{c} J_n D_n^{-1}(p) \left[I'_{nl\mp1}(\varkappa_n a) \mp \frac{\varkappa_n l}{nh^2a} I_{nl}(\varkappa_n a) \right] K'_{nl}(nha), \end{aligned}\right\} \tag{2.1}$$

where

$$\left.\begin{aligned} G_n(p) &= \frac{1}{nhaI'_{nl}(nha)} \left[I'^2_{nl}(\varkappa_n a) + \frac{l^2q^2}{\varkappa_n^2 h^2a^2} I^2_{nl}(\varkappa_n a) \right], \\ D_n(p) &= \left[I'^2_{nl}(\varkappa_n a) + \frac{q^2l^2}{\varkappa_n^2 h^2a^2} I^2_{nl}(\varkappa_n a) \right] K_{nl}(nha) \\ &\quad - \frac{\varkappa_n}{nh} I_{nl}(\varkappa_n a) I'_{nl}(\varkappa_n a) K'_{nl}(nha). \end{aligned}\right\} \tag{2.2}$$

Let us investigate the roots of the determinant in the limiting cases. If $q^2 \ll n^2h^2$, the determinant can be written in the form

$$D_n(p) = D_0 + \frac{q^2}{n^2h^2} D_1, \tag{2.3}$$

where

$$\left.\begin{aligned} D_0 &= \frac{I'_{nl}(nha)}{nha}, \\ D_1 &= \left(1 + \frac{l^2}{h^2a^2}\right) I_{nl}(nha) + \left[\frac{l^2}{h^2a^2} I^2_{nl}(nha) - I'^2_{nl}(nha)\right] K_{nl}(nha) \\ &\quad + \frac{nha}{2} \left[\left(1 + \frac{l^2}{h^2a^2}\right) I^2_{nl}(nha) - I'^2_{nl}(nha)\right] K'_{nl}(nha). \end{aligned}\right\} \tag{2.4}$$

The minimum root of the determinant is

$$p = -\chi^2 n^2 h^2 \frac{D_0}{D_1}. \tag{2.5}$$

The condition $q^2 \ll n^2h^2$ holds for any nha if $n^2l^2 \gg 1$. If $nha \ll 1$, the penetration time is

$$\tau_n = -\frac{1}{p} = \frac{\pi\sigma l}{c^2nh^2}. \tag{2.6}$$

It is independent of the dimensions of the conducting cylinder and determined by the spatial periods of the distribution of the currents that create the field.

For a steady-state process we can write the Fourier components in the form

$$\left.\begin{array}{c} \tilde f_n^{(e)}(r,t), \\ \tilde q_n^{(e)}(r,t) = -\frac{hr}{l} \tilde g_n^{(e)}(r,t) \end{array}\right\} = -\frac{4\pi}{c} j_{n0} nha F_n^{(e)} I'_{nl}(nha) \sin(\omega t - \Phi_n^{(e)}) \begin{array}{c} iK'_{nl}(nhr) \\ K_{nl}(nhr), \end{array} \tag{2.7}$$

$$\left.\begin{aligned} \tilde f_n(r,t) &= -\frac{4\pi i}{c} j_{n0} nha I'_{nl}(nhr) K'_{nl}(nha) \sin[\omega t - \Phi_r(r)], \\ \tilde g_n(r,t) &= \frac{4\pi}{c} j_{n0} \frac{nla}{r} I_{nl}(nhr) K'_{nl}(nha) \sin[\omega t - \Phi_\varphi(r)], \\ \tilde q_n(r,t) &= -\frac{4\pi}{c} j_{n0} nha I_{nl}(nhr) K_{nl}(nha) \sin[\omega t - \Phi_z(r)], \end{aligned}\right\} \tag{2.8}$$

$$\operatorname{tg} \Phi_\alpha(r) = \frac{\omega^2}{\chi^2 n^2 h^2} \left(\frac{D_1}{D_0} - f_\alpha\right), \tag{2.9}$$

α taking the values r, φ, z, where

$$\left.\begin{aligned} f_r &= -1 + \frac{nha}{2}\left(1 + \frac{l^2}{h^2a^2}\right) \frac{I_{nl}(nha)}{I'_{nl}(nha)} \\ &\quad + \left[\frac{l^2 I_{nl}(nha)}{h^2arI'_{nl}(nha)} + \frac{nhr}{2}\left(1 + \frac{l^2}{h^2r^2}\right)\right] \frac{I_{nl}(nhr)}{I'_{nl}(nhr)}, \\ f_\varphi &= -1 + \frac{nha}{2}\left(1 + \frac{l^2}{h^2a^2}\right) \frac{I_{nl}(nha)}{I'_{nl}(nha)} \\ &\quad + \left[\frac{I_{nl}(nha)}{I'_{nl}(nha)} + \frac{nhr}{2}\right] \frac{I'_{nl}(nhr)}{I_{nl}(nhr)}, \\ f_z &= \frac{nha}{2}\left[\left(1 + \frac{l^2}{h^2a^2}\right) \frac{I_{nl}(nha)}{I'_{nl}(nha)} + \frac{rI'_{nl}(nhr)}{aI_{nl}(nhr)}\right]. \end{aligned}\right\} \tag{2.10}$$

On the axis, the phase shift of each component is nonzero.

Using the summation equations, we can obtain expressions for the phase shifts in the case of stellarator and torsatron windings.

Quantum electronics

Solid-state laser with externally forced Q switching

N. M. Galaktionova, A. A. Mak, and A. P. Khyuppenen

(Submitted September 6, 1973)
Zh. Tekh. Fiz., 44, 1883-1889 (September 1974)

An experimental investigation of the modulation of the radiation of a stabilized YAG : Nd^{3+} laser is reported; the resonator loss is modulated over a wide range of frequencies and modulation indices. By varying the loss modulation of a single-mode laser all the usual operating conditions of solid state lasers can be obtained. The modulation indices are measured. The results are in good agreement with the solutions of the linearized kinetic equation over a wide range of modulation. The mechanisms by which the resonator loss is modulated is discussed.

1. Despite the large number of published papers in the field, at the present time many modes of operation of solid state lasers have not received a satisfactory explanation. Various mechanisms have been used to interpret the different modes of operation. Spike generation[1–3] is explained by fluctuations in the loss and pumping inside the active medium. These fluctuations[4] are due to instabilities in the shape of the resonator and its optical length. Regular pulse operation, which, as a rule, is obtained when a large number of transverse modes are generated in spherical resonators,[5–7] is due to the interaction of transverse modes which are very close in frequency,[8] or saturation absorption.[5,7] The mechanism by which periodic packets of spikes are emitted is still unclear.[9] Hence, all the explanations of the kinetic modes of operation reduce to some form of modulation (random or periodic) of the loss or gain of the active medium. Experimental investigations of the emission kinetics have been carried out; but without good stabilization of the laser parameters one cannot determine the origin of this modulation.[6,10,11]

In the present paper we show experimentally that both under single-mode and multimode conditions all the well-known dynamic modes of operation can be obtained by harmonic modulation of the resonator loss; simulation of these modes of operation can be achieved by changing the frequency and the depth of modulation in Q-switching.

2. In the experiments we use a stabilized cw YAG: Nd^{3+} laser; the resonator construction and the measures taken to ensure stability are described in ref. 12. The optical arrangement of the laser and the experimental apparatus are shown in Fig. 1. The laser is pumped with high-pressure krypton arc lamps in circular cylindrical exciters with a diffuse scattering coating. We use active elements 3 mm in diameter and 50 mm in length. The thermal birefringence of the active elements is compensated with a 90° rotator. All the elements inside the resonators are clear and inclined to the axis of the resonator. The Q switch consisted of a Glan prism and a Pockels call which contains lithium niobate. The optic axis of the crystal is perpendicular to the cut. The x and y crystallographic axes make an angle of 45° with the plane of the electric vector transmitted by the polarizer. The electric field in the cell is parallel to the plane of the extraordinary ray. The dependence of the loss on the voltage and the frequency characteristic of the modulator are checked by modulating the constant flux when the modulator is removed from the resonator. The loss is calibrated by internal-resonator modulation at low frequencies, the modulation in which is independent of frequency. We thus measure the modulation factor of the radiation m_p for a given value of the modulator voltage, and the modulation factor of the loss m_γ is found from the equation[12]

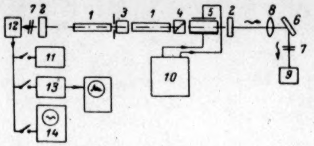

Fig. 1. Experimental arrangement. 1) Active elements; 2) resonator mirrors [τ_1 = 0.05%, τ_2 = 3%]; 3) polarization rotator; 4) Glan prism; 5) Pockels cell; 6) rotatable mirror; 7) neutral filters; 8) focusing lens; 9) image-converter tube; 10) sonic generator; 11) DC voltmeter, 12) photodiode; 13) measuring amplifier; 14) spectrum analyzer; 15) oscilloscope.

$$m_p = m_\gamma \frac{n}{n-1}, \tag{1}$$

where n is the excess of the pumping above the threshold. The amplitude of the loss rate introduced into the resonator in modulation is defined as $\Delta\gamma = m_\gamma\gamma$; where γ is the

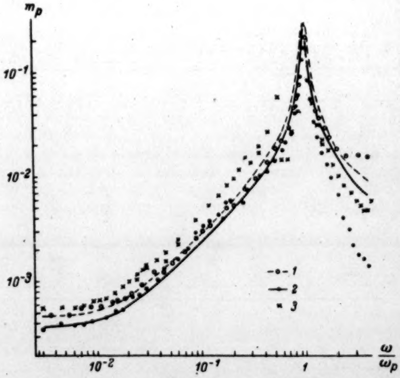

Fig. 2. Frequency characteristics of the emission modulation. 1) Theoretical and experimental values when an axial transverse mode is generated, $m_\gamma = 6.6 \cdot 10^{-5}$, $n = 1.15$, $\omega_p = 3.6 \cdot 10^5$ sec^{-1}; 2) the same quantities and spectral composition of the emission, $m_\gamma = 8.1 \cdot 10^{-5}$, $n = 1.3$, $\omega_p = 4.3 \cdot 10^5$ sec^{-1}; 3) experimental values when several transverse modes are generated, $m_\gamma = 1.5 \cdot 10^{-4}$, $n = 1.5$, $\omega_p = 4.2 \cdot 10^5$ sec^{-1}.

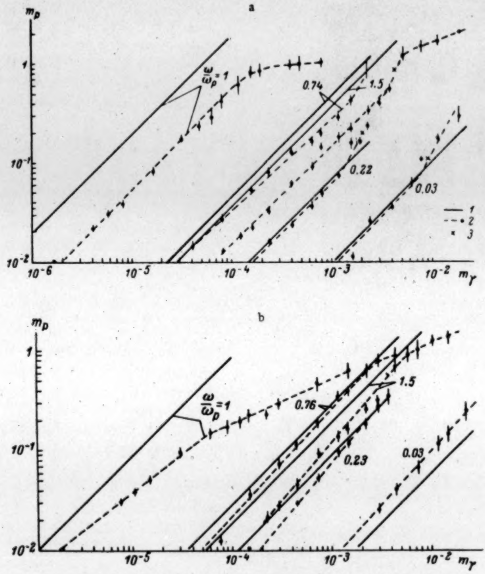

Fig 3. Amplitude characteristics of the emission modulation. 1) Theoretical values; 2) experimental values; 3) values for which random radiation pulses begin. a) $m_\gamma = 6.6 \cdot 10^{-5}$, $n = 1.15$, $\omega_p = 3.6 \cdot 10^5$ sec^{-1} when generating the fundamental transverse mode; b) $m_\gamma = 1.5 \cdot 10^{-4}$, $n = 1.5$, $\omega_p = 4.2 \cdot 10^5$ sec^{-1} when generating several transverse modes.

loss rate of the resonator, which is found by measuring the frequency of relaxation oscillations ω_p, and is given by[12]

$$\gamma = \frac{\omega_p^2 \tau}{n-1}, \qquad (2)$$

where τ is the lifetime of the upper excited level of the working transitions, $\tau = 2 \cdot 10^{-4}$ sec.

The modulation of the emission is measured by a dc voltmeter (the constant component) and an amplifier (the variable component of the photodiode signal). The frequency spectrum of the modulation is monitored by ASChKh-1 and SCh-8 analyzers. The emission output is photographed from the screen of an oscilloscope. The transverse modes are monitored on an image-converter tube, onto the cathode of which we project the far field radiation by means of a lens. The spectrum of the longitudinal modes consists of two to three groups with three to four modes in each group. The overall width of the spectrum is less than 0.2 Å. The laser noise in the measuring apparatus enables us to measure the modulation factor of the radiation in the frequency range from 20 Hz to 300 KHz up to a value of $3 \cdot 10^{-3}$. Measurement of the harmonic oscillations, previously calibrated by the spectrum analyzer, increases the range of sensitivity to 10^{-4}.

3. The frequency and amplitude characteristics are measured in the following sequence. A stop 1.5 mm in diameter is placed in the resonator, the modulator is calibrated, and readings are taken of the modulation characteristic under single-mode conditions. The stop is then removed, and without changing the pumping or adjusting the mirrors, we investigate multimode operation at the same frequencies and modulator voltage. In measuring the amplitude characteristics for different depths of loss modulation we photograph the emission signal. The results of the measurements of single-mode radiation modulation are compared with the results of calculations carried out using the equation[12]

$$m_p = \Delta\gamma \left[\frac{\omega^2 + 4\beta^2}{(\omega^2 - \omega_p^2)^2 + 4\beta^2\omega^2} \right]^{1/2}, \qquad (3)$$

where ω is the angular modulation frequency, and $\beta = n/2\tau$ is the attenuation constant.

Figures 2 and 3 show the results of measurements of the emission modulation. The measurements show that when an axial transverse mode is generated the modulation is less than the theoretical value. This tendency is pronounced for $\omega \geq \omega_p$. Under multimode conditions the amplitude and frequency characteristics of the overall emission with the exception of the region around $\omega = \omega_p$, are close to single-mode operation.

Figure 4 shows the emission in single-mode lasing for different frequencies and modulation depths. Harmonic modulation of the loss up to a certain value of the modulation depth independent of the ratio ω/ω_p, gives rise to harmonic modulation of the emission, the value of which

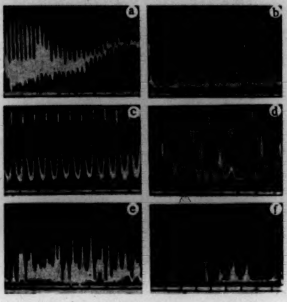

Fig. 4. Oscillograms of the radiation for different values of the loss modulation parameters. a) $\omega/\omega_p = 3\cdot10^{-2}$, $m_\gamma = 1.1\cdot10^{-2}$, i_p = 50 μsec/div; b) 0.37, $0.7\cdot10^{-2}$ 20 μsec/div; c) 1, $5.3\cdot10^{-4}$, 20 μsec/div; d) 0.12, $0.1\cdot10^{-2}$, 15 μsec/div; e) 0.49, $5.3\cdot10^{-3}$, 20 μsec/div; f) 2.6, $2.7\cdot10^{-2}$, 20 μsec/div.

is proportional to the loss modulation factor. The limiting value $m_\gamma^{\lim}$, up to which the emission follows the loss modulation is a minimum for $\omega = \omega_p$, and is $\sim 0.6\cdot10^{-4}$, and increases as the difference $(\omega - \omega_p)$ increases. Thus, for $\omega/\omega_p = 0.03$, $m_\gamma^{\lim} \sim 10^{-2}$. The modulation factor for the limiting values of $m_\gamma^{\lim}$ at all frequencies lies in the range 0.1-0.3. A further increase in the modulation depth of the loss gives rise to another mode of operation, the form of which depends on the ratio ω/ω_p. The damped-pulse mode of operation is obtained at low modulating frequencies $\omega/\omega_p = 0.02$-0.06 (Fig. 4a). Equidistant packets of regular pulses occur for $\omega/\omega_p = (0.1$-$0.4)$. The repetition period of the packets is equal to or a multiple of the modulation period, while the pulses in a packet follow one another at the frequency of the relaxation oscillations. This mode of operation is unstable, and with fixed modulation parameters we observed from one to three or four pulses in each packet (Fig. 4b, d). At frequencies close to the relaxation frequency regular pulses are observed (Fig. 4c). Spikes which are random in amplitude and repetition frequency are observed (Fig. 4e), at higher loss modulation factors; the values are smaller the closer the modulation frequency is to the relaxation frequency. This value is smaller than 10^{-2} for all the modulation frequencies, and is 10^{-4} for $\omega = \omega_p$. At frequencies greater than ω_p the spikes follow each other at intervals which are a multiple of the modulation period τ_M. For example, in Fig. 4f the time between the first two pulses is $8\tau_M$, between the four following pulses is $3\tau_M$, and between the two following pulses is $7\tau_M$. A similar sequence is also observed for multimode operation.

4. Stable lasing in the absence of loss modulation, and the possibility of simulating the kinetics of harmonic loss modulation leads to the assumption that such modulation of the laser parameters is always present. One of the probable reasons for this in pulsed lasers is natural longitudinal and transverse mechanical oscillations excited in the active element by thermal shock. In this case, if the active element is a weak selector for long waves λ_0, determined by the length of the resonator, the losses in such a resonator depend on the transmission of the selector. Modulation of the transmission of such a selector when the optical length of the element is changed with frequency Ω, can be represented in the form

$$\left.\begin{aligned}\tau &= 1-\frac{F}{2}\left[1-J_0(\beta)+2\sum_{k=1}^{\infty}J_{2k}(\beta)\cos 2k\Omega t\right],\\ \beta &= \frac{4\pi}{\lambda_0}h,\quad F=\frac{4R}{(1-R)^2},\quad \Delta\omega = 2(1+\beta)\Omega,\end{aligned}\right\} \tag{4}$$

where R is the reflectance of the ends of the element, $\Delta\omega$ is the width of the modulation frequency spectrum, h and Ω are the amplitude and frequency of the natural longitudinal oscillations of the active element respectively, and J_k are the Bessel functions of the first kind and k-th order.

Numerical calculation shows that for $h \sim \lambda_0/2$ the frequency of the relaxation oscillations lies in the modulation frequency bands. When the ends of the element are cut at the Brewster angle, Q switching gives rise to natural transverse modes of oscillation, which are excited in the element when there is pulsed heating which is nonuniform over the cross section. As our experiments have shown,[12] even for a spherical resonator, an amplitude of the angular oscillations of the ends of approximately 1" leads to spike generation. It can be shown that in the case of transverse oscillations the frequency of relaxation oscillations lies in the modulation frequency band.

Hence, we can conclude that modulation of the radiation of single-mode solid state lasers is induced, and is determined by the modulation of the loss and the pumping. The variety of kinetic modes of operation is determined by the nature of the transients in solid state lasers, and by nonlinear interaction between the modulated electromagnetic field and the active medium.

The authors thank V. B. Volkonskii for the modulator and for consultation.

Aberrations in systems with plane and spherical detection apertures

V. V. Izokh, A. V. Sergeev, and I. Yu. Shmidov

V. I. Lenin Belorussian State University, Minsk

(Submitted July 4, 1973; resubmitted January 19, 1974)
Zh. Tekh. Fiz., 44, 1889-1895 (September 1974)

A computer comparison has been made of the ray aberrations in the images obtained from systems with plane and spherical detection apertures. The aberrations in the image of object points lying near the origin of coordinates of the object plane for a spherical aperture are smaller than the aberrations of a plane aperture for a given angular aperture. As the distance from the center of the object increases the aberrations in a spherical detecting aperture exceed those for a plane aperture. Furthermore, an increase in the angular aperture of the detection apertures of the imaging system leads to an increase in the size of the regions in the object plane for which the aberrations for a spherical receiving aperture do not exceed those for a plane aperture.

Digital holography is currently the subject of considerable interest. It is difficult to overestimate the usefulness of computers in constructing images in acoustic and microwave holography. There is a possibility of using an amplitude detector to measure the diffraction field of an object without a reference wave and to reconstruct the object from this field by means of a computer. This possibility has been studied theoretically[1,2] and demonstrated experimentally.[3] In this note we carry out a comparative evaluation of the aberrations in the images constructed from a measurement of the diffraction field of an object at points in the plane of the detection aperture at a distance z = d from the object and at points in a spherical aperture of radius $\rho = a$ (Fig. 1).

We turn first to the aberrations of an image constructed from the field values measured at points in a plane detection aperture.

According to the theory of inverse diffraction,[4] the field distribution in the plane of the reconstructed image is related to the field distribution in the object plane, $U_1(x_1, y_1, 0)$, by

$$U_3(x_3, y_3, z_3) = -\frac{1}{4\pi^2}\iiiint\limits_{-\infty}^{\infty} U_1(x_1, y_1, 0)\left[\frac{\partial}{\partial z_1}\frac{\exp jk_1 r_{1p}}{r_{1p}}\right]_{z_1=0} \times\left[\frac{\partial}{\partial z_2}\frac{\exp - jk_2 r_{2p}}{r_{2p}}\right]_{z_2=d}\operatorname{rect}\left(\frac{x_{2p}}{D_{xp}}\right)\operatorname{rect}\left(\frac{y_{2p}}{D_{yp}}\right)dx_1 dy_1 dx_{2p} dy_{2p}, \quad (1)$$

where

$$r_{1p} = [(x_{2p} - x_1)^2 + (y_{2p} - y_1)^2 + d^2]^{1/2}, \quad (2)$$

$$r_{2p} = [(x_3 - x_{2p})^2 + (y_3 - y_{2p})^2 + (z_3 - d)^2]^{1/2}, \quad (3)$$

D_{xp} and D_{yp} are the dimensions of the plane detection aperture, subscript "p" corresponds to the field in the plane, $k_1 = 2\pi/\lambda_1$, λ_1 is the wavelength of the illuminating wave, $k_2 = 2\pi/\lambda_2$, λ_2 is the wavelength of the reconstruction wave, and

$$\operatorname{rect}(x) = \begin{cases} 1 & \text{for } |x| \leqslant \frac{1}{2}, \\ 0 & \text{otherwise.} \end{cases} \quad (4)$$

According to the theory for the formation of images by linear systems,[5] Eq. (1) implies that

$$H_p = \iint\limits_{-\infty}^{\infty}\left[\frac{\partial}{\partial z_1}\frac{\exp jk_1 r_{1p}}{r_{1p}}\right]_{z_1=0}\left[\frac{\partial}{\partial z_2}\frac{\exp - jk_2 r_{2p}}{r_{2p}}\right]_{z_2=d} \times \operatorname{rect}\left(\frac{x_{2p}}{D_{xp}}\right)\operatorname{rect}\left(\frac{y_{2p}}{D_{yp}}\right)dx_{2p} dy_{2p} \quad (5)$$

is the pulsed response of the system. Carrying out the corresponding calculations in the integrand in (5), we find

$$H_p = \iint\limits_{-\infty}^{\infty} A_p(x_{2p}, y_{2p}) \exp j\varphi_p(x_{2p}, y_{2p})\, dx_{2p} dy_{2p}, \quad (6)$$

where

$$A_p(x_{2p}, y_{2p}) \simeq \frac{k_1 k_2}{d\,|z_3 - d|}\operatorname{rect}\left(\frac{x_{2p}}{D_{xp}}\right)\operatorname{rect}\left(\frac{y_{2p}}{D_{yp}}\right), \quad (7)$$

$$\varphi_p(x_{2p}, y_{2p}) \simeq k_1 r_{1p} - k_2 r_{2p} - \pi \quad (8)$$

with

$$k_1 r_{1p} \gg 1, \quad k_2 r_{2p} \gg 1. \quad (9)$$

According to ref. 5, the image aberrations are governed by the phase component of the pulsed response of the system, (8). The structure of (8) allows us to use the method proposed in ref. 6 for calculating the third-order aberrations; using this method, we find that the aberrations of an image formed by a system with a plane detection aperture are described by

$$\Delta_p = \frac{1}{8}\left(\frac{k_2}{|z_3 - d|^3} - \frac{k_1}{d^3}\right)\beta_p^4 + \left(\frac{k_1}{d^3} - \frac{k_2 M_p}{|z_3 - d|^3}\right)\beta_p^2\alpha_p^2 + \frac{1}{2}\left(\frac{k_2 M_p^2}{|z_3 - d|^3} - \frac{k_1}{d^3}\right)\alpha_p^4 + \frac{1}{4}\left(\frac{k_2 M_p^2}{|z_3 - d|^3} - \frac{k_1}{d^3}\right)\beta_p^2\gamma^2 + \frac{1}{2}\left(\frac{k_1}{d^3} - \frac{k_2 M_p^3}{|z_3 - d|^3}\right)\gamma^2\alpha_p^2, \quad (10)$$

where

$$\beta_p^2 = x_{2p}^2 + y_{2p}^2, \quad \alpha_p^2 = x_1 x_{2p} + y_1 y_{2p}, \quad \gamma^2 = x_1^2 + y_1^2, \quad (11)$$

$$M_p = \frac{|z_3 - d|}{d}\frac{k_1}{k_2}. \quad (12)$$

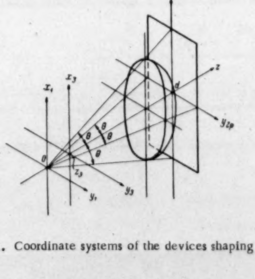

Fig. 1. Coordinate systems of the devices shaping the image.

The first term in (10) corresponds to spherical aberration, the second to coma, the third to astigmatism, the fourth to field curvature, and the fifth to distortion.[7]

Let us find the conditions under which these aberrations vanish. There is no spherical aberration if

$$\frac{k_2}{|z_3-d|^3}-\frac{k_1}{d^3}=0 \quad \text{or} \quad \frac{|z_3-d|^3\lambda_2}{d^3\lambda_1}=1. \tag{13}$$

Coma vanishes if

$$\frac{k_1}{d^3}-\frac{k_2M_p}{|z_3-d|^3}=0 \quad \text{or} \quad \frac{|z_3-d|^3\lambda_2}{d^3\lambda_1}=M_p. \tag{14}$$

Using (12) we find

$$|z_3-d|=d. \tag{15}$$

There is no astigmatism or field curvature if

$$\frac{k_2M_p^2}{|z_3-d|^3}-\frac{k_1}{d^3}=0 \quad \text{or} \quad \frac{\lambda_2}{\lambda_1}=\frac{|z_3-d|}{d}. \tag{16}$$

Distortion vanishes if

$$\frac{k_1}{d^3}-\frac{k_2M_p^3}{|z_3-d|^3}=0 \quad \text{or} \quad \lambda_1=\lambda_2. \tag{17}$$

We see from (13)-(17) that if the magnification satisfies $M_p \neq 1$, it is impossible to simultaneously suppress all aberrations.

We turn now to the aberrations of an image reconstructed from measurements of the field at points in a spherical detection aperture of radius $\rho = d$. The pulsed response of the system in this case is

$$H_s=\int_0^{\rho}\int_0^{2\pi}\left[\frac{\partial}{\partial z}\frac{\exp jk_1r_{1s}}{r_{1s}}\right]_{z_1=0}\left[\frac{\partial}{\partial \rho}\frac{\exp -jk_2r_{2s}}{r_{2s}}\right]_{\rho=d} r\,dr\,d\varphi, \tag{18}$$

where

$$r_{1s}=[(x_{2s}-x_1)^2+(y_{2s}-y_1)^2+z_{2s}^2]^{1/2}, \tag{19}$$

$$r_{2s}=[(x_3-x_{2s})^2+(y_3-y_{2s})^2+(z_3-z_{2s})^2]^{1/2}, \tag{20}$$

$$x_{2s}=r\cos\varphi,\ \ y_{2s}=r\sin\varphi,\quad z_{2s}=(d^2-r^2)^{1/2},\ \ r=d\sin\theta. \tag{21}$$

Here, the subscript "s" corresponds to the field at points of the spherical detection aperture. In general, it is extremely complicated to evaluate Eq. (18), so we will simplify it, using power-series expansions of r_{1s} and r_{2s}:

$$r_{1s}=[d^2+\gamma^2-2(x_1x_{2s}+y_1y_{2s})]^{1/2}\simeq d+\frac{\gamma^2}{2d}-\frac{x_1x_{2s}+y_1y_{2s}}{d}$$
$$-\frac{1}{8d^3}[\gamma^4-4\gamma^2(x_1x_{2s}+y_1y_{2s})+4(x_1x_{2s}+y_1y_{2s})^2]+\dots \tag{22}$$

under the condition

$$\gamma^2-2(x_1x_{2s}+y_1y_{2s})<d^2, \tag{23}$$

and

$$r_{2s}=[d^2+\rho_s^2-2(x_3x_{2s}+y_3y_{2s}+z_3z_{2s})]^{1/2}$$
$$\simeq d+\frac{\rho_s^2}{2d}-\frac{x_3x_{2s}+y_3y_{2s}+z_3z_{2s}}{d} \tag{24}$$
$$-\frac{1}{8d^3}[\rho_s^4-4\rho_s^2(x_3x_{2s}+y_3y_{2s}+z_3z_{2s})$$
$$+4(x_3x_{2s}+y_3y_{2s}+z_3z_{2s})^2]+\dots \tag{24}$$

under the condition

$$\rho_s^2-2(x_3x_{2s}+y_3y_{2s}+z_3z_{2s})<d^2, \tag{25}$$

where

$$d^2=x_{2s}^2+y_{2s}^2+z_{2s}^2, \tag{26}$$

$$\rho_s^2=x_3^2+y_3^2+z_3^2. \tag{27}$$

We also use the conditions

$$k_1r_{1s}\gg 1,\ \ k_2r_{2s}\gg 1. \tag{28}$$

Retaining, in (18), the second-degree expansion terms in (22) and (24), and using (28), we find that the field distribution of a point image shaped by our system in the paraxial approximation, specified by the condition[8]

$$0\leqslant r\leqslant r_s\ll d, \tag{29}$$

is

$$H_s=\int_0^{r_s}\int_0^{2\pi}B_s\exp j\left[k_1\left(d+\frac{\gamma^2}{2d}\right)-k_2\left(d+\frac{\rho_s^2}{2d}+z_3\right)\right.$$
$$\left.-\frac{rD}{d}\cos(\varphi-\delta)\right]r\,dr\,d\varphi, \tag{30}$$

where

$$B_s=\frac{d-z_3}{d^2}\left[\left(\frac{k_1+k_2}{d}\right)^2+\left(k_1k_2-\frac{1}{d^2}\right)^2\right]^{1/2}, \tag{31}$$

$$D=[(k_1x_1-k_2x_3)^2+(k_1y_1-k_2y_3)^2]^{1/2}, \tag{32}$$

$$\delta=\operatorname{arc\,tg}\frac{k_1y_1-k_2y_3}{k_1x_1-k_2x_3}. \tag{33}$$

We see from (30) that the ideal image of a point occurs, in the paraxial approximation, under the condition

$$k_1\gamma^2-k_2\rho_s^2=0 \tag{34}$$

and is equal to

$$H_{si}=B_s\frac{r_sJ_1\left(r_s\frac{D}{d}\right)}{\frac{D}{d}}, \tag{35}$$

where $J_1(x)$ is the Bessel function of the first kind of index unity.

To find the transverse magnification of the image formed by our system, M_s, we exploit its circular symmetry, finding from (34)

$$M_s=\left(\frac{\lambda_2}{\lambda_1}-\frac{z_3}{\gamma^3}\right)^{1/2}. \tag{36}$$

We turn now to the aberrations of an image reconstructed from the field values at points of a spherical detection aperture. As in the case of a plane aperture, we must analyze the quantity

$$\Delta_s=k_1r_{1s}-k_2r_{2s}. \tag{37}$$

Substituting (22) and (24) into (37), and carrying out the corresponding calculations, we find

$$\Delta_s=\frac{1}{8d^3}(k_2M_s^4-k_1)\gamma^4+\frac{1}{2d^3}(k_1-k_2M_s^3)\gamma^2\alpha_s^2$$
$$+\frac{1}{2d^3}(k_2M_s^2-k_1)\alpha_s^4+\frac{k_2}{8d^3}$$
$$\times[z_3^3-4z_{2s}z_3+4z_{2s}^2z_3+2M_s^2(z_3-2z_{2s})\gamma^2$$
$$+2M_s(z_{2s}-2z_3)\alpha_s^2]\,z_3, \tag{38}$$

where

$$\alpha_s^2=x_1x_{2s}+y_1y_{2s}. \tag{39}$$

According to ref. 7, the first term in (38) does not cause image aberrations, the second gives the distortion, the third gives the astigmatism, and the fourth gives the defocusing, which occurs because the image plane does not coincide with the object plane.

Let us find the conditions under which these aberrations vanish. The distortion vanishes if

$$M_s^3=\frac{\lambda_2}{\lambda_1}. \tag{40}$$

The astigmatism vanishes if

$$M_s^2=\frac{\lambda_2}{\lambda_1}. \tag{41}$$

The defocusing vanishes if the image and object planes coincide, i.e., if $z_3 = 0$.

Accordingly, all the aberrations can be suppressed simultaneously only under the conditions $z_3 = 0$ and $\lambda_1 = \lambda_2$, i.e., with $M_s = 1$.

Comparing the aberrations of the images reconstructed from field values at points of a plane receiving aperture with those of a spherical aperture we see that the astigmatism and distortion are common to both images.

Equations (10) and (38) cannot be used directly for a quantitative comparison of the image aberrations in the two cases, so we compare the ray aberrations associated with Δ_p and Δ_s according to ref. 7.

For the components of the ray aberrations in the case of a plane detection aperture we have

$$\begin{aligned}\delta x_p=|z_{3_p}-d|\frac{\partial\Delta_p}{\partial x_{2p}}&=|z_{3_p}-d|\Big[\frac{1}{2}\Big(\frac{k_2}{|z_{3_p}-d|^3}-\frac{k_1}{d^3}\Big)\beta_p^2x_{2p}\\&+\frac{1}{2}\Big(\frac{k_1}{d^3}-\frac{k_2M_p}{|z_{3_p}-d|^3}\Big)(\beta_p^2x_1+2\alpha_p^2x_{2p})+\Big(\frac{k_2M_p^2}{|z_{3_p}-d|^3}-\frac{k_1}{d^3}\Big)\alpha_p^2x_1\\&+\frac{1}{2}\Big(\frac{k_2M_p^2}{|z_{3_p}-d|^3}-\frac{k_1}{d^3}\Big)\gamma^2x_{2p}+\frac{1}{2}\Big(\frac{k_1}{d^3}-\frac{k_2M_p^3}{|z_{3_p}-d|^3}\Big)\gamma^2x_1\Big],\end{aligned} \tag{42}$$

$$\begin{aligned}\delta y_p=|z_{3_p}-d|\frac{\partial\Delta p}{\partial y_{2p}}&=|z_{3_p}-d|\Big[\frac{1}{2}\Big(\frac{k_2}{|z_{3_p}-d|^3}-\frac{k_1}{d^3}\Big)\beta_p^2y_{2p}\\&+\frac{1}{2}\Big(\frac{k_1}{d^3}-\frac{k_2M_p}{|z_{3_p}-d|^3}\Big)(\beta_p^2y_1+2\alpha_p^2y_{2p})+\Big(\frac{k_2M_p^2}{|z_{3_p}-d|^3}-\frac{k_1}{d^3}\Big)\alpha_p^2y_1\\&+\frac{1}{2}\Big(\frac{k_2M_p^2}{|z_{3_p}-d|^3}-\frac{k_1}{d^3}\Big)\gamma^2y_{2p}+\frac{1}{2}\Big(\frac{k_1}{d^3}-\frac{k_2M_p^3}{|z_{3_p}-d|^3}\Big)\gamma^2y_1\Big],\end{aligned} \tag{43}$$

and in the case of a spherical aperture we have

$$\begin{aligned}\delta x_s=|z_{3s}-d|\frac{\partial\Delta_s}{\partial x_{2s}}&=|z_{3s}-d|\Big[\frac{1}{2d^3}(k_1-k_2M_s^3)\gamma^2x_1\\&+\frac{1}{d^3}(k_2M_s^2-k_1)\alpha_s^2x_1+\frac{k_2M_s}{4d^3}(d\cos\theta-2z_{3s})x_1z_{3s}\Big],\end{aligned} \tag{44}$$

$$\begin{aligned}\delta y_s=|z_{3s}-d|\frac{\partial\Delta_s}{\partial y_{2s}}&=|z_{3s}-d|\Big[\frac{1}{2d^3}(k_1-k_2M_s^3)\gamma_2y_1\\&+\frac{1}{d^3}(k_2M_s^2-k_1)\alpha_s^2y_1+\frac{k_2M_s}{4d^3}(d\cos\theta-2z_{3s})y_1z_{3s}\Big],\end{aligned} \tag{45}$$

where

$$z_{3_p}=d\Big(1-M_p\frac{\lambda_1}{\lambda_2}\Big), \tag{46}$$

$$z_{3s}=\gamma\Big(\frac{\lambda_2}{\lambda_1}-M_s^2\Big)^{1/2}, \tag{47}$$

and θ is the angular aperture of the detection apertures of the imaging systems.

We see from Eqs. (42)-(45) that δy_p and δy_s contain no information about the behavior of the ray aberrations

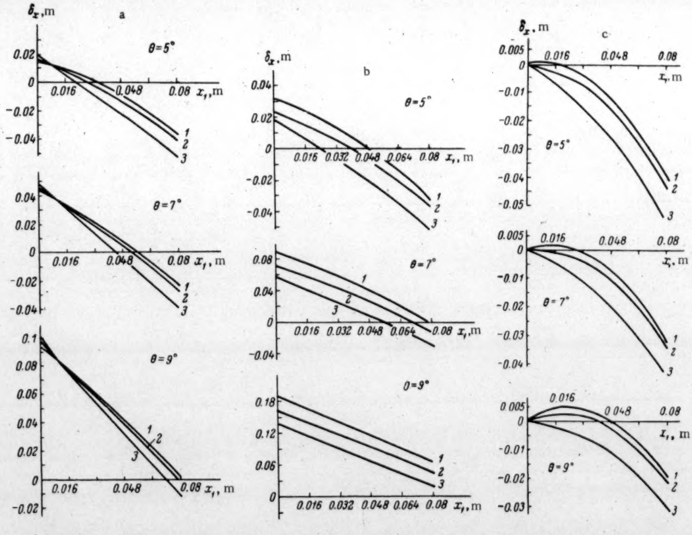

Fig. 2. Difference between the magnitudes of the image aberrations in the cases of plane and spherical apertures as a function of the position of the object points. a) x_{2_p} = d tan θ, y_{2_p} = 0, x_{2s} = d sin θ, y_{2s} = 0; b) x_{2_p} = d tan θ, y_{2_p} = d tan θ; x_{2s} = d sin θ/√2, y_{2s} = d sin θ/√2; c) x_{2_p} = 0, y_{2_p} = d tan θ, x_{2s} = 0, y_{2s} = d sin θ. The coordinates of the object points along the y_1 axis are: 1) 0; 2) 0.04; 3) 0.08 m.

not contained in δx_p and δx_s, so that it is sufficient to compare these latter two quantities.

We have used a Minsk-22 computer to calculate from Eqs. (42) and (44) the values of the difference

$$\delta x = |\delta x_p| - |\delta x_s| \tag{48}$$

for $M_p = M_s = 0.8$, $\lambda_1 = \lambda_2 = 0.1$ m, and $d = 1$ m as a function of x_1, y_1, and θ. Figure 2 shows the results calculated for three different points in the detection aperture.

We see that in the case of a spherical detection aperture the aberrations in the images of object points lying near the origin of coordinates in the object plane do not exceed the aberrations corresponding to a plane aperture for a given angular aperture. As the distance from the center of the object increases, the aberrations in the spherical detection aperture begin to exceed those corresponding to a plane aperture. Furthermore, as the angular aperture of the detection apertures of the imaging systems increases there is an enlargement of the regions in the object plane for which the aberrations in a spherical aperture are no larger than those in a plane aperture.

The authors thank V. G. Tyukul'min and B. D. Maleev for assistance in the calculations.

Correlation analysis of fine-structure images

A. A. Kolesnikov and N. V. Lapteva
A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad

(Submitted August 3, 1973; resubmitted March 1, 1974)
Zh. Tekh. Fiz., 44, 1896-1902 (September 1974)

The solution of several technical problems, such as study of certain physical processes, ultimately reduces to an analysis of fine-structure images, i.e., images consisting of elements whose dimensions are much smaller than that of the image itself (the analysis field). The final goals of the analysis are different in different cases, but they can usually be reached if the integral distribution of these elements with respect to their dimensions is found. Among such problems are the analysis of thin sections in metallography, the study of noise in photographic materials, the study of the composition of powders, the study of the populations of microorganisms, etc.

Direct methods of statistical analysis involving a systematic measurement of a large number of elements are extremely cumbersome and laborious. Indirect measurement methods frequently permit a simpler solution. For example, in certain cases in which it is possible to exploit a priori information about the elements of the image the problem can be solved by analyzing the autocorrelation function of the image, which can be measured quite simply. The correlation-analysis method opens up certain possibilities regarding automatic measurements and thus automatic control of technological or physical processes.

NOTATION AND STATEMENT OF THE PROBLEM

Assume that we are to analyze some region Ω of area S containing N elements of arbitrary shape (Fig. 1). For generality, we assume that the elements can overlap in some arbitrary manner. We will use the following notation: x, y are the values of the coordinates X and Y with respect to the origin; x_i, y_i are the coordinates of the conventional center of element i; R is the radius vector running from the origin to point x, y; R_i is the radius vector of the conventional center of element i; R_{0i} is the radius vector of a point with respect to the i-th center; $\tau(X, Y)$ is the transparency at point X, Y from the i-th element; t(X, Y) is the transparency at point X, Y of the analysis region; P(r) and W(r) = dP(r)/dr are the integral and differential distributions of the length of the vector running from the center of an element to its boundary at angle φ; $P_\tau\{t_i, x_i\ y_i\}$ is the distribution with respect to transparency; and $W_{2N}(x_1, x_2 \ldots x_N; y_1, y_2 \ldots y_N)$ is the 2N-dimensional density distribution of the coordinates of the centers of the elements. In its most general form the problem is one of determining $P(r, \varphi) = \text{Bep}\{R < r\}$ from the measured two-dimensional autocorrelation function $B_t(X, Y, \Delta X, \Delta Y)$.

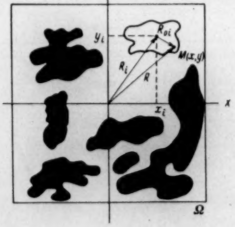

Fig. 1

SOLUTION OF THE PROBLEM

The solution of the problem can be divided arbitrarily into two steps. The first step is that of calculating the autocorrelation function for the given model of the object. We note that the choice of a model significantly affects both the calculation difficulties and the generality of the results. The best model for a particular application depends on the a priori information available about the object. As more a priori information is used, the algorithm for the analysis can be simplified, as can the apparatus itself.

The second step in the solution is that of determining the unknown distribution law from the autocorrelation function, which we assume known (measured). As is shown below, in this step also it is extremely important to have a priori information about the object being analyzed, since the problem generally does not have an unambiguous solution.

In the first step of the solution we use the method described in ref. 1. We define the transparency at any point of the analysis region as the product of the transparencies of each of the elements covering this point:

$$t(X,\ Y)=\prod_{i=1}^{N}\tau_i[X-x_i,\ Y-y_i]=\prod_{i=1}^{N}\tau(R_{0i}). \tag{1}$$

The autocorrelation function for the transparency of the object can be found by averaging the product:

$$B(X,\ Y,\ \Delta X,\ \Delta Y)=\underset{\tau_i}{E}\ \underset{x_iy_i}{E}\ t(X,\ Y)t^*(X-\Delta X,\ Y,\ \Delta Y), \tag{2}$$

where $\underset{\tau_i}{E}$ denotes an averaging over the transparencies of all spots, and $\underset{x_iy_i}{E}$ denotes an averaging over the distribution of the centers of the elements in the analysis region. In integral form, Eq. (2) is

$$\begin{aligned}B(X,\ Y,\ \Delta X,\ \Delta Y)=\iint_0^\infty\Big\{\iint_\Omega\cdots\int\prod_{i=1}^{N}\tau_i(X-x_i,\ Y-y_i)\\ \times\prod_{i=1}^{N}\tau_i^*(X-\Delta X-x_i,\ Y-\Delta Y-y_i)\\ \times W_{2N}(x_1,\ x_2,\ \ldots x_N;\ y_1,\ y_2\ldots y_N)\\ \times dx_1dx_2\ldots dy_N\Big\}W_\tau(X,\ Y,\ \Delta X,\ \Delta Y)\,d\tau d\tau^*.\end{aligned} \tag{3}$$

For a uniform and independent determination of the centers of the elements in the analysis region we can use

$$W_{2N}=\prod_{i=1}^{N} W_i(x_i)\prod_{i=1}^{N} W_i(y_i);\; W(x_i)W(y_i)=\begin{cases}\frac{1}{S} & \begin{smallmatrix}x_i\\ y_i\end{smallmatrix} \in \Omega\\ 0, & \begin{smallmatrix}x_i\\ y_i\end{smallmatrix} \bar{\in} \Omega,\end{cases} \qquad (4)$$

where S is the analysis area.

We assume that the elements are absolutely opaque, i.e., that

$$W_\tau(X,\ Y)=\begin{cases}\delta(0), & \text{if the point belongs to the element,}\\ \delta(1), & \text{if the point does not belong to the element.}\end{cases}$$

Then we can use (4) to significantly simplify (3):

$$B(X,\ Y,\ \Delta X,\ \Delta Y)=\rho^N, \qquad (5)$$

where

$$\rho=\frac{1}{S}\iint\limits_{\Omega}\tau(X-x_0,\ Y-y_0)\,\tau^*(X-\Delta X-x_0,\ Y-\Delta Y-y_0)\,dx_0dy_0 \qquad (6)$$

is the desired function, which is determined solely by the statistical properties of the elements. If, in addition, the number of elements and the analysis region are large, we can write (5) in exponential form:

$$B(X,\ Y,\ \Delta X,\ \Delta Y)=\exp\{-N[1-\rho(X,\ Y,\ \Delta X,\ \Delta Y)]\}. \qquad (7)$$

Under these assumptions the integrand in (6) can take on only two values: 0 or 1. We can therefore calculate ρ as the probability of an event in which elements whose centers are at point (X, Y) do not simultaneously overlap points $(X-\Delta X,\ Y-\Delta Y)$ and $(X-\Delta X-x_0,\ Y-\Delta Y-y_0)$.

Equation (6) can be written in polar coordinates:

$$\rho(r,\ \Delta R)=\frac{1}{S}\iint\limits_{\Omega}P(r-r_0)\,P(r-r_0-\Delta R)\,r_0dr_0d\varphi. \qquad (8)$$

The second step thus reduces to solving an integral equation of the type

$$\ln B(r,\ \varphi,\ \Delta R)=-\frac{N}{S}\left[S-\iint\limits_{\Omega}P(r-r_0)\,P(r-r_0-\Delta R)\,r_0dr_0d\varphi\right] \qquad (9)$$

for P(r).

In general this problem has an infinite set of solutions. Below we show that when we have a priori information about the objects being analyzed we can find a unique solution.

Example 1. We make the a priori assumptions that all the elements of the image are circular, that their centers are distributed uniformly over the analysis region, that the statistics of the elements are identical, and that the number of elements is large, so that we can assume the distribution law to be invariant with respect to direction, i.e., $P(r,\varphi)=P(r)$.

We choose the origin of coordinates as shown in Fig. 2, and we assume for simplicity that the analysis region is infinitely large. The probability that the center of a spot falls in an area $dS = r\,dr\,d\varphi$, does not cover the point $(x+\Delta R/2,\ 0)$, and, since the elements are circular, does not cover the point $(x-\Delta R/2,\ 0)$ is

$$d\rho=1\cdot P(r)\frac{r\,dr\,d\varphi}{S}.$$

Integrating in the right-hand half-plane, and multiplying by two, we find

$$\rho(r,\ \Delta R)=\frac{2}{S}\left\{\int\limits_0^{\Delta R/2}\int\limits_0^{2\pi}P(r)\,r\,dr\,d\varphi+2\int\limits_{\Delta R/2}^{\infty}\int\limits_{\arccos\Delta R/2r}^{\pi}P(r)\,r\,dr\,d\varphi\right\}$$

$$=\frac{4\pi}{S}\left\{\int\limits_0^{\infty}P(r)\,r\,dr-\frac{1}{\pi}\int\limits_{\Delta R/2}^{\infty}P(r)\,r\arccos\frac{\Delta R}{2r}\,dr\right\}.$$

Then the autocorrelation function is

$$\ln B(\Delta R)=-\frac{N}{S}\times\left\{S-4\pi\left[-\int\limits_0^{\infty}P(r)\,r\,dr-\frac{1}{\pi}\int\limits_{\Delta R/2}^{\infty}P(r)\,r\arccos\frac{\Delta R}{2r}\,dr\right]\right\}. \qquad (10)$$

A similar result is obtained in ref. 2. We can show that (10) can be solved for P(r). For this purpose we differentiate (10) with respect to ΔR, make the variable replacement $y = 1/r^2$, and introduce the following notation:

$$\Phi(y)=P\left(\frac{1}{\sqrt{y}}\right)y^{-3/2};\; h=\left(\frac{2}{\Delta R}\right)^2;$$

$$F(\Delta R)=\frac{\Delta R S}{2NB(\Delta R)}\frac{dB(\Delta R)}{d(\Delta R)}.$$

We then find the integral equation

$$F(\Delta R)=\int\limits_0^{h}\frac{\Phi(y)}{\sqrt{h-y}}\,dy,$$

which is called the Abel equation. After some straightforward manipulations, we find

$$\Phi(y)=\frac{S}{N}\left\{\int\limits_0^{y}\frac{B'(\Delta R)}{B(\Delta R)}\frac{d(\Delta R)}{\sqrt{y-\Delta R}}+\int\limits_0^{y}\Delta R\,\frac{B''(\Delta R)}{B(\Delta R)}\frac{d\,\Delta(R)}{\sqrt{y-\Delta R}}-\int\limits_0^{y}\Delta R\left[\frac{B'(\Delta R)}{B(\Delta R)}\right]^2\frac{d(\Delta R)}{\sqrt{y-\Delta R}}\right\}. \qquad (11)$$

This result can be used to calculate P(r) from the measured B(ΔR). The algorithm for processing the measured results is uncomplicated and easily programmable.

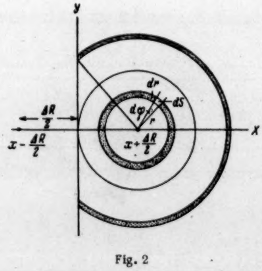

Fig. 2

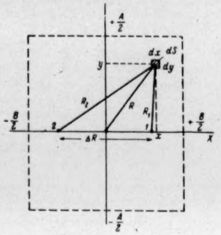

Fig. 3

Example 2. We now assume that the elements of the image are of an arbitrary shape but that the integral distribution of the lengths of the radius vectors P(r) can be approximated by a Rayleigh distribution:

$$P(r)=1-\exp\left(-\frac{r^2}{2\sigma^2}\right).$$

Figure 3 shows the analysis region, which is bounded by certain rectangles, within which there is a set of elements of arbitrary shape. Our previous assumptions remain valid. We will calculate $\rho(\Delta R)$ in accordance with (8). Using

$$P(r_1)=1-\exp\left[-\frac{y^2+(x-\Delta R)^2}{2\sigma^2}\right],$$

we find

$$P(r_2)=1-\exp\left[-\frac{y^2+(x+\Delta R)^2}{2\sigma^2}\right].$$

Then

$$\rho(\Delta R)=1-\frac{4\pi\sigma^2}{AB}\Phi\left(\frac{A}{2\sigma\sqrt{2}}\right)\Phi\left(\frac{B}{2\sigma\sqrt{2}}\right)+\frac{\sqrt{2\pi}}{A\sigma}\Delta R^2e^{-\frac{B^2}{8\sigma^2}}\Phi\left(\frac{A}{2\sigma\sqrt{2}}\right)$$
$$+\frac{\pi\sigma^2}{AB}e^{-\frac{\Delta R^2}{\sigma^2}}\Phi\left(\frac{A}{2\sigma}\right)\Phi\left(\frac{B}{2\sigma}\right), \qquad (12)$$

where

$$\Phi(x)=\frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt$$

is the Laplace function.

Substituting this equation into (7) and normalizing, we find

$$B_N=\frac{\exp\left\{-N\frac{2\pi\sigma^2}{AB}\left[4-e^{-\frac{\Delta R^2}{\sigma^2}}\right]\right\}-\exp\left(-N\frac{8\pi\sigma^2}{AB}\right)}{\exp\left\{-N\frac{6\pi\sigma^2}{AB}\right\}\left[\exp\left(N\frac{2\pi\sigma^2}{AB}\right)-1\right]}. \qquad (13)$$

This equation can be solved for σ, although the calculation is lengthy. However, if the dimensions of the analysis region are large, so that

$$\Phi\left(\frac{A}{2\sigma\sqrt{2}}\right)=\Phi\left(\frac{B}{2\sigma\sqrt{2}}\right)\simeq 1,$$

and if the exponential function in (13) can be approximated by the first two terms of its series expansion,

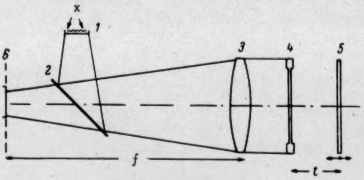

Fig. 4

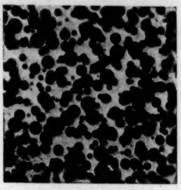

Fig. 5

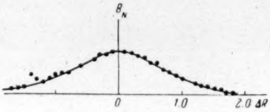

Fig. 6

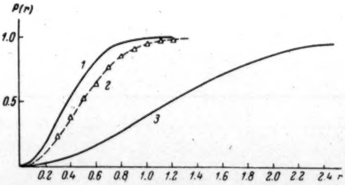

Fig. 7

$$\exp\left(N\frac{2\pi\sigma^2}{AB}\right)=1+N\frac{2\pi\sigma^2}{AB},$$

then the solution simplifies considerably, becoming

$$B_N=\frac{B(\Delta R)}{B(0)}\simeq e^{-\frac{\Delta R^2}{\sigma^2}}. \qquad (14)$$

Obviously, σ can be calculated from the measured B(ΔR).

EXPERIMENTAL RESULTS

In our experiments we use the optical-correlator arrangement shown in Fig. 4. The correlator consists of a light source 1, mirrors 2 and 5, lens 3, and object 4 (a transparency). The two-dimensional autocorrelation function is formed in the focal plane 6 of lens 3. The position of mirror 5 with respect to the transparency determines the maximum displacement with respect to each coordinate, due to the ratio $M = f/2t$, where f is the focal length of the lens and t is the distance along the optical axis between transparency 4 and mirror 5.

We studied a transparency (Fig. 5) consisting of $N = 500$ circles, whose centers were distributed uniformly over the analysis field. This uniformity was achieved by choosing the coordinates of each point from tables of random numbers;[4] an arbitrary overlap of the circles was permitted. The distribution of the radii of these circles obeys a Rayleigh law with $\sigma = 0.32$. Figure 6 shows the result of photometry of the autocorrelation function. Calculations from (14) yield $\sigma = 0.41$, quite close to the original value. Figure 7 shows curves of the function $P(r) = 1 - \exp(-r^2/2\sigma^2)$ plotted for $\sigma = 0.32$, 0.41, and 1.0 (curves 1-3, respectively). We see that the experimental curve for $\sigma = 0.41$ differs only slightly from that for $\sigma = 0.32$; the primary reason for the discrepancy is that the distribution of radii on the transparency obeys a discrete law, rather than the purely Rayleigh law, for which Eq. (14) holds.

CONCLUSIONS

1. We have shown that when certain a priori information is available about the elements of the image being studied the size distribution of elements can be determined from the measured autocorrelation function.

2. Simple equations have been derived for certain common cases: circular objects or objects of arbitrary shape for which the lengths of the radius vectors obey a Rayleigh law.

3. This calculation procedure can be used for objects of other shapes: rectangles, ellipses, etc., with arbitrary distribution laws.

4. The relatively simple algorithms for processing the measured results can be used for automatic analysis of fine-structure images.

Coherent instability of a beam in a vacuum chamber with an irregular boundary

E. S. Masunov

(Submitted January 15, 1973; resubmitted October 23, 1973)
Zh. Tekh. Fiz., 44, 1903-1908 (September 1974)

The longitudinal stability of charged-particle beams in accelerators and storage rings is analyzed. A general dispersion relation is derived for the case in which the vacuum chamber has an arbitrary irregularity which violates the azimuthal symmetry of the system. The growth rates are calculated taking account of the interaction of harmonics of the space-charge density waves. The motion of a single beam and of the simultaneous motion of two beams are analyzed separately.

The longitudinal instability of beams in charged-particle accelerators and storage rings is usually analyzed under the assumption that the transverse dimensions of the chamber and other external elements surrounding the beam are independent of the azimuthal angle θ (refs. 1-4). On the other hand, it is well known that the azimuthal symmetry is always violated in a real system. In large accelerators and storage rings the toroidal chamber will consist of separate regions with different transverse cross sections. The azimuthal symmetry can also be violated when there are any other irregularities in the shape of the chamber boundary, when deflecting plates are placed at certain points in the ring, when azimuthal cuts are provided in a waveguide for focusing a toroidal bunch,[5] etc.

In ref. 6 an attempt is made to take account of boundary irregularities, and the impedance of a chamber containing a beam is calculated for a particular case. It should be noted that it is assumed in this calculation[6] that the different harmonics of the space-charge density waves are independent; but this assumption is strictly valid only for regular systems, and it does not permit an analysis of effects due to an irregularity.

Our purpose here is to analyze the stability of the motion of one or several circulating beams in an arbitrary irregular chamber, taking harmonic interactions into account. The analogous problem for the case of a linear geometry is studied in ref. 7.

1. For simplicity we first consider a single freely circulating beam. The kinetic equation describing the longitudinal motion of the particles in the beam is

$$\frac{\partial f}{\partial t}+\Omega(W)\frac{\partial f}{\partial\theta}+2\pi eR\frac{df_0}{dW}\langle E_\theta\rangle=0, \tag{1}$$

where θ is the azimuth and W is the canonically conjugate momentum. Here, the angle brackets denote averaging of the longitudinal field over the transverse coordinates of the particles in the bunch. This averaging is valid if the frequency of the transverse oscillations differs markedly from that of the longitudinal oscillations in the beam. Since our basic purpose below is to analyze the longitudinal motion of the beam, independently of the transverse motion, we assume that this latter condition is always satisfied.

We assume that the chamber has N-fold symmetry in the azimuthal direction, i.e., it consists of N identical inhomogeneous parts. Then we seek the current density of the circulating beam in the form

$$j(\mathbf{r}^{\perp},\theta)=\lambda(\mathbf{r}^{\perp})\sum_{\hat m}j(\hat m)e^{i\hat m\theta-i\omega t}. \tag{2}$$

Here $\hat m = k+Nl$ are integers; $|k| \leq N/2$ for even N or $|k| \leq N-1/2$ for odd N; and $l = 0, \pm 1\ldots$. The field produced by the beam in the chamber can also be written in form (2). In an analysis of stability it is customary to analyze the total coupling impedance Z instead of $\langle E(\hat m)\rangle$. For the case of an irregular boundary the impedance should be defined by

$$2\pi R\langle E(\hat m)\rangle=\sum_{\hat n}Z_{\hat m,\hat n}j(\hat n). \tag{3}$$

Each diagonal element of the matrix Z is the average over the azimuth of the impedance corresponding to the given harmonic of the orbiting frequency. The off-diagonal elements $Z_{\hat m\hat n}$ are nonvanishing for irregular systems and can be calculated as described in the Appendix. It follows from the general form of $Z_{\hat m\hat n}$(A7) that the matrix Z is anti-Hermitian if we neglect damping at the walls.

Substituting (3) into the kinetic equation (1), we find a general dispersion relation for determining the growth rates for longitudinal instability of the beam:

$$\det\|I_{\hat n}\delta_{\hat m,\hat n}-ie^2\omega Z_{\hat m,\hat n}\|=0, \tag{4}$$

where

$$I_{\hat n}^{-1}=\frac{1}{\hat n}\int\frac{\frac{df_0}{dW}}{\hat n\Omega-\omega}dW. \tag{4a}$$

In addition to the ordinary radiative instability and the negative-mass instability, Eq. (4) can be used to analyze a specific instability (specific to irregular systems) due to the parametric interaction of space-charge density waves. Let us consider the solution of Eq. (4) for frequencies near $\omega_{\hat m,\hat n} = [2\hat m\hat n/(\hat m+\hat n)]\Omega_0$ (Ω_0 is the averaging orbiting frequency of the particles). We assume that $\omega_{\hat m,\hat n}$ differs significantly from the resonant frequencies of the chamber corresponding to the $\hat m$ and $\hat n$ harmonics and that the negative-mass instability also does not occur (for a monoenergetic beam this latter condition is satisfied if $\eta\,\mathrm{Im}\,Z_{\hat m,\hat n}/\hat m$ and $\eta\,\mathrm{Im}\,Z_{\hat n\hat n}/\hat n$, where $\eta = 1/\gamma^2 - 1/\gamma_{\mathrm{crit}}^2$, are negative). Then it can be shown that if the beam properties satisfy

$$4\left(\frac{\hat m-\hat n}{\hat m+\hat n}\right)^2\approx F_1+F_2^2, \tag{5}$$

where

$$F_1=i\frac{\alpha c}{2\pi\beta}\frac{Z_{\hat m,\hat n}}{\hat n},\quad F_2=i\frac{\alpha c}{2\pi\beta}\frac{d}{d\omega}\left[\omega\frac{Z_{\hat n\hat n}}{\hat n}\right]_{n\Omega_0},\quad \alpha=\frac{r_0N_e\eta}{2\pi R\gamma}, \tag{5a}$$

Eq. (4) has complex solutions. In the case in which Eq. (5) holds exactly, the growth rate μ is a maximum:

$$\mu = \pm i \frac{\omega_{\hat m,\hat n}}{\hat m - \hat n} \frac{c}{2\pi\beta} |\alpha Z_{\hat m,\hat n}|. \tag{6}$$

For a specified difference $\hat{m} - \hat{n} > 0$ the width of the resonance band is found from the condition

$$-\frac{\omega_{\hat m,\hat n}}{\Omega_0} \frac{c}{\pi\beta} \frac{|\alpha Z_{\hat m,\hat n}|}{\hat m^2 - \hat n^2} < \frac{\hat m + \hat n}{2(\hat m - \hat n)} \sqrt{F_1 + F_2^2}$$

$$-1 - \frac{F_2}{2} < \frac{\omega_{\hat m,\hat n}}{\Omega_0} \frac{c}{\pi\beta} \frac{|\alpha Z_{\hat m \hat n}|}{\hat m^2 - \hat n^2}, \tag{7}$$

from which we can determine the total number of interacting harmonics if we know $Z_{\hat m \hat n}$.

It follows from condition (5) that for beams with a large space-charge density (e.g., in the toroidal electron bunches used in ring systems,[5] with $N_e \sim 10^{13}$-10^{14}, $R \sim 5$ cm) the parametric interaction of the density waves becomes important even at low harmonics $\hat{m}$ and $\hat{n}$. As the violation of the azimuthal symmetry of the system surrounding the beam becomes more pronounced, the value of $|Z_{\hat m \hat n}|$ increases, and so does the growth rate.

When η Im $Z_{\hat n \hat n}/\hat n > 0$ the negative-mass instability is not dangerous if the relative spread in orbiting frequencies, Δ, satisfies

$$\Delta^2 > |F_1|. \tag{8}$$

Nevertheless, even in this case the effect considered above leads to a beam instability with a growth rate (6), although it is true that the resonance conditions themselves are slightly different; (5) and (7) should be replaced by analogous equations with F_1 replaced by $F_1 + \Delta^2$.

The result obtained above has a simple physical meaning: In a regular waveguide, as in free space, the harmonics of the fast and slow space-charge waves propagate independently at any beam density. An irregular boundary can lead to a coupling of the m-th harmonic of the fast wave and the n-th harmonic of the slow wave. Since the coupling between the slow and fast waves is active, the energy is continuously pumped from the slow wave to the fast wave. The slow wave carries a negative kinetic power, while the fast wave carries a positive kinetic power. Accordingly, the amplitudes of both waves grow, leading to the beam instability.

2. We now consider a slightly different case, in which two beams circulate simultaneously in an irregular chamber, instead of the single beam discussed above. We are interested in the longitudinal stability of such a two-beam system; we assume that the conditions for transverse stability are satisfied.

The dispersion relation (4) is replaced by

$$\det \| \delta_{\hat m,\hat n} - ie^2 \omega Z_{\hat m,\hat n} \{ I_{1,\hat n}^{-1} + I_{2,\hat n}^{-1} \} \| = 0, \tag{9}$$

where

$$I_{i,\hat n}^{-1} = \frac{1}{\hat n} \int \frac{\frac{df_{i0}}{dW}}{\hat n \Omega_i - \omega} dW, \tag{9a}$$

and Ω_i is the angular velocity of the first ($i = 1$) or second ($i = 2$) beam. If the particles are revolving in different directions, the Ω_i have opposite signs.

If the external system is azimuthally symmetric, Eq. (9) has complex solutions when the number of particles in orbit is $N_{1,2} \geqslant \gamma^3 R/r_0$. This case corresponds to the ordinary two-stream instability of the Buneman type;[2] the particle density per unit length does not reach this threshold in any existing accelerator.

Of much more interest is the beam interaction in the case $Z_{\hat m \hat n} \neq 0$. We see from (9) that under the condition

$$\hat m \Omega_1 + \hat n \Omega_2 = 0 \tag{10}$$

there is an intense interaction between the particles of the different beams, leading to an instability even when the space charge is small.

We first assume that $\eta_1 \operatorname{Im} Z_{\hat m, \hat m}/\hat m$ and $\eta_2 \operatorname{Im} Z_{\hat n \hat n}/\hat n$ are negative, corresponding to the case in which each of the beams is individually stable. Taking account of the resonant interaction between bunches we can show that (9) has complex solutions if

$$-Z_{\hat m,\hat m} Z_{\hat n,\hat n} < |Z_{\hat m,\hat n}|^2. \tag{11}$$

This latter condition is independent of $N_{1,2}$, and in the case of a toroidal chamber, with $Z_{\hat m,\hat n}$ given by Eq. (A7), this condition can be rewritten as

$$\frac{G^{(0)}}{\gamma_1 \gamma_2} < (1 \pm \beta_1 \beta_2) |G^{(\hat m - \hat n)}|. \tag{12}$$

The upper sign corresponds to the case of beams moving in opposite directions, and the lower sign corresponds to the case of the same direction.

If the quantities $\eta_1 \operatorname{Im} Z_{\hat m \hat m}/\hat m$ and $\eta_2 \operatorname{Im} Z_{\hat n \hat n}/\hat n$ have different signs (e.g., if $\eta_1 \operatorname{Im} Z_{\hat m \hat m}/\hat m > 0$ and $\eta_2 \operatorname{Im} Z_{\hat n \hat n}/\hat n < 0$), an instability of the first beam would lead to an instability of the second. An exceptional case is that in which

$$\alpha_2 \frac{\hat n^2}{\gamma_2^2} > -\alpha_1 \frac{\hat m^2}{\gamma_1^2}. \tag{13}$$

Now the second beam can stabilize the first beam, under the condition

$$\frac{G^{(0)}}{\gamma_1 \gamma_2} (1 \pm \beta_1 \beta_2) |G^{\hat m - \hat n} < \frac{G^{(0)}}{2 \hat m \hat n} \frac{1}{\sqrt{|\alpha_1 \alpha_2|}} \left[\alpha_2 \frac{\hat n^2}{\gamma_2^2} - \alpha_1 \frac{\hat m^2}{\gamma_1^2} \right]. \tag{14}$$

Finally, with $\eta_1 \operatorname{Im} Z_{\hat m \hat m}/\hat m > 0$ and $\eta_2 \operatorname{Im} Z_{\hat n \hat n}/\hat n > 0$, there is always an instability. Each of the beams can be stabilized separately if the relative spread in orbiting frequency $\Delta_{1,2}$ satisfies condition (8). But even in this case a resonant interaction can lead to an instability of the two-beam system, under the condition

$$\left(G^{(0)} + \frac{\Delta_1^2 \beta_1^2 \gamma_1^2}{\alpha_1} \right) \left(G^{(0)} + \frac{\Delta_2^2 \beta_2^2 \gamma_2^2}{\alpha_2} \right) < \gamma_1^2 \gamma_2^2 (1 \pm \beta_1 \beta_2)^2 |G^{(\hat m - \hat n)}|. \tag{15}$$

In particular, when particles with the same rest mass collide, we find from (15)

$$\frac{\Delta^2 \beta^2 \gamma^2}{|\alpha| G^{(0)}} - 1 < \gamma^2 (1 + \beta^2) \left| \frac{G^{(2\hat n)}}{G^{(0)}} \right|. \tag{16}$$

The longitudinal two-stream instability in a chamber having an irregular boundary is of the same nature as the instability in the case of a single beam; a parametric interaction between the fast space-charge wave of one beam and the slow wave of the second beam can occur, as was shown above, even when the particle density in the bunches is low. At large γ this instability can be dangerous for all low-frequency harmonics, e.g., in the case of a vacuum chamber in which there is an abrupt change in the cross section, $G^{(2n)}$ falls off no more rapidly than $1/\hat{n}$, and the quantity on the right-hand side of inequality (16) can be larger than or comparable to unity for all $\hat{n} < \gamma^2$.

It should be noted that at very large $\hat{n}$, corresponding to microwave frequencies, equations like (5) and (16) become invalid, since the analysis of the parametric interaction of space-charge density waves must now incorporate the approximate equality of ω and the resonant frequencies of the irregular parts of the chamber. This problem is solved in ref. 7 for linear geometry; it is shown that the approximate equality of ω and the resonant frequencies can both increase the growth rate or suppress the instability altogether. Analysis of these effects for cyclic systems having one or two beams is of independent interest and requires a separate analysis.

APPENDIX

To determine the field excited by the beam in any cross section of the chamber with a longitudinal coordinate θ, it is better to use the method of transverse cross sections.[8] The longitudinal component of the field E is sought in this case in the form

$$E_\theta = -i\sum_{\hat{m}}\left\{\sum_s A_{\hat{m},s}\nu_s^2\Phi_s + \frac{4\pi}{\omega}\lambda(\mathbf{r}^\perp)\, j(\hat{m})\right\} e^{i\hat{m}\theta - i\omega t}, \tag{A.1}$$

where $\Phi_s(\mathbf{r}^\perp, \theta)$ is the eigenfunction for the boundary-value problem

$$\nabla_\perp^2\Phi_s + \nu_s^2\Phi_s = 0 \tag{A.2}$$

with the boundary condition $\Phi_s = 0$ on the contour bounding the cross section $S_\perp$ perpendicular to the beam. In Eqs. (A.1) and (A.2), ν_s is the eigenvalue corresponding to the eigenfunction Φ_s. The unknown quantities $A_{\hat{m},s}$ can be found as in ref. 8. In the case in which the orbital radius is much larger than the transverse dimensions of the chamber, and the transverse beam current can be neglected, the $A_{\hat{m},s}$ are the solutions of

$$\sum_{\hat{m},s_1}\left\{M^{\hat{n},\hat{m}}_{s,s_1} + i\frac{\omega}{c}\zeta D^{\hat{n},\hat{m}}_{s,s_1}\right\} A_{\hat{m},s_1} = \frac{4\pi}{\omega}\sum_{\hat{m}}[\nu_s^2\langle\Phi_s\rangle]^{(\hat{n}-\hat{m})}\, j(\hat{m}). \tag{A.3}$$

Here the matrix M is Hermitian, and all its elements can be written in terms of the functions Φ_s and their derivatives:

$$M^{\hat{n},\hat{m}}_{s,s_1} = \left(\frac{\omega^2}{c^2} - \frac{\hat{n}^2}{R^2}\right)\delta_{s,s_1}\delta_{\hat{n},\hat{m}} - [\nu_s^2]^{(\hat{n}-\hat{m})}\delta_{s,s_1} + \frac{i}{R}\left(\hat{n}Q^{\hat{n},\hat{m}}_{s,s_1} - \hat{m}Q^{\hat{n},\hat{m}}_{s,s_1}\right) - \Lambda^{\hat{n},\hat{m}}_{s,s_1},$$

$$Q^{\hat{n},\hat{m}}_{s,s_1} = \frac{1}{2\pi R}\oint d\theta\int dS_\perp\left(\nabla_\perp\Phi_s,\ \nabla_\perp\frac{\partial\Phi_{s1}}{\partial\theta}\right)e^{i(\hat{m}-\hat{n})\theta},$$

$$\Lambda^{\hat{n},\hat{m}}_{s,s_1} = \frac{1}{2\pi R^2}\oint d\theta\int dS_\perp\left(\nabla_\perp\frac{\partial\Phi_s}{\partial\theta},\ \nabla_\perp\frac{\partial\Phi_{s1}}{\partial\theta}\right)e^{i(\hat{m}-\hat{n})\theta},$$

$$[\nu_s^2]^{(\hat{n}-\hat{m})} = \frac{1}{2\pi}\oint d\theta\,\nu_s^2(\theta)\, e^{i(\hat{m}-\hat{n})\theta}. \tag{A.4}$$

The matrix $D^{\hat{n},\hat{m}}_{s,s_1}$ gives the damping at the walls, whose surface impedance is ζ. The elements of matrix D themselves can be expressed in terms of the functions Φ_s:

$$D^{\hat{n},\hat{m}}_{s,s_1} = \frac{1}{2\pi}\oint d\theta\int dS_\perp\frac{\partial\Phi_s}{\partial\tau}\frac{\partial\Phi_{s1}}{\partial\tau}e^{i(\hat{m}-\hat{n})\theta}, \tag{A.5}$$

where τ is the unit vector normal to the contour bounding cross section $S_\perp$.

From the solutions found for Eq. (A.3) we can calculate the field in (A.1) and the elements of matrix $Z_{\hat{m},\hat{n}}$. Without going into the details of the method used to seek the solutions of $A_{\hat{m},s}$ for an arbitrary frequency ω, we write $Z_{\hat{m},\hat{n}}$ in the long-wavelength approximation:

$$Z_{\hat{m},\hat{n}} = i\frac{8\pi^2 R}{\omega}\sum_{\substack{s,s_1\\ \hat{m}_1,\hat{n}_1}}\langle\Phi_s\rangle^{(\hat{m}-\hat{m}_1)}\langle\Phi_{s1}\rangle^{(\hat{n}_1-\hat{n})}\left\{\left(\frac{\omega^2}{c^2} - \frac{\hat{n}_1^2}{R^2}\right)\delta_{s,s_1}\delta_{\hat{n}_1\hat{m}_1} + \frac{i}{R}\left(\hat{m}_1 Q^{\hat{m}_1,\hat{n}_1}_{ss_1} - \hat{n}_1 Q^{\hat{m}_1,\hat{n}_1}_{s_1 s}\right) - \Lambda^{\hat{m}_1\hat{n}_1}_{ss_1} + i\frac{\omega}{c}\zeta D^{\hat{m},\hat{n}_1}_{ss_1}\right\}. \tag{A.6}$$

This equation simplifies if the particular shape of the cross section is specified. Let us assume, e.g., that the waveguide has a circular cross section. Then by writing the functions Φ_s as in (2) in ref. 8, and expressing the matrices Q and Λ in terms of the roots of the Bessel function, again as in ref. 8 [see Eq. (4a)], we find, after summing over s, s_1, $\hat{m}_1$, and $\hat{n}_1$, that Eq. (A.6) becomes

$$Z_{\hat{m},\hat{n}} = i\frac{2\pi R}{\omega}\left(\frac{\omega^2}{c^2} - \frac{\hat{m}\hat{n}}{R^2}\right)G^{(\hat{m}-\hat{n})} + 2i\frac{\omega}{c}\zeta\oint d\theta\sqrt{\frac{1}{b^2} + \left(\frac{db}{Rd\theta}\right)^2}\, e^{i(\hat{n}-\hat{m})\theta}. \tag{A.7}$$

Here

$$G^{(\hat{m}-\hat{n})} = \frac{1}{2\pi}\oint\left(\frac{1}{2} + 2\ln\frac{b(\theta)}{a}\right)e^{i(n-m)}d\theta, \tag{A.8}$$

$b(\theta)$ is the variable radius of the cross section, and a is the beam radius.

If we set $\hat{m} = \hat{n}$ in (A.8) and assume that $b(\theta)$ is a piecewise-constant function, we find the equation of ref. 6 for $G^{(0)}$.

Zh. Tekh. Fiz., 44, 1909-1916 (September 1974)

The steady state of a high-current relativistic electron beam in a homogeneous external magnetic field is analyzed; diamagnetism and space charge are taken into account. The relations between the current and the minimum external field required for beam transport are derived. Currents considerably above the Alfvén limit can only be transported by hollow beams.

INTRODUCTION

The recent interest in high-current electron beams with 10^4-10^6 A and particle energies of 10^5-10^7 eV stems from the strong self-fields and the large amount of stored energy, which can be used effectively in a variety of applications.[1-5] A problem which arises in this connection is that of developing efficient methods for shaping and transporting these beams.

The transport methods used in practice generally involve gas focusing at pressures of the order of 10^{-2}-1 torr, but in certain applications the presence of gas in the chamber is either undesirable or ruled out altogether. Accordingly, there is interest in the possibility of beam transport in vacuum by a longitudinal magnetic field, which, in practice, must be comparable to the self-field of the beam.

Our purpose here is to determine the external magnetic field required for the flow of a specified total current and a specified total particle energy, taking the beam diamagnetism and space charge into account. Even in this formulation the problem is not unambiguous since the result must depend on the particle distribution in phase space, which is governed by conditions prevailing at the cathode. The most graphic model, which is the one usually adopted in the theory of low-current beams[6] and which is generalized below to the case of high-current electron beams, is the "laminar-flow model," described by the self-consistent hydrodynamic equations at zero temperature.[7] In cases of practical interest, however, the motion of the particles in a high-current electron beam differs markedly from laminar flow, and the kinetic approach must be adopted. We believe that the use of the hydrodynamic equations for a beam with a local Maxwellian temperature[8] is difficult to justify under conditions such that particle collisions can essentially be neglected.

We adopt a system of units in which e = m = c = 1; the unit of current is then 17 kA, the unit of energy is 0.511 MeV, the unit of magnetic stiffness is 1.7 kG · cm, and the unit of power is 8.7 GW.

1. HYDRODYNAMIC BEAM

We consider nonintersecting particle trajectories in the beam, which is assumed to be steady-state, axisymmetric, and homogeneous in the propagation direction (the z axis). The system of equations describing this state is

$$(\boldsymbol{\beta}\nabla)\boldsymbol{\beta}\gamma = \mathbf{E} + [\boldsymbol{\beta}\mathbf{B}]; \operatorname{curl}\mathbf{B} = 4\pi\rho\boldsymbol{\beta}; \ \operatorname{div}\mathbf{E} = 4\pi\rho, \tag{1}$$

where **E** and **B** are the electric and total magnetic fields, β and γ are the particle velocity and energy, and ρ is the charge density. All quantities are functions of the radius r alone in the polar coordinate system; we have $\beta_r \equiv 0$, so that the continuity equation is satisfied automatically. We can then write

$$\left.\begin{array}{c} \dfrac{\gamma\beta_\theta^2}{r} + E_r + \beta_\theta B_z - \beta_z B_\theta = 0, \\ B_z' = -4\pi\rho\beta_\theta; \ (rB_\theta)' = 4\pi\rho r\beta_z; \ (rE_r)' = 4\pi\rho r \end{array}\right\} \tag{2}$$

with the boundary conditions $B_z(r_e) = B_e$, $B_{\theta i} = 0$, $E_{ri} = 0$. Below, the subscripts "i" and "e" denote quantities at the inner and outer surfaces of the (generally hollow) beam; B_e represents the external magnetic field.

The hydrodynamic system thus only yields four equations for six quantities: ρ, β_z, β_θ, E_r, B_θ, and B_z. We can express two of these quantities as functions of the radius, reflecting the ambiguity mentioned above. As one auxiliary condition we take the total energy of the particles over a cross section to be constant; this case corresponds to the injection of a monoenergetic beam. We write the corresponding condition as

$$\gamma' = E_r. \tag{3}$$

We are now left with only a single relation between hydrodynamic quantities; the various forms of this relation lead to various models for the beam.[1)] In choosing this relation we must take account of the physical restrictions: The density and longitudinal velocity must be nonnegative.

As a typical model, for which we can find an analytic solution, we consider a monochromatic beam, i.e., one in which the longitudinal velocity is uniform over the cross section. Using the notation

$$\gamma_\parallel = (1-\beta_z^2)^{-1/2}; \ \gamma_\perp = \frac{\gamma}{\gamma_\parallel} \tag{4}$$

and eliminating the fields and densities from (2), we find an equation for $\gamma_\perp$:

$$[\gamma_\perp' r(\gamma_\perp^2-1)^{-1/2}]' = \frac{\gamma_\perp(\gamma_\perp^2-1)^{3/2}}{r}, \tag{5}$$

The solution of this equation can be expressed in terms of elliptic Jacobi functions and depends on the single parameter C, which takes on any value between $-\infty$ and γ_e^2:

$$\gamma_\perp(r) = \begin{cases} \sqrt{C}\, cn\left(i\sqrt{C-1}\ln\dfrac{r}{r_i}; \sqrt{\dfrac{C}{(C-1)}}\right) \text{ for } C > 1, \\ cn\left(i\sqrt{1-C}\ln\dfrac{r}{r_i}; (1-C)^{-1/2}\right) \text{ for } C < 1. \end{cases} \tag{6}$$

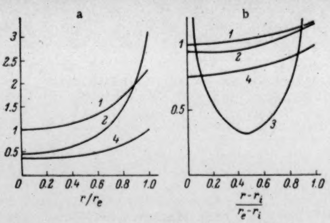

Fig. 1. Distribution of the principal electrodynamic quantities over the beam cross section. a) Continuous hydrodynamic beam, $\gamma_e = 3$, $I = I_{max} = 1.8$ (30.7 kA), $r_eB_e = 6.93$ (11.8 kG·cm); b) hollow kinetic and hydrodynamic beams, $\gamma_e = 3$, $I = 17.7$ (300 kA), $r_eB_e = 27$ (45.5 kG·cm). 1) Transverse energy $\gamma_\perp$; 2) charge density ρ for a hydrodynamic beam; 3) ρ for a kinetic beam; 4) longitudinal magnetic field B_z.

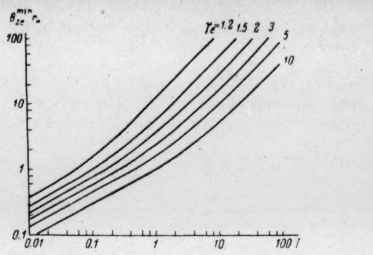

Fig. 2. Minimum external magnetic field B_e as a function of the total beam current I for the hollow hydrodynamic model and for various total energies γ_e (the curves are labelled).

We write the principal physical quantities in terms of $\gamma_\perp(r)$ as follows:

$$\left.\begin{aligned} E_r &= \frac{\gamma_\parallel}{r}[(\gamma_\perp^2-1)(\gamma_\perp^2-C)]^{1/2};\\ rB_z &= (\gamma_\perp^2-1)^{1/2}+\gamma_\perp(\gamma_\perp^2-C)^{1/2},\\ 4\pi\rho &= \frac{\gamma_\parallel\gamma_\perp}{r^2}[2\gamma_\perp^2-1-C]. \end{aligned}\right\} \tag{7}$$

The total beam current I and the external field are related by the parametric relations

$$I = \frac{1}{2}\beta_z\gamma_\parallel[(\gamma_{\perp e}^2-1)(\gamma_{\perp e}^2-C)]^{1/2};$$

$$r_eB_e = (\gamma_{\perp e}^2-1)^{1/2}+\gamma_{\perp e}(\gamma_{\perp e}^2-C)^{1/2}. \tag{8}$$

From (6) we can determine, in terms of the same parameters C and $\gamma_{\perp e}$, the hollowness coefficient of the current, $\mu = r_i/r_e$. We note that with $C > 1$ the quantity $\gamma_{\perp i}^2$ is equal to C; with $C < 1$ we have $\gamma_{\perp i} = 1$, corresponding to purely longitudinal particle motion at the linear beam surface. Figure 1 shows a typical distribution of the hydrodynamic quantities over the beam cross section.

Specification of the total particle energy γ_e determines $\gamma_{\perp e} = \gamma_e/\gamma_\parallel$, so that the $r_eB_e(I)$ curves for γ_e = const must be a single-parameter family. Interestingly, if we choose the hollowness coefficient of the current as this parameter, we find that these curves are double-valued, implying the existence of a limiting current. Increasing the current for a given hollowness coefficient increases the sag in the potential and the transverse-motion energy. If this energy becomes comparable to the total energy we find that the longitudinal velocity and thus, the current, begin to decrease, although the magnetic stiffness and charge density in the beam continue to increase. In a beam with a low hollowness coefficient the limiting transportable current is of the order of the Alfvén current, although the physical origin of this limitation is the transverse sag of the potential, rather than the self-magnetic field.

Transport of currents considerably higher than the Alfvén limit $I_A = \sqrt{\gamma_e^2 - 1}$ in a magnetic field is possible, according to (8), only at large negative values of C, since both $\gamma_\parallel$ and $\gamma_{\perp e}$ are always smaller than γ_e. On the one hand, this restriction implies $\gamma_{\perp i} = 1$, i.e., that the particles have only a longitudinal velocity at the inner surface of the hollow beam. On the other hand, the asymptotic form of (6) for $C \to -\infty$ yields

$$\mu = 1 - \frac{\operatorname{arch}\gamma_{\perp e}}{|C|^{1/2}}, \tag{9}$$

from which we see that the beam must have a strongly defined hollow structure. In principle, the transported current can be arbitrarily large if the hollow nature is sufficiently pronounced and if the magnetic stiffness is sufficiently high.

Of more interest in practice is the optimum beam, corresponding to the lowest magnetic stiffness for a given current, i.e., corresponding to the optimum choice of a hollowness coefficient. Possibilities of this optimization are illustrated in Fig. 2, which shows the envelopes of the family discussed above for various total energies. At small currents $r_eB_e^{min} \sim I^{1/2}$; at large currents $r_eB_e^{min} \sim I$, and the complete behavior of the curves is described, with an accuracy sufficient in practice, by the approximation

$$r_eB_e^{min} \approx \frac{2}{\gamma_e}\sqrt{\gamma_e^2-1}\left[\frac{I}{I_0}+\frac{I^2}{I_0^2}\right]^{1/2};\ I_0 = \frac{(\gamma_e^2-1)^{3/2}}{2\gamma_e^2}. \tag{10}$$

The optimum hollowness coefficient increases with increasing current.

This model of a monochromatic beam is not, of course, clearly defined. However, a study of other models (e.g., that with ρ = const) by numerical methods yields qualitatively the same results. Furthermore, in the high-current limit, for which the hollowness coefficient approaches unity and the details of the "internal" beam structure become unimportant, the asymptotic behavior turns out to be the same for the various models.

2. KINETIC DESCRIPTION OF THE BEAM

As mentioned above, real high-current beams generally have a relativistic "temperature," i.e., there is a difference between the energy of the microscopic motion and the energy corresponding to the average macroscopic velocity. Let us examine how seriously this effect influences the transport properties of the magnetic field and the beam diamagnetism.

When the system is homogeneous with respect to θ and z and steady-state in time, the kinetic equation without a collision term is satisfied identically by an arbitrary nonnegative function $f(H, P_\theta, P_z)$ of three integrals of motion: the Hamiltonian, the generalized angular momentum, and the generalized longitudinal momentum, which are related to the particle momentum **p** and the electromagnetic potentials Φ, A_θ, and A_z by

$$H = [1 + p_r^2 + p_\theta^2 + p_z^2]^{1/2} + \Phi;\quad P_\theta = r(p_\theta + A_\theta);\quad P_z = p_z + A_z. \tag{11}$$

The charge and current densities are then

$$\rho = \int f d\mathbf{p} = -\frac{\partial U}{\partial \Phi};\quad j_\theta = \int f \frac{p_\theta}{H - \Phi} d\mathbf{p} = \frac{\partial U}{\partial A_\theta};$$

$$j_z = \int f \frac{p_z}{H - \Phi} d\mathbf{p} = \frac{\partial U}{\partial A_z}, \tag{12}$$

where

$$U(\Phi, A_\theta, A_z, r) = \frac{2}{r} \int f p_r^2 dH dP_\theta dP_z, \tag{13}$$

and the integration is carried out over the region in phase space in which $p_x^2 \geq 0$.

By virtue of the symmetry of Eqs. (12), self-consistent equations for the potentials Φ, A_θ, and A_z can be written in the form

$$\begin{pmatrix} \frac{1}{r}\frac{d}{dr} r \frac{d}{dr} & 0 & 0 \\ 0 & \frac{d}{dr}\frac{1}{r}\frac{d}{dr} r & 0 \\ 0 & 0 & \frac{1}{r}\frac{d}{dr} r \frac{d}{dr} \end{pmatrix} \mathbf{R} = 4\pi \nabla_{\mathbf{R}} U(\mathbf{R}, r), \tag{14}$$

where **R** is the three-dimensional vector with components $\{-\Phi, -iA_\theta, -iA_z\}$.

For comparison with the laminar flow discussed above we again consider monoenergetic and monochromatic beams. We also assume that all particles have the same generalized angular momentum. On the one hand, this condition corresponds to the actual conditions that prevail for injection from a ring cathode in a longitudinal magnetic field; on the other, it ensures that each particle moves from the outer beam radius to the inner beam radius. For our purposes, this situation is the limiting case opposite that of the laminar flow discussed in Sec. 1.

The distribution functions corresponding to this model are

$$f = f_0 \delta(H) \delta(P_\theta) \delta(P_z) \tag{15}$$

and

$$U(\mathbf{R}, r) = \frac{2f_0}{r}(R^2 - 1)^{1/2}. \tag{16}$$

The addition of arbitrary constants to the arguments of the δ functions is equivalent to the addition of constants to the potentials and thus does not alter the physical state. In this case, over the entire volume occupied by the beam, $\Phi \equiv -\gamma$, $A_\theta \equiv -p_\theta$, and $A_z \equiv -p_z$. The boundary conditions for Eqs. (14) are conveniently specified at the inner beam surface:

$$\mathbf{R}_i = \{\sqrt{1 + p_{\theta i}^2 + p_{zi}^2};\ ip_{\theta i};\ ip_{zi}\};\quad \mathbf{R}_i' = \left\{0;\ -iB_{zi} - \frac{ip_{\theta i}}{r_i};\ 0\right\}. \tag{17}$$

We can now show that distribution function (15) actually corresponds to a monochromatic beam. Multiplying the first component of (14) by A_z, multiplying the third by Φ, and taking the difference we find, taking account of the boundary conditions, the first integral

$$p_z = \text{const}\,\gamma,$$

from which we see that the longitudinal velocity is constant over the cross section and that Eq. (14) is in fact two-dimensional.

The solution of Eq. (14) allows us to write the following equations in terms of the properties at the inner boundary:

$$\gamma_e = -\Phi_e;\quad r_e B_e = \frac{d}{dr} r A_\theta \Big|_e;\quad I = -\frac{r_e}{2} \beta_z \frac{d\Phi}{dr}\Big|_e;\quad p_{\theta e} = -A_{\theta e}. \tag{18}$$

We can also write an equation for the dimensionless outer beam radius $f_0 r_e$, determined from the condition $R_e^2 = 1$ (we note that the normalization constant f_0 only determines the absolute dimension of the beam and does not appear in the final results). Used along with a kinematic equation at the outer boundary, $p_{\theta e}^2 = \gamma_e^2/\gamma_\parallel^2 - 1$, this equation allows us to write the magnetic stiffness $r_e B_e$ and the current in terms of the three quantities γ_e, B_z, and $\mu = r_i/r_e$, as in Sec. 1.

In the limiting case of a low beam density, to a first approximation we then have

$$B_e r_e \approx -\frac{2p_e}{1 \mp \mu};\quad I \approx \frac{1}{2} \beta_z \frac{(\gamma_e - \gamma_i)}{\ln \frac{2}{1 + \mu}}, \tag{19}$$

where the upper sign corresponds to $p_i \approx -p_e$ and the lower to $p_i \approx p_e$, corresponding to two different projections on the beam cross section (Figs. 3a and 3b). The first of these states, which is somewhat analogous to that of the hydrodynamic case with $c < 1$, permits a greater range of possibilities in high-current transport, while the second has marked diamagnetic properties. By varying the hollowness coefficient we can easily find the envelope of this family, i.e., the minimum field required for propagation of a given (small) current:

$$\gamma_i = \gamma_\parallel;\quad r_e B_e^{\min} \approx 4\sqrt{\ln 2}\, I^{1/2} (\gamma_e^2 - 1)^{-1/4}. \tag{20}$$

Condition (20) differs from the corresponding limiting case in (10) only in that the coefficient $4\sqrt{\ln 2} \approx 3.33$ appears instead of $2\sqrt{2} \approx 2.83$.

As in the hydrodynamic case the current is limited by the transverse sag of the electrostatic potential; hence it is reasonable to expect that a high current can only propagate in a hollow beam; then neglecting 1/r in com-

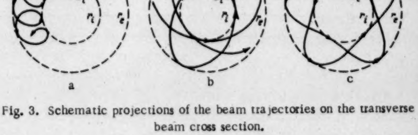

Fig. 3. Schematic projections of the beam trajectories on the transverse beam cross section.

parison with d/dr, we find the plane approximation, in which Eq. (14) becomes

$$\mathbf{R}''=\frac{8\pi I_0}{r_i}\nabla_R\sqrt{R^2-1} \tag{21}$$

and agrees formally with the equation describing the nonrelativistic motion of a material point in a centrally symmetric field. Without going into the details of the solution (see ref. 10), we write the distribution of the principal electrodynamic quantities over the cross section:

$$\left.\begin{aligned}\gamma_\perp\equiv-\frac{\Phi}{\gamma_\parallel}=R\cosh(\varepsilon-\psi);\ p_\theta\equiv-A_\theta=R\sinh(\varepsilon-\psi),\\ p_z\equiv-A_z=\beta_z\gamma_\perp\gamma_\parallel,\end{aligned}\right\} \tag{22}$$

where sinh ε = $p_{\theta i}$ and where the functions R(r) and ψ(r) are written implicitly in quadratures [the r(R) functional dependence is double valued]:

$$\left.\begin{aligned}r-r_i=\int_1^R\frac{RdR}{Q(R)};\quad \psi(r)=B_{zi}\int_1^{R(r)}\frac{dR}{RQ(R)},\\ Q=\left[\frac{8\pi I_0}{r_i}R^2\sqrt{R^2-1}-B_{zi}^2(R^2-1)\right]^{1/2}.\end{aligned}\right| \tag{23}$$

From simple physical considerations and (22) it again follows that the maximum transportable current corresponds to ε = 0, i.e., to the case in which there is no orbiting motion at the inner boundary of the beam. The density distribution for this case is also shown in Fig. 1. Despite the pronounced difference between this density distribution and that of the hydrodynamic case we note that the potential and magnetic field behave in essentially the same manner within the beam.

Corresponding to the optimum beam, i.e., to the minimum magnetic field for a specified current, there is also a definite longitudinal velocity,

$$\beta_z^{\text{opt}}=\sqrt{\frac{(\gamma_e^2-1)}{(\gamma_e^2+1)}}, \tag{24}$$

for which we have the following relation between the field and the current:

$$r_eB_e^{\min}=\frac{4\gamma_e}{\gamma_e^2-1}I,\quad I\gg\gamma_e, \tag{25}$$

which agrees exactly with hydrodynamic equation (10) over its entire range of applicability. Accordingly, the "temperature" effect turns out to be important in the transport of optimum beams only at low currents.

3. DIAMAGNETISM OF A HIGH-CURRENT ELECTRON BEAM

We see from the discussion above that in any finite magnetic field a charged beam rotates, i.e., produces diamagnetic currents which displace the magnetic field from the beam volume. This effect becomes particularly important for total currents on the order of I_A, for which the orbital velocity is relativistic.

In general, beam states providing the maximum transportable current yield a relatively low diamagnetism, for the particles in them must have a minimum transverse energy, due primarily to the sag of the electrostatic potential. In the hydrodynamic case the maximum diamagnetism comes from states for which C → 1 [see (7) and (8)] and

$$\frac{B_{ze}}{B_{zi}}\to\frac{(\gamma_{\perp e}+1)^2}{4}; \tag{26}$$

the ratio of the internal radius to the external radius tends toward zero, or the beam becomes continuous. We note that the diamagnetism increases with increasing total particle energy and with decreasing longitudinal energy ($\gamma_{\perp e}\to\gamma_e$). In all cases, however, the internal field has the same sign as the external field; otherwise a hydrodynamic equilibrium would not be possible.

In general, the kinetic beam model yields analogous results. For a highly hollow beam the diamagnetism corresponding to the transport of high currents is relatively low; from Eqs. (22) and (23) we find

$$\frac{B_{ze}}{B_{zi}}=\cosh(\psi_e-2\varepsilon)=\gamma_{\perp e}\gamma_{\perp i}+\sqrt{(\gamma_{\perp e}^2-1)(\gamma_{\perp i}^2-1)}, \tag{27}$$

and in the optimum beam ($\gamma_{\perp i}=1$) this ratio decreases even further, to $\gamma_{\perp e}$. We note that in this approximation only trajectories of the type shown in Fig. 2a are described, for which the inner part of the beam rotates in the direction opposite the rotation of the outer part. Obviously, motion like that in Fig. 3b, which is possible in the case of a small hollowness coefficient, provides a large azimuthal current and, correspondingly, a large diamagnetism. Numerical solution of Eq. (14) confirms this conclusion; as the diamagnetism increases, the hollowness coefficient decreases. We note that trajectories of the type in Fig. 3b correspond to negative values of the generalized angular momentum; this case is possible, e.g., when a cathode moves in a magnetic field directed opposite to the guiding field.

Also of interest is the hypothetical situation in which the internal field is directed opposite the external field. Such an equilibrium state, or "E layer," is known to actually be possible in the case of neutralized beams[11] and has been achieved in practice.[12] For charged beams this state should correspond to the trajectories shown in Fig. 3c, which do not qualitatively contradict the conditions for a force equilibrium. However, in the numerical study of the equations for values of r_eB_e and γ_e which are achievable in practice, no such states were found.

The authors thank A. A. Kolomenskii for his interest and É. N. Chaikovskaya for the extensive numerical calculations.

[1)] The second condition in ref. 9, although not contradictory, does not follow, as the author asserts, from any physical consideration; it is an artificial restriction.

Electron energy spectrum in a high-current vacuum diode

S. P. Bugaev, V. I. Koshelev, and M. N. Timofeev

Institute of Atmospheric Optics, Siberian Branch,
Academy of Sciences of the USSR, Tomsk

(Submitted August 3, 1973)
Zh. Tekh. Fiz., 44, 1917-1921 (September 1974)

In an experimental study of the electron energy spectrum in a high-current vacuum diode it is found that the energy spectra for single-point and multipoint cathodes are similar in shape. When current flows stably from the surface of the cathode-burst plasma the spectrum is smooth; when the current is unstable, the spectrum displays lines. The measured spectrum agrees satisfactorily with that constructed from current and voltage oscillograms recorded simultaneously. The maximum energy of the beam electrons is studied as a function of the cathode–anode gap and the length of the voltage pulse. Anomalous electrons, with energies above the applied voltage, are detected. It is concluded from the experimental results that the limiting energy of these anomalous electrons is not a function of the length of the voltage pulse (10^{-8}-10^{-7} sec) or the gap size (d = 4-32 mm) but is a function of the maximum energy of the beam electrons (E_{max} = 150-300 kV). For a multipoint cathode this limiting energy is $E_{lim} \approx 3E_{max}$; for a single-point cathode it is $E_{lim} \approx 2E_{max}$. The experimental data do not furnish an adequate basis for discussing in detail the mechanism by which electrons are accelerated to energies exceeding the applied voltage.

Study of the shaping of electron beams in plasma-cathode diodes has revealed stable and unstable current-flow regimes.[1,2] In the unstable case electrons are detected at energies above the applied voltage,[3] and ions are found to be accelerated in electron beams.[4] Refinements in the techniques for shaping intense electron beams[5,6] led to the use of cathodes with explosive electron emission.[7] Study of this phenomenon revealed high-energy electrons[8] and ions of the cathode-burst plasma accelerated toward the anode[9] and cathode.[10]

Below we report a study of the electron energy spectrum during stable and unstable current flow from the surface of a cathode-burst plasma. We present data on the properties of the high-energy electrons as a function of the diode geometry and the length of the high-voltage pulse.

EXPERIMENTAL APPARATUS AND PROCEDURE

Figure 1 shows the experimental apparatus. A negative voltage pulse is shaped by a lumped-capacitance (C_{pu} = 400 pF) GIN-300 generator (1). The pulse height is 300 kV and its rise time is τ_{fr} = 5 nsec. The pulse length is varied over the range 10^{-8}-10^{-7} sec by a cutoff switch in vacuum chamber 2. The vacuum, produced by an oil-vapor pump, is $5 \cdot 10^{-5}$ torr.

The cathode in the experiments consists of a single point (Cu, Mo) or a multipoint copper cathode with a packing density of 10^2 cm^{-2}. The interelectrode gap is 4-32 mm. The anode is a high-transmission molybdenum grid.

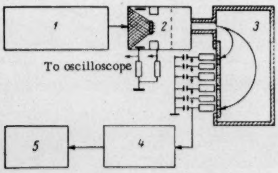

Fig. 1. Block diagram of the experimental apparatus.

A simultaneous oscilloscope display is made of the current pulse (taken from a Rogowski loop) and the voltage pulse (from a capacitative divider), and the energy spectrum is measured by semicircular-focusing spectrometer[11] 3. The recording circuit of the spectrometer uses 20 aluminum sheets with memory elements using FT-1 capacitors. A readout device sends a signal to amplifying electrometer 4 (input resistance of 1000 Ω); the signal is recorded by a KSP-4 electronic potentiometer 5.

A graphical method is used to construct the electron energy spectrum for various gaps from the simultaneously recorded current and voltage oscillograms. For this purpose the amplitude of the voltage pulse, $U_d(t)$, is partitioned into a certain number of intervals in steps of ΔU. The average current for the given time interval, i(t), is then determined. Then the data are analyzed on the basis of the equation

$$\frac{dN}{dU_d} = \frac{i(t)}{e}\left(\frac{dU_d}{dt}\right)^{-1}, \tag{1}$$

where e is the electron charge and N is the number of electrons. A similar problem is solved in ref. 12.

EXPERIMENTAL RESULTS

The energy spectra corresponding to the single-point cathode and the multipoint cathode are similar, so we will discuss only the spectra for the multipoint cathode.

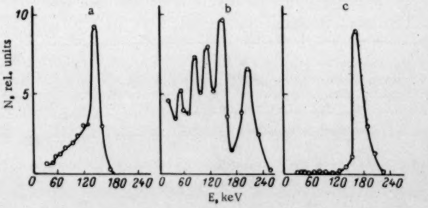

Fig. 2. Energy spectra. a) d = 4 mm, τ_p = 100 nsec; b) 20 mm, 100 nsec; c) 20 mm, 12 nsec.

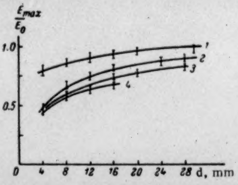

Fig. 3. Maximum electron energy in the beam as a function of the anode–cathode gap. 1) Single point, τ_p = 10 to 100 nsec; 2) multipoint cathode, τ_p = 100 nsec; 3) multipoint cathode, τ_p = 12 nsec; 4) multipoint cathode, τ_p = 10 nsec.

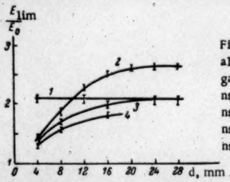

Fig. 4. Limiting energy of the anomalous electrons as a function of the gap. 1) Single point, τ_p = 10 to 100 nsec; 2) multipoint cathode, τ_p = 100 nsec; 3) multipoint cathode, τ_p = 12 nsec; 4) multipoint cathode, τ_p = 10 nsec.

Figure 2 shows the energy spectra for various gaps and pulse lengths. As the gap is increased in size, the spectrum changes markedly, going from a single-peak spectrum into a line spectrum. A high-voltage pulse with a length of $\sim 1 \cdot 10^{-8}$ sec is used to obtain an electron beam with a narrow energy spectrum (half-width 10-15%).

Figure 3 shows the maximum energy of the electrons in the beam found for single-point and multipoint cathodes as a function of the cathode–anode gap and the length of the voltage pulse. The energies are given in relative units; E_0 is the electron energy at the maximum voltage across the diode (300 kV). The maximum electron energy for the single-point cathode is slightly larger and is independent of the voltage-pulse length.

Study of the energy characteristics of the electron beam shows electrons at energies above the applied voltage (anomalous electrons); they make up 0.1-1% of the total charge which flows. The limiting energy of the anomalous electrons, detected by the spectrometer, is independent of the gap and the length of the voltage pulse (within the experimental errors) for the case of a single-point cathode; for a multipoint cathode it is higher, and its functional dependence on the gap typically displays saturation (Fig. 4). To confirm that these are actually high-energy electrons, rather than the results of the incidence of reflected electrons on the sheets, we place irises in the vacuum chamber of the spectrometer, which block the low-energy part of the spectrum. We find no change in the shape of the high-energy tail of the distribution.

Using the simultaneous recordings of the current and voltage as described above, we construct the spectrum. Figure 5 shows the constructed and measured spectra for a gap of 12 mm. We see that the agreement is satisfactory.

DISCUSSION OF RESULTS

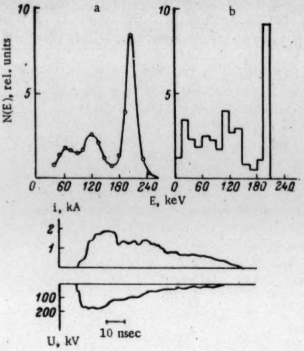

Fig. 5. Energy spectra. a) Measured (d = 12 mm, τ_p = 100 nsec); b) spectrum constructed from the current and voltage oscillograms (d = 12 mm, τ_p = 100 nsec).

The energy characteristics of the electron beam are functions of the nature of the high-voltage pulse generator, the parameters of the discharge circuit, and the physical processes involved in the current flow from the surface of the cathode-burst plasma.[13,14] In numerical calculations we determine the shape of the energy spectrum of an electron beam shaped by a lumped-capacitor generator; the equivalent circuit is shown in Fig. 6. The switching is assumed ideal. The calculation is carried out for a plane diode with a constant perveance p; this is a legitimate assumption in the case of large gaps, for which we can neglect the penetration of the cathode plasma into the gap. The spectrum is analyzed on the basis of the system of equations

$$\left.\begin{aligned} \int_0^{t_p} \frac{i(t)}{C}\,dt + L\frac{di(t)}{dt} - U_d(t) = 0, \\ i(t) = pU_d^{3/2}(t), \\ \frac{dN}{dU_d} = \frac{i(t)}{e}\left(\frac{dU_d}{dt}\right)^{-1}, \end{aligned}\right\} \qquad (2)$$

where L and C are the inductance and capacitance, respectively, of the generator. Solution of this system of equations is trivial for the discharge of the capacitance; the energy spectrum is "table-shaped" (1 in Fig. 6). The inductance is taken into account in a calculation of the spectrum on an M-220 computer (2 in Fig. 6); the result agrees satisfactorily with the experimental results.

However, it is found experimentally that the shape of the energy spectrum depends on the current-flow conditions; in the case of stable current flow, the spectrum is smooth (Fig. 2a), but as the gap is lengthened (d > 10 mm), a modulation appears in the electron current. There are

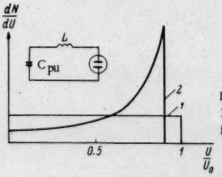

Fig. 6. Theoretical spectral shape. 1) Inductance of generator not taken into account; 2) taken into account.

spikes exceeding the amplitude of the basic signal by a factor of 1.5-2, implying an unstable current flow. Here the spectrum has lines (Figs. 5 and 2b). The spectral oscillations are observed at low energies. At a voltage pulse length of 12 nsec an electron beam with a smooth spectrum is shaped (Fig. 2c), so we conclude that the time over which the unstable current flow sets in is longer than $1 \cdot 10^{-8}$ sec.

It follows from the experimental results on the electron-beam energy spectrum (4 in Fig. 3) that the limiting energy of the anomalous electrons is not a function of the voltage pulse length or the gap size, but is a function of the maximum energy of the beam electrons. Over the range $E_{\max}$ = 150-300 keV (Fig. 3), the energy $E_{\lim}$ is essentially a linear function of $E_{\max}$, described by $E_{\lim} \approx 3E_{\max}$ for the multipoint cathode and $E_{\lim} \approx 2E_{\max}$ for the single-point cathode. No functional dependence of the limiting electron energy on the cathode material is found. The independence of the limiting energy from the gap size implies that the current-flow conditions do not affect the acceleration, and the independence of this energy from the length of the voltage pulse implies short characteristic acceleration times. The appearance of electrons at an anomalously high energy can result from an overvoltage across the accelerating gap. Another possible mechanism is stochastic acceleration of electrons in the cathode-burst plasma by the plasma turbulence,[15] which occurs as a result of the electron-drift instability.[16,17] It should be noted that the operating conditions are different for the single-point and multipoint cathodes: In the case of the multipoint cathode the current from a single point is two or three orders of magnitude lower than that in the case of a single-point cathode. There is also an important difference in the topology of the electric field at the cathodes. These factors apparently influence the acceleration efficiency. These experimental results do not furnish an adequate basis for a detailed discussion of the mechanism accelerating electrons to energies exceeding the applied voltage.

In studying the procedure for constructing the spectrum from the current and voltage oscillograms we construct spectra for two current-flow regimes. In the case of large gaps (d = 20 mm), in which case the modulation of the electron current is pronounced, a large number of partitions is required if the current over a single interval is to be essentially constant. This circumstance gravely complicates construction of the spectrum. This method seems to be workable if the modulation of the electron current and of the voltage is weak. The method can distinguish energy peaks in the spectrum separated by ~60 keV (Fig. 5).

The authors thank V. V. Kremnev for useful discussion.

Multiphase, uniform, secondary-emission microwave discharge at a solid surface

G. S. Luk'yanchikov

P. N. Lebedev Physics Institute,
Academy of Sciences of the USSR, Moscow

(Submitted June 4, 1973; resubmitted February 19, 1974)
Zh. Tekh. Fiz., 44, 1922-1928 (September 1974)

The electron velocity distribution function, the threshold for the onset of the secondary-emission discharge, and the growth rate are determined for the case in which the high-frequency electric field is perpendicular to the surface. The results are applied to a microwave system with a large distance between the walls and to a single-ended discharge with a weak restoring force.

INTRODUCTION

In many theoretical papers on secondary-emission rf discharges at surfaces perpendicular to the high-frequency electric field (e.g., refs. 1-4), it is assumed that only electrons emitted in a narrow phase range (single phase) $\Delta\varphi_1 \ll \pi/2$, in resonance with the field, participate in the discharge.

It is thus assumed that most of the electrons participating in the discharge are monoenergetic. A condition for the occurrence of the discharge is that the field reach a level such that the secondary-emission yield is $\sigma > 1$ for electrons in resonance with the field. The spread of the initial electron velocities and the functional dependence on the collision energy W_c are neglected (only a single point in the functional dependence of σ on the energy is used − that energy W_1 at which the yield is $\sigma = 1$).

This approach is justified if the transit time of an electron between the two walls (a double-ended discharge) or the time interval between emission and collision with the same surface (a single-ended discharge) is so short that the spread in the initial electron velocities does not lead to a large spread in the field phases corresponding to the collision with the wall. A typical situation in which this resonant treatment is legitimate is that of a discharge in the narrow "capacitance" gap of a cavity resonator. However, in an apparatus in which a high level of microwave power is used and in which the walls are far apart (e.g., rf heating in thermonuclear devices, cavity resonators, waveguides, etc.), the approximation based on monoenergetic, in-phase electrons is not valid; even the thermal spread of initial velocities[1)] leads, over the long transit time, to an important spread in field phases at collision or at secondary emission.

In the discharge a distribution of electrons with respect to emission phase is established, and since electrons from a broad energy interval[2)] participate in the discharge, it is necessary to take account of the functional dependence of σ on energy over the entire range of energies which an electron can acquire in the microwave field. It is necessary to determine this distribution function in order to study the secondary-emission discharge.

Miller et al.[7] have determined the distribution functions for certain particular cases through numerical experiments, and Stanskii et al.[8] found the conditions for onset of a discharge for an arbitrary electron distribution function.

STATEMENT OF THE PROBLEM

We are concerned here with the initial stage of the discharge, in which we can neglect space-charge effects; we are to find the electron distribution with respect to emission phase and determine the threshold field for a discharge between two infinite plates in an alternating electric field perpendicular to the surface and exerting a force $F\sin\omega t$ on an electron. We make the following assumptions.

1. The time between electron emission, t_1, and collision with the second wall is so long that electrons emitted at any phase $\varphi_1 + 2\pi k$ (k is an integer, and $\varphi_1 = \omega t_1$) can be assumed to be distributed uniformly in the region in front of the surface with which they will collide. It is not difficult to show that condition for a uniform distribution of in-phase electrons is

$$\frac{t_f}{T} \gg \frac{v_m}{\Delta v}. \tag{1}$$

Here $T = 2\pi/\omega$, Δv is the half-width of the distribution with respect to initial velocities of the in-phase electrons (at $T_e = 2$-4 eV, we have $\Delta v \sim 10^6$ m/sec), $v_m = F/m\omega$, m is the electron mass, and t_f is the time the electron spends in the field between the walls. This condition holds, e.g., in a standard centimeter-range waveguide at a microwave power of 100-1000 kW for the case of a double-ended discharge between walls or a single-ended discharge on any structural element, in the presence of a force which turns emitted electrons back toward the surface (e.g., electrostatic forces). It is easy to show that if the transit time of the electron in the restoring field satisfies (1) a single-ended discharge is analogous to a double-ended discharge.

2. We assume that the functional dependence of σ on the collision energy is

$$\sigma = \frac{W_c}{W_1}, \tag{2}$$

which is a good approximation of the secondary-emission characteristics for most materials in the initial stage.

3. In analyzing the electron dynamics in front of the discharge surface we neglect the initial velocity[3)] and assume that the electron motion is governed completely by the microwave field. This assumption is valid since most of the electrons must have an energy[4)] $W_c \sim W_1 \gg 2$-4 eV.

EQUATIONS OF MOTION

Integrating $\ddot{x} = (F/m)\sin\omega t$ (the x axis is perpendicular to the emitting surface and parallel to F), and using assumption 3, we find equations for the electron velocity to the wall and for the dimensionless coordinate of an arbitrary electron, $\xi = xm\omega^2/F$:

$$\dot{x} = \frac{F}{m\omega}(-\cos\varphi + \cos\varphi_1), \tag{3}$$

$$\xi = -\sin\varphi + \varphi\cos\varphi_1 + c. \tag{4}$$

Here, $\varphi = \omega t$. Since the in-phase electrons are distributed uniformly, c can take on any value.

PHASE RANGE FOR THE PRIMARY AND SECONDARY CURRENTS

First we note that only electrons created at the wall in the phase range $\varphi_1 = (0-\pi/2) + 2\pi k$ can leave the wall and participate in the discharge, since they have a velocity component $(F/m\omega)\cos\varphi_1$ directed away from the wall.

We seek the phase range over which electrons can strike an obstacle in their path. Figure 1c shows the electron coordinate as a function of the field phase according to Eq. (4). As an example, we consider an electron with a dc velocity component corresponding to the creation phase $\pi/3$. We see from Fig. 1c that, between phase a_2, at which the electron velocity vanishes (Fig. 1b), and phase a_1, no electron having this dc velocity can reach an object in the x direction. Over the range a_1-a_2, on the other hand, the number of particles reaching the opposite surface is proportional to electron velocity (3) (Fig. 1b). It is easy to see that $a_2 = 2\pi k - \varphi_1$ (where k is any integer). We find point a_1 from (4), assuming that the coordinate of an electron at phase a_2 is equal to that of an electron at phase a_1: $\xi(a_1) - \xi(a_2) = 0$. As a result, we find an equation for the point a_1:

$$\sin a_1 = a_1\cos\varphi_1 + \varphi_1\cos\varphi_1 - \sin\varphi_1. \tag{5}$$

Through numerical solution of Eq. (5) we find that electrons created in the phase range $(0-1.35) + 2\pi k$ lead to $a_1 \leq \pi + 2\pi k$. Obviously, for these particles $a_2 > 3\pi/2 + 2\pi k$ (Fig. 1b).

This result means that an object lying in the path of the electrons is struck by electrons with dc velocity components corresponding to creation phases between 0 and 1.35 in such a manner that the electrons have a cosine distribution between phases $\pi + 2\pi k$ and $3\pi/2 + 2\pi k$ (Fig. 1b). The phase range $(\pi - 3\pi/2) + 2\pi k$ is precisely that over which secondary electrons created at the opposite surface can escape from this surface toward the original wall, since they have dc velocity components directed away from the surface.

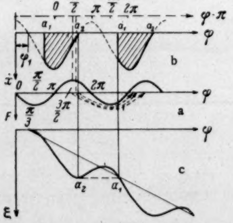

Fig. 1. a) Force exerted on an electron; b) cosine function corresponding to the velocity of electrons emitted at phase $\varphi_1 = 1.05$ (the cross-hatching shows the flow density of in-phase electrons at various field phases; c) dimensionless electron coordinate as a function of the field phase.

DISTRIBUTION FUNCTIONS OF THE PRIMARY AND SECONDARY CURRENTS

Since particles with the same translational velocity are distributed uniformly over the direction of motion with the density n_1, the current i_1 that they produce to a unit area of the wall is given as a function of the field phase by

$$i_1 = \frac{F}{m\omega}(-\cos\varphi + \cos\varphi_1)\,n_1,$$

if $0 < \varphi_1 - 2\pi k < 1.35$. Multiplying and dividing by $\cos\varphi_1$, we find

$$i_1 = \frac{(-\cos\varphi + \cos\varphi_1)}{\cos\varphi_1} I_1, \tag{6}$$

where $I_1 = (Fn_1/m\omega)\cos\varphi_1$ is the time average of the current to a unit surface area of particles with the translational velocity corresponding to creation phase φ_1.

Since we treat the surface on which the electrons are incident as an emitting surface, it is more convenient to shift the reference point for the phase φ by π, so that the active phase range, i.e., that over which electrons can escape the surface, gives from 0 to $\pi/2$, rather than from π to $3\pi/2$ (the dashed axis at the top of Fig. 1). Now Eq. (6) becomes

$$i_1 = \frac{\cos\varphi + \cos\varphi_1}{\cos\varphi_1} I_1. \tag{7}$$

Equation (7) gives the distribution of the current of primary particles with respect to arrival phase φ. We find the distribution of the secondary current i with respect to emission phase by multiplying (7) by σ, in accordance with (2) and (3):

$$i(\varphi) = \frac{W}{W_1}\frac{(\cos\varphi + \cos\varphi_1)^3}{\cos\varphi_1} I_1. \tag{8}$$

where $W = F^2/2m\omega^2$. We see that I_1, any current of primary particles emitted at phase φ_1, produces a current of secondary particles distributed with respect to creation phase φ according to

$$\cos^3\varphi + a\cos^2\varphi + b\cos\varphi + c, \tag{9}$$

where $0 \leq a \leq 3$, $0 \leq b \leq 3$, and $0 \leq c \leq 1$. These coefficients are functions of the emission phase of the primary electron current, φ_1.

Up to this point we have used $_1$ as the creation phase of the primary electrons at one surface and φ as the arrival phase of the primary electrons and the creation of the secondary electrons at the other surface.

It is not difficult to show that the total secondary current, which consists of the sum of the secondary currents i due to the primary electron I_1 with various creation phases φ_1, is also distributed with respect to creation phase according to (9): $D_1(\cos^3\varphi_1 + A_1\cos^2\varphi_1 + B_1\cos\varphi + C_1)$, where D_1 is a coefficient with units of particles per square centimeter per second; A_1, B_1, and C_1 can take on any values in the range specified above for *a*, b, and c.

We now find the numerical values of A_1, B_1, and C_1.

OPERATOR PRODUCING THE SECONDARY DISTRIBUTION FOR A SPECIFIED PRIMARY DISTRIBUTION

We replace I_1 in (8) by $(D_1/2\pi)(\cos^3\varphi_1 + A_1\cos^2\varphi_1 + B_1\cos\varphi_1 + C_1)\Delta\varphi_1$, which is the average current of electrons emitted in the narrow phase range $\Delta\varphi_1 \ll \pi/2$.

Integrating the resulting equation over φ_1 from 0 to 1.35, after converting from $\Delta\varphi$ to $d\varphi$, we find the distribution of secondary electrons with respect to creation phase $D(\cos^3\varphi + A\cos^2\varphi + B\cos\varphi + C)$:

$$\frac{W}{2\pi W_1}\int_0^{1.35}\frac{(\cos\varphi+\cos\varphi_1)^3}{\cos\varphi_1}D_1(\cos^3\varphi_1+A_1\cos^2\varphi_1+B_1\cos\varphi_1+C_1)\,d\varphi_1 = D(\cos^3\varphi+A\cos^2\varphi+B\cos\varphi+C). \tag{10}$$

We simplify the notation by defining

$$\frac{2\pi DW_1}{D_1W}=H. \tag{11}$$

Expanding the quantity in parentheses in the integrand, and assuming the coefficients of a given power of φ on the left-hand and right-hand sides of the equation to be equal, we find, after integration,

$$\left.\begin{aligned} A_1\cdot 0.976+B_1\cdot 1.36+C_1\cdot 2.5+0.785&=H,\\ A_1\cdot 2.36+B_1\cdot 2.93+C_1\cdot 4.07+2&=HA,\\ A_1\cdot 2+B_1\cdot 2.36+C_1\cdot 2.93+1.76&=HB,\\ A_1\cdot 0.588+B_1\cdot 0.666+C_1\cdot 0.785+0.534&=HC.\end{aligned}\right\} \tag{12}$$

Equation (12) gives the relationships among the parameters of the primary current (D_1, A_1, B_1, C_1) and the secondary current (D, A, B, C).

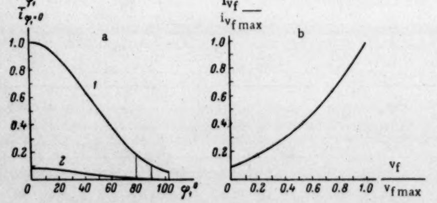

Fig. 2. a) Relative current density of the particles which is established during the discharge as a function of the creation phase φ_1; b) relative current density as a function of the relative translational velocity $v_f = (F/m\omega)\cos\varphi_1$ ($v_{f\,max} = F/m\omega$).

STEADY-STATE DISTRIBUTION FUNCTION AND THE THRESHOLD FIELD

We seek that distribution function which is not changed as a result of the interaction of the current with the wall, i.e., that for which $A_1 = A$, $B_1 = B$, and $C_1 = C$. For this purpose we solve system (12) under the assumptions $A_1 = A$, $B_1 = B$, $C_1 = C$.

A computer solution of Eq. (12) yields the unique solution $A_0 = 2.18$, $B_0 = 1.78$, $C_0 = 0.51$, $H_0 = 6.66$.

Accordingly, the basic current is distributed with respect to creation phase φ_1 according to

$$i_1(\varphi_1) = D_1(\cos^3\varphi_1 + 2.18\cos^2\varphi_1 + 1.78\cos\varphi_1 + 0.51). \tag{13}$$

This equation gives the current distribution with respect to the relative translational velocity (Fig. 1), since $\cos\varphi_1 = v_f m\omega/F$, where v_f is the translational velocity [see (3)].

We can now easily find the condition for which the discharge is self-sustaining. At the threshold power $D/D_1 = 1$; from (11) we find $W/W_1 = 2\pi/6.66$. Accordingly, the threshold field required for the discharge is found from the simple equation

$$W = 0.94W_1. \tag{14}$$

STABILITY OF THE DISTRIBUTION FUNCTION. GROWTH RATE OF THE DISCHARGE

Function (13) is the solution of our original problem only if it is stable. Let us analyze the stability of distribution function (13) with respect to small deviations of A, B, and C from the values $A_0 = 2.18$, $B_0 = 1.78$, $C_0 = 0.51$.

In (12) we replace A_1, B_1, C_1 by $A_0 + A_n$, $B_0 + B_n$, $C_0 + C_n$, respectively, where A_n, B_n, C_n are much smaller than A_0, B_0, C_0, respectively. We find the deviations ΔA_{n+1}, ΔB_{n+1}, ΔC_{n+1} from A_0, B_0, C_0, which are acquired by the secondary distribution function after the interaction of the primary distribution function with the wall. Neglecting terms of second order with respect to ΔA_n, ΔB_n, ΔC_n, we find

$$\left.\begin{aligned} \Delta A_{n+1}&=\Delta A_n\frac{(k_{aa}-A_0k_{ha})}{H_0}+\Delta B_n\frac{(k_{ab}-A_0k_{hb})}{H_0}+\Delta C_n\frac{(k_{ac}-A_0k_{hc})}{H_0},\\ \Delta B_{n+1}&=\Delta A_n\frac{(k_{ba}-B_0k_{ha})}{H_0}+\Delta B_n\frac{(k_{bb}-B_0k_{hb})}{H_0}+\Delta C_n\frac{(k_{bc}-B_0k_{hc})}{H_0},\\ \Delta C_{n+1}&=\Delta A_n\frac{(k_{ca}-C_0k_{ha})}{H_0}+\Delta B_n\frac{(k_{cb}-C_0k_{hb})}{H_0}+\Delta C_n\frac{(k_{cc}-C_0k_{hc})}{H_0}.\end{aligned}\right\} \tag{15}$$

Here k_{aa}, k_{ab}, k_{ac}, ... are the coefficients in system (12), and $H_0 = 6.66$. Substituting in the numerical values we find

$$\left.\begin{aligned} \Delta A_{n+1}&=3.6\cdot 10^{-2}\Delta A_n \quad -4.5\cdot 10^{-3}\Delta B_n \quad -0.21\Delta C_n,\\ \Delta B_{n+1}&=3.9\cdot 10^{-2}\Delta A_n \quad -9\cdot 10^{-3}\Delta B_n \quad -0.23\Delta C_n,\\ \Delta C_{n+1}&=1.3\cdot 10^{-2}\Delta A_n \quad -5.1\cdot 10^{-3}\Delta B_n \quad -7.3\cdot 10^{-2}\Delta C_n.\end{aligned}\right\} \tag{16}$$

If each deviation ΔA_{n+1}, ΔB_{n+1}, ΔC_{n+1} is smaller in absolute value than the preceding deviation ΔA_n, ΔB_n, ΔC_n, respectively, the function is stable. It is easy to see that for (16) we have

$$|\Delta A_{n+1}|<|\Delta A_n|;\ |\Delta B_{n+1}|<|\Delta B_n|;\ |\Delta C_{n+1}|<|\Delta C_n|. \qquad (17)$$

Consequently, function (13) is stable with respect to small perturbations in A, B, and C.

To evaluate the growth rate of the discharge we denote by τ the time over which most of the electrons manage to move from one surface to the other. From (11) for the case $H = H_0$ we find $D/D_1 = (W/W_1)\,1.06$. Then we easily find the time evolution of the discharge:

$$D_1 = D_0 e^{\frac{(1.06W/W_1-1)}{\tau}t}, \qquad (18)$$

where D_0 is the amplitude of function (13) at time $t = 0$.

CONCLUSION

There exists a single stable distribution (13) which can remain constant over time; we have found the threshold field for the occurrence of a discharge for this distribution. A question which remains is that of whether there can exist a group of unstable distribution functions, whose coefficients A, B, C are not equal to A_0, B_0, C_0, which vary with the time and which have a threshold field lower than (14). Such functions apparently do not exist, for otherwise we would observe a change in the form of function (13) at the threshold field [since we can always distinguish in the current a small group of particles having function (13) and which are distributed arbitrarily with respect to creation phase.] Since this change is in fact not observed, the very existence of a stable function implies that there are no unstable functions having a threshold lower than that in (14).

Equation (10) has been integrated over the range 0-1.35, while the active range of field phases is 0-1.57 + 2πk. The explanation is that, if $1.35 < \varphi_1 - 2\pi k < 1.57$, then $a_1 > 0$ (the dashed axis in Fig. 1b); particles with these emission phases do not lead to cosine distribution (7) over the entire active range $0 < \varphi - 2\pi k < 1.57$. In addition to this phase range, which we have not considered, there is the range $1.57 < \varphi_1 - 2\pi k < 1.78$ (the vertical dashed lines in Figs. 1a and 1b), which, although passive, contributes to the discharge, since secondary electrons from this range reach the active range $0 < \varphi - 2\pi k < 1.57$ after times shorter than T (the dashed curves in Fig. 1a). Analysis of the role of these small ranges under the assumption that most of the electrons obey function (13) leads to a refinement of threshold field (14):

$$W \approx 0.92W_1. \qquad (19)$$

Figure 2a (curve 2) (for which the scale is five times larger) shows the additional correction function, which takes the role of these small ranges into account in a first approximation. Curve 1 is the basic distribution.

Since the maximum possible value is $W_c = 4W$, we see from (19) that this entire analysis holds for materials for which the linearity of σ continues to $\sigma \geq 3.68$. If the functional dependence of σ on W_c becomes a horizontal line at values $\sigma < 3.68$, a field stronger than that according to (19) would be required for a secondary-emission discharge.

A uniform multiphase discharge can occur in many microwave devices for which (1) holds. In particular, an understanding of the behavior of secondary-emission discharges yields a correct interpretation of many experiments on microwave-plasma interactions carried out in systems in which the walls are far apart.[9-11]

In conclusion the author thanks I. E. Andreev, A. I. Kossyi, and V. A. Silin for help and valuable comments, and G. M. Batanov and M. M. Savchenko for useful discussion.

---

1) The initial velocities of secondary electrons are known to have an approximately Maxwellian distribution with $T_e \sim$ 2-4 eV, which is a weak function of the energy of the primary electrons.[5]

2) Gorovets and Rybak[6] were the first to point out the possible existence of secondary-emission discharges with electrons emitted in a broad phase range.

3) However, a spread in these initial velocities leads to a spatial equilibration of the density of in-phase electrons along the x direction.

4) We are not able to incorporate the role of reflected electrons, which usually constitute 10-20% of the total number of secondary electrons.[5] We can assume that they do not play a very important role in the discharge: Although they are characterized by a large value of σ, because of their high velocity, it is shown in the analysis below that fast particles have a good chance of reaching the wall during the unfavorable phase of the field and do not produce another generation of electrons. However, this question requires special study.

Discharge in a cylindrical diode with surface ionization

V. P. Osoka and A. V. Potarov

(Submitted April 18, 1973; resubmitted November 30, 1973)
Zh. Tekh. Fiz., 44, 1929-1937 (September 1974)

A low-pressure discharge in a cylindrical diode is analyzed for the case in which surface ionization plays a role in addition to volume ionization. Results are calculated for a series of discharges which differ in gap length. Surface ionization at the anode can affect the electron density distribution over the length of the discharge. A cutoff of the steady-state discharge which is observed in long gaps is explained.

INTRODUCTION

An electrical discharge in a cylindrical diode is analyzed theoretically in refs. 1 and 2 on the basis of the transport equations for a nonisothermal, partially ionized gas using the Grad 13-moment method. Surface ionization is assumed to be unimportant. However, under certain conditions surface ionization can affect the characteristics of the plasma sheath, particularly at the anode.[3,4] Just how strongly surface ionization affects the parameter distribution in the discharge as a whole has not been clarified. Since alkali metals are widely used in practice, either as an ionizing impurity or as the basic plasma material, we feel it is worthwhile to study numerically discharges with surface ionization taken into account. We base our analysis on the magnetogasdynamic equations of the Grad 13-moment approximation.[5-7] We consider a discharge in a cylindrical diode with an azimuthal magnetic field, like that in coaxial sources and plasma accelerators. One of the cases for which calculations are carried out corresponds to refs. 1 and 2 in terms of geometric dimensions. We analyze separately the establishment of limits for the existence of a discharge and determine why a steady-state discharge cannot be maintained in short gaps or long gaps.

The system of equations used here differs from that of ref. 1 in that the electron-production rate is written in a different manner; several secondary terms, proportional to the degree of ionization, are taken into account. The limits of the applicability of this system of equations are examined in ref. 1. The boundary conditions are written more precisely, in accordance with ref. 3. The boundary conditions take account of surface ionization at the cathode and at the anode.

The solution obtained here can be interpreted as dealing with a plasma moving along the axis of a cylindrical gap, with the restrictions specified in ref. 1.

SYSTEM OF EQUATIONS

After conversion to a form convenient for our calculations, we write the system of differential equations for the problem of a cylindrical discharge in an azimuthal field in the following manner:

$$J_{ir} = -D_{ia}\left(1+\frac{T_e}{T}\right)\frac{dn_e}{dr} - D_{ia}\frac{n_e}{T}\left\{\frac{dT}{dr}+\frac{dT_e}{dr}+\frac{\alpha_{Ta}}{\lambda_e}\left[q_{er}+\left(\frac{5}{2}kT_e+e\mathcal{E}\right)\frac{j_r}{e}\right] - \frac{\alpha}{kn_e}\frac{dp}{dr}-\frac{\chi_e}{\lambda_e\nu_0}\left[j_r\tau_{ea}^{-1}-(1-\alpha)\omega j_z\right]\right\}, \tag{1}$$

$$q_{er} = -\frac{\lambda_e}{1+(\gamma\omega\tau_0)^2}\frac{dT_e}{dr}-\left(\frac{5}{2}kT_e+e\mathcal{E}\right)\frac{j_r}{e}+\frac{\chi_e}{1+(\gamma\omega\tau_0)^2}(j_r+\gamma\omega\tau_0 j_z), \tag{2}$$

$$q_{ir}+q_{ar} = -\lambda_T\frac{dT}{dr}, \tag{3}$$

$$\frac{1}{r}\frac{d}{dr}\left[r\left(J_{ir}-\varepsilon\alpha\frac{j_r}{e}\right)\right] = K_1 n_a n_e - \Gamma_2 \equiv \Gamma, \tag{4'}$$

if $\Gamma \geq 0$. If, on the other hand, $\Gamma < 0$, we have

$$\frac{1}{r}\frac{d}{dr}\left[r\left(J_{ir}-\varepsilon\alpha\frac{j_r}{e}\right)\right] = \Gamma_1 - \frac{Sn_e^3}{T_e^{3/2}}, \tag{4''}$$

$$\frac{1}{r}\frac{d}{dr}(rq_{er}) = j_r E'_r - 3k\varkappa n_e\tau_0^{-1}(T_e-T), \tag{5}$$

$$\frac{1}{r}\frac{d}{dr}[r(q_{ir}+q_{ar})] = 3k\varkappa n_e\tau_0^{-1}(T_e-T), \tag{6}$$

$$\frac{dp}{dr} = -\frac{1}{c}j_z B, \tag{7}$$

$$\frac{dJ}{dr} = 2\pi r j_z, \tag{8}$$

$$\frac{1}{r}\frac{d}{dr}(rj_r) = 0, \tag{9}$$

$$\frac{d\varphi}{dr} = -E'_r. \tag{10}$$

We supplement this system with the equations

$$E'_r = \frac{j_r[A^2+(G\omega\tau_0)^2]}{A\sigma} - \frac{k}{e}\left\{\frac{T_e}{n_e}\frac{dn_e}{dr}+\left[1-\alpha_T\frac{1-\frac{\gamma(\omega\tau_0)^2G}{A}}{1+(\gamma\omega\tau_0)^2}\right]\frac{dT_e}{dr} + \frac{\varkappa(\omega\tau_0)^2G}{A}\left[\frac{\alpha}{kn_e}\frac{dp}{dr}-\frac{dT}{dr}-\frac{dT_e}{dr}-\frac{T+T_e}{n_e}\frac{dn_e}{dr}\right]\right\}, \tag{11}$$

$$j_z = -\frac{\omega\tau_0}{1-\Delta+\varkappa(1-\alpha)(\omega\tau_0)^2}\left\{j_r+\frac{\alpha_T^2}{\frac{5}{2}\chi_e}\left[q_{er}+\left(\frac{5}{2}kT_e+e\mathcal{E}\right)\frac{j_r}{e}\right]\right\}, \tag{12}$$

$$p = n_e kT_e + (n_a+n_e)kT, \tag{13}$$

$$\alpha = \frac{n_e}{n_e+n_a}, \tag{14}$$

$$B = \frac{2J}{cr} \tag{15}$$

and equations for the kinetic coefficients,

$$\frac{1}{\tau_{ai}} = \frac{16}{3}n_e\left(\frac{kT}{\pi m}\right)^{1/2}Q_{ai},\quad \frac{1}{\tau_{aa}} = \frac{16}{3}n_a\left(\frac{kT}{\pi m}\right)^{1/2}Q_{aa},$$

$$\frac{1}{\tau_{ea}} = \frac{16}{3}n_a\left(\frac{kT_e}{2\pi m_e}\right)^{1/2}Q_{ea},\quad \frac{1}{\tau_{ia}} = \frac{n_a}{n_e}\frac{1}{\tau_{ai}},$$

$$\Lambda_{ei} = \frac{3kT_e}{2e^3}\left[\frac{kT_eT}{\pi n_e(T+T_e)}\right]^{1/2},\quad \Lambda_{ii} = \frac{T}{T_e}\Lambda_{ei},$$

$$\frac{1}{\tau_{ei}} = \frac{16}{3}n_e\left(\frac{2\pi kT_e}{m_e}\right)^{1/2}\left[\frac{e^2}{2kT_e}\right]^2\ln\Lambda_{ei},\quad \frac{1}{\tau_{ee}} = \frac{\sqrt{2}}{\tau_{ei}},$$

$$\frac{1}{\tau_{ii}}=\frac{16}{3}n_e\left(\frac{4\pi kT}{m}\right)^{1/2}\left[\frac{e^2}{2kT}\right]^2\ln\Lambda_{ii},$$

$$\tau_0^{-1}=\tau_{ei}^{-1}+\tau_{ea}^{-1},$$

$$\tau_e^{*-1}=0.4\tau_{ee}^{-1}+1.3\tau_0^{-1},$$

$$\tau_i^{*-1}=0.4\tau_{ii}^{-1}+0.7375\tau_{ia}^{-1},$$

$$\tau_a^{*-1}=0.4\tau_{aa}^{-1}+0.7375\tau_{ai}^{-1},$$

$$b_{ia}=-0.3375\tau_i^*\tau_{ai}^{-1},$$

$$b_{ai}=--0.3375\tau_a^*\tau_{ia}^{-1},$$

$$\delta=1-b_{ia}b_{ai},$$

$$\omega=\frac{eB}{m_ec},\quad \varepsilon=\frac{m_e}{m},$$

$$\lambda_e=\frac{5}{2}\frac{k^2n_eT_e}{m_e}\tau_e^*,$$

$$\lambda_i=\frac{5}{2}\frac{k^2n_eT}{m}\tau_i^*,$$

$$\lambda_a=\frac{5}{2}\frac{k^2n_aT}{m}\tau_a^*,$$

$$\nu_0=-0.6\tau_{ei}^{-1}+0.2\tau_{ea}^{-1},$$

$$\lambda_T=\lambda_a+\lambda_i\frac{(1-b_{ai})^2}{\delta\left[1+(\varepsilon\omega\tau_i^*\delta^{-1})^2\right]},$$

$$\chi_e=\alpha_T\frac{kT_e}{e},$$

$$\alpha_T=\frac{5}{2}\tau_e^*\nu_0,$$

$$\gamma=\tau_e^*\tau_0^{-1},$$

$$\alpha_{Ta}=\frac{1}{2}\tau_e^*\tau_{ea}^{-1},$$

$$\Delta=\alpha_T\nu_0\tau_0,$$

$$\varkappa=2\varepsilon\tau_0^{-1}\tau_{ai}\alpha,$$

$$\sigma=\frac{n_ee^2}{m_e}\tau_0,$$

$$D_{ia}=\frac{2\tau_{ai}\alpha kT}{m},$$

$$A=1-\frac{\Delta}{1+(\gamma\omega\tau_0)^2}+\varkappa(1-\alpha)(\omega\tau_0)^2,$$

$$G=1+\frac{\gamma\Delta}{(1+\gamma\omega\tau_0)^2},$$

$$S=\frac{4\pi\sqrt{2\pi}\,e^{10}\ln\sqrt{2}}{9m_e^{1/2}k^{9/2}}. \tag{16}$$

Here, r, θ, z are cylindrical coordinates; the z axis runs parallel to the magnetizing current J. Also, m_e, m, T_e, T are the masses and temperatures of the electrons and heavy particles, respectively; n_e, n_a are the densities of electrons and atoms; q_{ir}, q_{ar}, q_{er} are the radial components of the specific energy fluxes of ions, neutrals, and electrons, respectively; J_{ir} is the radial specific diffusive flux of ions; j_r, j_z are the radial and longitudinal components of the current density; p is the pressure; E_r' is the radial component of the electric field in the coordinate system fixed in the plasma; B is the magnetic induction, which is directed azimuthally; α is the degree of ionization; Q_{aa}, Q_{ea} are the diffusion cross sections; K_1 is the ionization-rate coefficient; $\mathcal{E}$ is the ionization potential; k is the Boltzmann constant; e is the electron charge; and c is the speed of light in vacuum.

Equation (1) describes the diffusive ion flux,$^{1)}$ Eqs. (2) and (3) describe the energy fluxes, Eqs. (5) and (6) describe conservation of the electron and heavy-particle energy, Eq. (8) is the definition of the magnetization energy, Eq. (9) is the current-conservation equation, Eq. (10) is the definition of the potential φ, and Eq. (7) is a particular case of the equation of motion, written under the assumption that there is no radial projection of the mean mass velocity. When this equation is satisfied the total flux of atoms and ions toward the walls vanishes. Equation (4) is the ion-balance equation. The term Γ, which describes the rate of charged-particle formation, assumes different forms, depending on whether ionization predominates over recombination. If so, ionization is incorporated through the ionization-rate coefficient[1] K_1, and the recombination term Γ_2 is chosen in accordance with the principle of detailed balance through the use of the statistical equation from ref. 8. If, on the other hand, recombination predominates over ionization, the equation for the recombination rate from ref. 9 is used, and the ionization term Γ_1 is written taking account of the statistical relation.

BOUNDARY CONDITIONS

The boundary conditions at the cathode, $r = r_k$, are the conditions which hold at the outer boundary of the corresponding sheath:

$$J_{ir}-\varepsilon\alpha\frac{j_r}{e}=-\frac{1}{4}(\xi_i^-)^*n_ev_i, \tag{17}$$

$$q_{er}=\frac{j_{\text{E}}^{(k)}}{e}(2kT+e\varphi_k+e\mathcal{E})-\frac{1}{4}\xi_e^-n_ev_e$$
$$(2kT_e+e\varphi_k+e\mathcal{E})\exp\left(-\frac{e\varphi_k}{kT_e}\right), \tag{18}$$

$$T=T_k, \tag{19}$$

$$p=p_k, \tag{20}$$

$$J=J_k, \tag{21}$$

$$j_r=j_k, \tag{22}$$

$$\varphi=0. \tag{23}$$

These are supplemented by the equations for the cathode potential barrier $\varphi_k > 0$:

$$\left.\begin{aligned}&e\varphi_k=kT_e\ln\left[\frac{(1+\mathscr{K})(1-R_e)}{2\mathscr{K}}\right],\\&\mathscr{K}=\frac{en_ev_i\left(1-\frac{\beta}{\alpha}\right)+2(j_r+j_{\text{E}}^{(k)})}{en_ev_e-2j_{\text{E}}^{(k)}},\quad \beta=\frac{\exp\left(-\frac{e\varphi_k}{kT_k}\right)}{\frac{1}{\beta_k}-1+\exp\left(-\frac{e\varphi_k}{kT_k}\right)}.\end{aligned}\right\} \tag{24}$$

Here

$$v_i=\sqrt{\frac{8kT}{\pi m}},\quad v_e=\sqrt{\frac{8kT_e}{\pi m_e}},\quad \beta_k=\frac{\alpha_k}{1+\alpha_k},\quad (\xi_i^-)^*=2\left(1-\frac{\beta}{\alpha}\right),$$

$$\alpha_k=A^*\exp\left(\frac{e\varphi_k^*-e\mathcal{E}}{kT_k}\right),\quad \xi_e^-=\frac{2-j_{\text{E}}^{(k)}\left(\frac{1}{4}en_ev_e\right)^{-1}}{2-(1-R_e)\exp\left(-\frac{e\varphi_k}{kT_e}\right)},$$

$j_{\text{E}}^{(k)}$ is the thermionic-emission current density, $e\varphi_k^*$ is the effective work function for surface ionization, A^* is the coefficient in the equation for the degree of positive surface ionization, R_e is the elastic-reflection coefficient for electrons, and v_i and v_e are the mean thermal velocities of ions and electrons.

The boundary conditions at the anode, $r = r_a$, are

$$J_{ir}-\varepsilon\alpha\frac{j_r}{e}=\frac{1}{4}(\xi_i^-)^*n_ev_i, \tag{25}$$

$$q_{er}=-\frac{j_{\text{E}}^{(a)}}{e}(2kT+e\varphi_a+e\mathcal{E})+$$

$$+\frac{1}{4}\xi_e^- n_e v_e (2kT_e + e\varphi_a + e\mathcal{E}) \exp\left(-\frac{e\varphi_a}{kT_e}\right), \qquad (26)$$

$$T = T_a. \qquad (27)$$

To determine the anode potential barrier $\varphi_a > 0$ (the plasma potential near the anode is higher than the electrode potential) we have the system of equations

$$\left.\begin{aligned} e\varphi_a &= kT_e \ln\left[\frac{(1+\mathscr{K})(1-R_e)}{2\mathscr{K}}\right], \\ \mathscr{K} &= \frac{en_e v_i\left(1-\frac{\beta}{\alpha}\right)+2\left(-j_r+j_E^{(a)}\right)}{en_e v_e - 2j_E^{(a)}}, \quad \beta = \frac{\exp\left(-\frac{e\varphi_a}{kT_a}\right)}{\frac{1}{\beta_a}-1+\exp\left(-\frac{e\varphi_a}{kT_a}\right)} \end{aligned}\right\} \qquad (28)$$

where

$$\beta_a = \frac{\alpha_a}{1+\alpha_a},$$

$$\alpha_a = A^* \exp\left(\frac{e\varphi_a^* - e\mathcal{E}}{kT_a}\right),$$

$$\xi_e^- = \frac{2 - j_E^{(a)}\left(\frac{1}{4}en_e v_e\right)^{-1}}{2-(1-R_e)\exp\left(-\frac{e\varphi_a}{kT_e}\right)},$$

$$(\xi_i^-)^* = 2\left(1-\frac{\beta}{\alpha}\right),$$

$j_E^{(a)}$ is the thermionic-emission current density, and $e\varphi_a^*$ is the effective work function for surface ionization.

In Eqs. (17) and (25) the term $\varepsilon\alpha(j_r/e)$ gives a correction to the motion of the center of mass of an element of the plasma with respect to the electrode.

CALCULATION PROCEDURE

System (1)-(10) with boundary conditions (17)-(23) is integrated numerically from the cathode to the anode by the Runge–Kutta method. This integration requires a knowledge of auxiliary parameters at the initial boundary: n_e, T_e, and $q_{ir} + q_{ar}$. In general, the integration yields parameters at the final boundary which differ from the boundary conditions there, conditions (25)-(27). The discrepancies are used in Newton's method to refine the values of these auxiliary parameters at the initial boundary; then the calculation is repeated. The calculation is iterated until the desired agreement is achieved between the values of the parameters at the final boundary. The initial approximation at the initial boundary is found by a random-search method.

NUMERICAL CALCULATIONS

We report here the results calculated for a series of cylindrical diodes2) with anode radius $r_a = 2.5$ cm and cathode radius $r_k = 1.85$-2.4 cm. A lithium plasma is assumed; the kinetic and gas-kinetic characteristics are taken from ref. 1. The cathode and anode temperatures are assumed to be $T_k = T_a = 2700$°K, the current density of the discharge at the cathode is assumed to be $|j_k| = 2.5$ A/cm^2, the plasma pressure at the cathode is assumed to be $p_k = 85$ μbar, and the azimuthal magnetic field is assumed to be $B_k = 50$ G. The thermionic-emission current density is assumed to be $j_E^{(k)} = 2$ A/cm^2. We also use $R_e = 0.15$ and $A^* = 0.5$.

The results of the numerical solution are shown in Figs. 1-4. Figure 1 shows the characteristic plasma parameters as a function of the cathode radius. Here

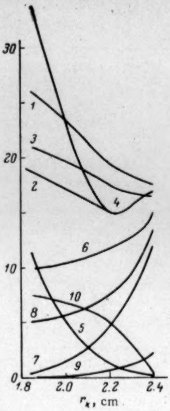

Fig. 1. Characteristic plasma parameters as a function of the cathode radius at a fixed anode radius ($r_a = 2.5$ cm). 1) $(n_e)_{\max} \cdot 10^{-12}$, cm^{-3}; $(n_e)_{\min} \cdot 10^{-12}$ cm^{-3}; 3) $(n_e)_k \cdot 10^{-12}$ cm^{-3}; 4) $(n_e)_a \cdot 10^{-12}$ cm^{-3}; 5) $(T - T_W)_{\max} \cdot 10^{-1}$ °K; 6) $(T_e)_k \cdot 10^{-3}$ °K; 7) $(T_e)_a \cdot 10^{-3}$ °K; 8) φ_k, V; 9) φ_a V; 10) $\Delta\varphi \cdot 10$ V.

$(\Delta T)_{\max} = T_{\max} - T_k$, and $\Delta\varphi$ is the potential difference between the given spatial point and the outer boundaries of the sheaths at the anode and cathode. Figure 2 shows the profiles of the plasma parameters for $r_k = 2$ cm, under which conditions we find $\varphi_k = 5.574$ V and $\varphi_a = 0.186$ V. Here $\delta = (r - r_k)/(r_a - r_k)$, $q_{rr} = q_{ar} + q_{ir}$, and φ is the potential difference between the given spatial point and the outer boundary of the cathode sheath. Figure 2 shows profiles of gas-kinetic quantities characteristic of viscous effects: the times5 τ_e, τ_i, and τ_a; the mean free paths3) $l_e = v_e\tau_e$, $l_i = v_i\tau_i$, $l_a = v_i\tau_a$; and the quantity $\omega\tau_0$ for the case $r_k = 2$ cm.

Figure 4 shows the change in the profile of the degree of ionization α due to a lengthening of the interelectrode gap. The points are the calculated degrees of ionization at the outer boundaries of the cathode and anode sheaths.

The extreme values adopted for the length of the interelectrode gap are at the boundaries for the existence of a solution. Numerical determination of the exact boundaries requires a great deal of computer time.

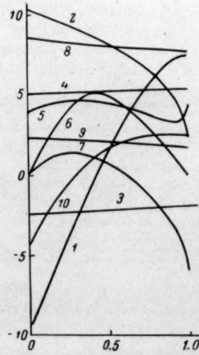

Fig. 2. Profiles of the plasma parameters in the interelectrode region. 1) $q_{Tr} \cdot 10^2$, W/cm^2; 2) $T_e \cdot 10^{-3}$ °K; 3) j_r, A/cm^2; 4) $I \cdot 10^{-2}$, A; 5) $n_e \cdot 10^{-13}$, cm^{-3}; 6) $(T - T_W) \cdot 10^{-1}$ °K; 7) $\varphi \cdot 10$, V; 8) $p \cdot 10^{-1}$ μbar; 9) $q_{er} \cdot 10^{-1}$ W/cm^2; 10) $j_{ir} \cdot 10$, A/cm^2.

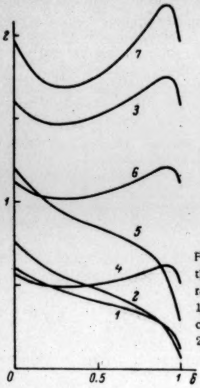

Fig. 3. Profiles of the characteristic times, mean free paths, and Hall parameters in the interelectrode region. 1) $\omega\tau_0 \cdot 0.5$; 2) $l_e \cdot 10$, cm; 3) $l_i \cdot 10^2$ cm; 4) l_a, cm; 5) $\tau_e \cdot 10^9$ sec; 6) $\tau_i \cdot 2 \cdot 10^7$, sec; 7) $\tau_a \cdot 10^6$ sec.

ANALYSIS OF THE DATA

An inspection of Fig. 3 reveals that the characteristic times and mean free paths for the various plasma components differ markedly. The atoms have the longest mean free path. The characteristic mean free paths for diffusion effects, l_a^*, lie in the range[5] $0.33\, l_a < l_a^* < 0.53\, l_a$. In the case of narrow gaps the Knudsen numbers for neutrals, $\mathrm{Kn}_a = l_a^*/(r_a - r_k)$, are larger than unity, so that these results on the characteristics of the heavy component should be considered formal but instructive in these discharge cases, e.g., they are useful for estimating the order of magnitude of the change in the discharge energy.

This circumstance has essentially no effect on the accuracy of the values found for the plasma properties associated with the electron component: The maximum deviation of the heavy-particle temperature from the wall temperature according to these calculations is about 4%, and we can assume that the state of the atoms, which is incorporated in the calculation of the properties of the electronic gas, is described within an error much smaller than this.

The quantities τ_a, l_e, and $\omega\tau_0$ are highly inhomogeneous over the gap. The calculations show that this inhomogeneity arises and becomes more pronounced as the gap is lengthened. From Fig. 2 we see that the potential φ near the cathode generally rises somewhat and then decreases over the greater part of the gap, acquiring a value at the anode lower than that at the cathode. The electron temperature falls off from the cathode toward the anode, and the decrease becomes more pronounced as the gap is lengthened; the temperature near the anode can be lower than the heavy-particle temperature and the anode temperature. The profile of the electron density in the case of long gaps is qualitatively different for that in the case of short gaps: In long gaps the density increases in the immediate vicinity of the anode surface, and a minimum is formed in the $n_e(r)$ profile near the electrode. Figure 1 shows that lengthening of the gap is accompanied by a significant decrease in the anode potential drop φ_a. Accordingly, the observed local increase in the electron density at the anode results from the establishment of conditions favoring emission from the plasma sheath of ions produced by surface ionization.

Figure 4 shows that the degree of ionization in the gap in the case of surface ionization changes significantly as the gap is lengthened. The convex $\alpha(r)$ profile for short gaps is replaced by a more complex profile, having a concave region on the anode side. The degree of ionization at the cathode and that at the anode reach minima at certain intermediate gap lengths. The maximum value of n_e in the plasma displays the same behavior. The maximum degree of ionization in the plasma increases with the gap length, but a reduction of the cathode radius for a given distance from the anode (r_a = const) causes a reduction of the density n_e.

According to Fig. 1, lengthening of a gap leads to an increase in the densities $(n_e)_{\max}$ and $(n_e)_k$, an increase in the potential difference between the outer boundaries of the sheath at the anode and cathode, $\Delta\varphi$, and a reduction of the temperatures $(T_e)_k$ and $(T_e)_a$ and of the potential drops near the electrodes in the sheath, φ_k and φ_a. The electron density near the anode, $(n_e)_a$, and the minimum density in the plasma, $(n_e)_{\min}$, reach their lowest values at a certain intermediate gap length. In the case of short gaps the minimum electron density is observed near the anode, in long gaps it is observed in the plasma. In long gaps the absolute maximum of the electron density occurs near the anode. This absolute maximum near the anode does not yet lead, in the cases for which calculations were carried out, to an absolute maximum of the degree of ionization in the same part of the discharge, since the reduction of the electron temperature near the anode is accompanied at p_k = const by an increase in n_a.

Inspection of these results shows why no solutions exist for a steady-state discharge in the case of short or long gaps.[4)] With a short gap, a discharge cannot occur at a current $|j_k| > j_E^{(k)}$ at any value of T_e and φ_k because the production of ions in the plasma is inadequate; the current of these ions is required to make up the difference $(|j_k| - j_E^{(k)})$. The limit on the existence of solutions at long gaps is determined by the limit $(T_e)_a \to 0$. As shown above, lengthening of the gap is accompanied by an increase in the electron density at the outer boundary of the cathode sheath, due to an increase in the total number of charged particles produced in the plasma. According to the boundary conditions adopted here, an increase in the electron density at the cathode results in a reduction of the cathode potential drop φ_k. Thus the electron energy

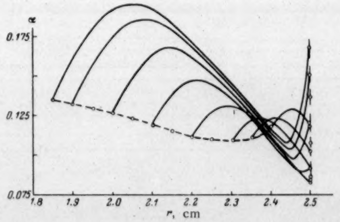

Fig. 4. Profiles of the degree of ionization as a function of the width of the interelectrode gap for a fixed anode radius (r_a = 2.5 cm).

and temperature in the plasma near the cathode fall off. As the gap is lengthened, the energy expended by the electron gas in plasma ionization is increased. The initial electron energy in the plasma near the cathode and the energy acquired from the electric field in the case of long gaps is inadequate to maintain a positive absolute temperature for the electrons over the entire gap.

---

1) This corresponds to ion motion with respect to the center of mass of the plasma under conditions such that the ion flux is equal in magnitude but opposite in direction to the diffusive flux of atoms.

2) The computer program, worked out for use over broad ranges of discharge parameters, is applied here to the case in which certain terms in the equations can be neglected. However, a calculation on the basis of the complete program yields important information required for choosing the zeroth approximations in more complicated cases and for developing approximate-calculation methods. The parameters for the calculation are chosen so that the results of refs. 1 and 2 can be used in the numerical solution.

3) The characteristic mean free paths shown in this figure give an idea of the differences and inhomogeneities over the cross section of the corresponding Knudsen numbers.

4) In the case of short gaps or long gaps the discharge can apparently exist only in a different form, an oscillatory form, consisting of contracted arcs, as the electrode material, as the vapor of the electrode material undergoes combustion.

Kinetic energy of ions produced by surface ionization.
I. Distribution over the velocity components

(Submitted October 29, 1973; resubmitted January 22, 1974)
Zh. Tekh. Fiz., 44, 1938-1945 (September 1974)

The experimental ion distribution over velocity components is obtained taking account of the angular distribution of particles from the surface. The experimental ion distribution corresponds to the calculated distribution. Surface ionization of silver on oxidized tungsten is used to show the dependence of the ion current on the ionizer temperature according to the Saha–Langmuir equation. Ionizer surface temperature in the range 1365–1100°K obtained from the experimental distribution curves and those measured by an optical pyrometer agree to within ±10°.

The energy and angle distributions of particles from a surface is of considerable interest and can be one of the most productive methods for studying the state of desorbed particles, the properties of a surface, and the interaction between particles and a surface.

The measurement of the kinetic energies of the positively charged component of a beam of desorbed particles is less complicated technically and can answer many of the questions involving surface ionization. The study of the distribution of initial ion energies in surface ionization of molecular beams can help to explain many characteristics of the state of thermal equilibrium and dissociative ionization on a surface.

In these experiments the distribution of initial energies of positively charged ions is measured for ionization on hot tungsten and rhenium surfaces. In this part the equation for the shape of the experimentally observed particle distribution over velocity components is derived and the ion source and the results of control measurements of the ionizer surface temperature are described. Measurements of the initial energies of ions produced in surface ionization of atoms and simple inorganic molecules are given in Part II.

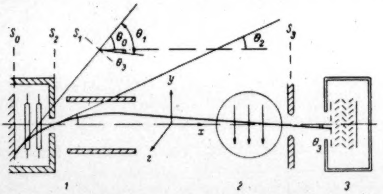

Fig. 1. Simplified diagram of ion motion in a mass spectrometer. 1) Ion source; 2) mass analyzer; 3) electron multiplier.

TEMPERATURE DEPENDENCE OF THE EXPERIMENTAL DISTRIBUTION CURVE

The kinetic energies of ions produced on an ionizer surface have been investigated on an MI 13-09 mass spectrometer with a special ion source, using the so-called deflection method.[1] When analyzing initial energies, the deflection method is used to investigate ion motion in the direction coinciding with the force lines of the magnetic field of the mass analyzer and corresponding to the motion "along the slit" of a Nier, or similar type, source with an ion-optical slit system (the y direction, Figs. 1 and 2). In principle, this method gives the energy of ions in the direction studied to within $1 \cdot 10^{-3}$ eV. The basis of the deflection method is that only those particles whose velocity in the y direction is compensated by the voltage of the deflecting capacitor are incident on the ion collector of the mass spectrometer. Since the initial (here, thermal) ion velocity V_y in this direction cannot be distorted, or distorted only negligibly, the dependence of the current taken from the ion collector on the deflecting voltage contains information on the ion distribution over the velocity component V_y. To analyze this distribution it is necessary to obtain an expression for the ion current density through the plane of the collector.

Only singly charged positive ions are considered.

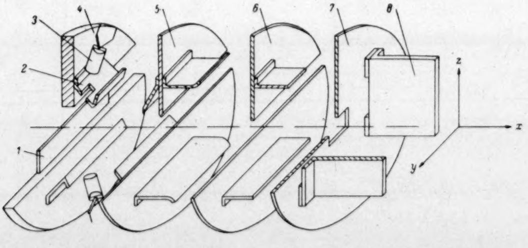

Fig. 2. Schematic diagram of the ion source. 1) Ionizer; 2) evaporator shield; 3) evaporator; 4) thermocouple; 5, 6, 7) extracting, accelerating, and collimating electrodes, respectively; 8) deflecting capacitor.

When atomic or molecular ions are produced the velocity distribution coincides with the Maxwell–Boltzmann distribution of the neutrals; the number of particles per phase volume element is

$$dn = C\exp\left[-\frac{mc^2}{2kT}\right]c^2 dc\, d\Omega\, d\tau$$

$$= C'\exp\left[-\frac{m(V_x^2+V_y^2+V_z^2)}{2kT}\right]dV_x dV_y dV_z d\tau, \tag{1}$$

where C is a constant, $c = \sqrt{V_x^2 + V_y^2 + V_z^2}$ is the ion thermal velocity, $d\Omega = \sin\theta d\varphi d\theta$ is the solid angle element, $d\tau_g = dxdydz$ for particles in the gaseous phase, (ionization by electrons and photons), and $d\tau_s = dydz$ for particles departing from the surface (the ionization surface in particular). In both cases the element $d\tau$ refers to the ionization region. Momentum transfer during ionization due to electron impact[2] is not taken into account here. The value of T is either the temperature of the ionizer surface or the temperature of the walls of the ionization chamber. From the time the ions are produced until they are deflected after acceleration to an energy ev, the ion velocity vector varies in magnitude from $V_0 = c$ to $V = \sqrt{c^2 + 2ev/m}$ and its direction in the laboratory coordinate system varies through an angle $\theta_1 = \theta_0 + \theta_3$ (Fig. 1), where θ_0 is the angle between the direction $\bar{c}$ and the normal to the plane of the ionization S_0; θ_3 is angle of incidence of the ions on the collector (the plane S_3). The particle flux density from the surface S_0 at the solid angle element $d\Omega$ equals the flux through the area dS_1, the normal to which is formed by the angle θ_0 with the normal to dS_0

$$d\nu_1 = C_1 V_0 \exp\left[-\frac{mc^2}{2kT}\right]c^2 dc\, d\Omega\, dS_1. \tag{2}$$

The flux of accelerated ions exiting from the slit of the source in the plane S_2 is

$$d\nu_2 = C_2 V\cos\theta_0 \exp\left[-\frac{mc^2}{2kT}\right]c^2 dc\, d\Omega\, dS_2$$

$$= C_2 V\cos\theta_0\cos\theta_2 \exp\left[-\frac{mc^2}{2kT}\right]c^2 dc\, d\Omega\, dS_0, \tag{3}$$

where $\cos\theta_2 = \sqrt{V_x^2 + 2ev/m}/\sqrt{c^2 + 2ev/m}$, and the normalization constant C_2 must include the decrease in ion density due to acceleration (the condition for a constant number of particles). When ev = 0, $\theta_2 = \theta_0$, and c = const, Eq. (3) becomes the well-known expression[3,4] for a radiative flux.

Considering the plane of the collector S_3, we obtain

$$d\nu_3 = C_3 V\cos\theta_0\cos\theta_2\cos\theta_3 \exp\left[-\frac{mc^2}{2kT}\right]c^2 dc\, d\Omega\, dS_0$$

$$= C_3 V_x\cos\theta_0\cos\theta_3 \exp\left[-\frac{mc^2}{2kT}\right]c^2 dc\, d\Omega\, dS_0. \tag{4}$$

Usually in mass analysis the ions are accelerated to energies of several kiloelectron volts (here, ev = 3 keV), and the thermal energy of the particles, taken over one degree of freedom in the case of surface ionization, is ≤ 0.1 eV $\ll$ ev. It can be assumed that $\theta_3 \simeq 1$, $\cos\theta_2 \simeq 1$, and $V_x \simeq \sqrt{2ev/m} \simeq$ const to within $2\cdot 10^{-5}$. This situation has theoretical significance and leads to the absence of a dependence of the limits of integration with respect to $d\tau$ on the initial velocity projection. Integration cannot be taken directly over $d\tau$ and dV_y since the ratio of the area of effective ionization to the square of the distance between the ionizer and the collector (with a correction for acceleration) is ~0.005. The small working area is determined in one measurement by the width of the ionizer or of the slit of the source (0.2–0.4 mm), and in the other by the length of the collimating slit, reduced to 0.6 mm, and the slit of the ion collector. Thus, one can assume with fair accuracy that the detection currents are proportional to the flux from the volume element or from the area element. The error introduced by this approximation is several times smaller than the instrumental distortions (see below), and henceforth when treating the experimental data it will be included with them.

Thus, the current across the collector is

$$dI_n \simeq C_4 \exp\left[-\frac{mc^2}{2kT}\right]c^2\cos\theta_0 dc\, d\Omega$$

$$= C_4' \exp\left[-\frac{m(V_x^2+V_y^2+V_z^2)}{2kT}\right]\frac{V_x}{\sqrt{V_x^2+V_y^2+V_z^2}}dV_x dV_y dV_z. \tag{5}$$

In the analysis of initial velocities using the deflection method the ions incident on the collector have a velocity in the Y direction from V_y to $V_y + dV_y$, an arbitrary initial velocity in the X direction, and, in the limits from $-V_{z0}$ to V_{z0}, which are determined by discrimination at the slits, in the z direction. Thus, the ion flux density from the surface incident on the collector is

$$\frac{dI_n}{dV_y} = C_5 \int\limits_{-V_{z0}}^{V_{z0}} dV_z \int\limits_0^{\infty} \exp\left[-\frac{m(V_x^2+V_y^2+V_z^2)}{2kT}\right]\frac{V_x dV_x}{\sqrt{V_x^2+V_y^2+V_z^2}}. \tag{6}$$

The measured voltage U across the deflecting capacitor is related to the projection of velocity V_y by

$$U = \varkappa V_y\sqrt{\frac{m}{2}} = \varkappa\sqrt{E_y},$$

where $\varkappa$ is the instrumental constant. For convenience considering energies $E_x = mV_x^2/2$ and $E_z = mV_z^2/2$, we obtain

$$\frac{dI_n}{dU} = C_6\frac{dI_n}{dV_y} = C_6' \int\limits_{-\sqrt{E_{z0}}}^{\sqrt{E_{z0}}} d(\sqrt{E_z}) \int\limits_0^{\infty} \exp\left[-\frac{E_x + E_z + \varkappa^2 U^2}{kT}\right]$$

$$\times\sqrt{\frac{E_x}{E_x + E_z + \varkappa^2 U^2}}\, d(\sqrt{E_x}). \tag{7}$$

For ions produced in the gaseous phase we obtain the well-known result confirmed by experiment:[5]

$$\frac{dI_{r.}}{dU} = C''\exp\left[-\frac{\varkappa^2 U^2}{kT}\right].$$

ERRORS

Since the absolute value of the ion thermal energies is small and only fairly precise measurements are of practical interest, the instrumental errors should be calculated to within ±0.001 eV. With regard to the inhomogeneity of the surface of the metal ribbons used as ionizers the distribution of initial ion energies can be distorted both by the contact field of spots and by the strong electric field applied to compensate for it. In practice, the smallest errors of the true distribution are attained for a certain compromise value of the electric field voltage, which in the experiments is $F \simeq 2\cdot 10^3$ V/cm. Experiment shows that the measured energy kT* has a time-constant instrumen-

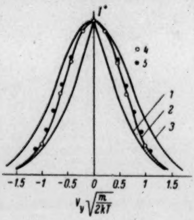

Fig. 3. Distribution of ions over V_y for a fixed temperature in the interval 1700-2100°K. 1) Calculated curve corresponding to the absence of errors and strong discrimination with respect to V_z; 2) experimental distribution of $^{107}Ag^+$, $^{208}pb^+$, $^{39}K^+$, and $^{23}Na^+$ ions (surface ionization beams); 3) calculated distribution curve for ions from the gaseous phase; 4) points calculated from Eq. (8); 5) experimental points of the distribution of $^{184}W^+$, $^{187}Re^+$, $^{39}K^+$, and $^{23}Na^+$ thermions.

tal correction $\mathcal{E} = 0.021$ eV, which also includes the effect of the finite dimensions of the ionization region and the collector. For a change in the optimum field voltage of 25% the value of $\mathcal{E}$ had a two-fold increase. Examination of the possible cases indicates that the instrumental effect appears in the form of an error of the initial angular distribution of ions due to an artificial increase in E_y. Taking this error mechanism into account, we obtain an expression relating the recorded curve to the Maxwellian distribution of ions:

$$\frac{dI_n}{dU} = \text{const} \int\limits_{-\sqrt{E_{z0}}}^{\sqrt{E_{z0}}} d(\sqrt{E_z}) \int\limits_0^{\infty} \exp\left[-\frac{E_x + E_z + \varkappa^2 U^2}{kT}\right] \times \sqrt{\frac{E_x}{E_x + E_z + \varkappa^2 U^2 + \mathcal{E}}}\, d(\sqrt{E_x}). \quad (8)$$

The absolute value of the error can be obtained directly from the experimental curves if the ionizer temperature is known to within 100-200°K and if it is assumed that the kinetic energy of the ion corresponds to the temperature of the ionizer surface.[6]

Equation (8) is used to determine $\mathcal{E}$. When $\varkappa^2U^2 = \mathcal{E}$, the half-width of the distribution at a height determined by (8) should be $\sqrt{\mathcal{E}}$. The equation can be solved by numerical methods.

The thermal energy kT can be determined from the half-width of the experimental curve at a height determined by (8) under the condition $\varkappa^2U^2 = kT$. For this purpose we can use the half-width of the line at a height 0.157 I_0, which for $\mathcal{E} \to 0$ and $V_{z0} \to 0$ should be kT (curve 1 in Fig. 3), and we can use the equality $kT \simeq kT^* - \mathcal{E} - E_{z0}$ which is satisfied with fair accuracy for $\mathcal{E} \leq 0.04$ eV.

EXPERIMENTAL PART

The measurements are carried out with an ion source with slits which produce a field with axial symmetry (Fig. 2). This kind of ion-optical system allows the ion thermal velocities to be measured in the direction of the axis of symmetry and is independent to a considerable degree of the contamination of the electrodes. The distribution function is recorded by an ÉPP-09 automatic potentiometer with continuous scanning of the deflecting voltage. The ion currents are enhanced by a secondary electron multiplier.

Taking account of the geometry of the MI 13-09 instrument, the dimensions of the deflecting plates, and the distance between them and the stray field, the constant $\varkappa$ for an accelerating voltage of 3 kV is 0.0986 $eV^{1/2}$ per 1 V of deflecting voltage. The change in scale on the abscissa for an accelerating voltage of 1.5 kV corresponds completely to this variation, which indicates that distortions of the ion velocity are absent in the region from the extracting electrode to the collector (the field voltage at the ionizer surface does not change in these experiments).

A necessary reduction in the length of the source and collector slits produces a perceptible loss of current strength. For this reason, atomic beams of fairly high intensity are used to obtain experimental curves with fairly small fluctuations in the ion current. In particular, in the case of tungsten ionization the beam density of atomic silver is ~ 10^{14} and for ionization in oxidized tungsten and rhenium it is 10^{13} $cm^{-2} \cdot sec^{-1}$.

To inhibit electron emission from the ionizer, potential of + 100 V is applied to it with respect to the evaporator screen.

A uniform surface temperature of the working area[7] should provide an equally probable ionization of beams with an arbitrary projection of velocity – from zero to the maximum that can be recorded. The uniformity of the ionizer temperature and the beams incident on it is checked experimentally by recording the distribution function for tungsten and rhenium (the ionizer material) thermions, potassium (the impurity atoms) thermions, and ions incident on the ionizer from silver and lead beams. There is a very different dependence of the yield of these ions on the ionizer temperature; therefore, any change in the temperature along the length of the working area of the ionizer (or for the incident beams and their inhomogeneity) leads to a different shape of the experimental distribution curves.

The ionizer is a wire 0.2 mm in diameter or a ribbon 0.02 × 0.5 mm with the same length 16 mm. The current conductors are plane molybdenum springs with a cross section 0.1 × 5 mm and a length of 15 mm. The evaporators are heated open nickel cylinders 1.5 mm in diameter and 1.5-2 mm long. The distribution recorded for a series of ions in an experiment with tungsten wire ionizer 0.15 mm in diameter and 32 mm long coincides with the other measurements. After a period in which the ion source is not in use, the distribution curves are reproduced in all the experiments to within ±0.5% during the entire time of the experiments, regardless of changes in the ionizers and replacement of ribbons by wires, and vice versa.

For a Langmuir treatment[8] of each new ionizer and for oxidation of tungsten according to the method of ref. 9, the temperature of the wires and ribbons is established from the distribution of potassium ions. When oxygen is admitted, the filament voltage of the ionizer is increased until the resistance of the oxidized wire or ribbon is equal to the resistance in vacuum for a given temperature.

A 50-100° change in the ionizer temperature in the 2000°K region changes the evaporator temperature by several degrees. A constant evaporator temperature is maintained to within ±1° by regulating the filament current and monitoring the emf of the thermocouple of the PP-51 potentiometer.

The experiments are carried out at a pressure of $p = 5 \cdot 10^{-8}$–$1 \cdot 10^{-7}$ torr, which is measured with an ion pump.

CONTROL MEASUREMENTS

A comprehensive method is used to check the validity of Eq. (8) and its constants. First, the temperature of the working surface of the ionizer is determined by an optical pyrometer independently of the other measurements. Second, the use of an ionizing surface with a known work function φ^* and a beam of hard-to-ionize atoms with a known ionization potential J is used to check the correspondence between the temperature dependence of the ion current and the Saha–Langmuir equation:

$$I = C \exp\left[\frac{e(\varphi^* + \sqrt{eF} - J)}{kT}\right], \tag{9}$$

in which the values of kT obtained from the experimental distribution curves should appear.

Since the measurement of the ionizer temperature by an optical pyrometer simultaneously with the measurement of the ion currents and the recording of the distribution function would require a considerable alteration of the chamber or ion source of the mass spectrometer, these two measurement processes are performed separately. In these experiments the ionizer is an oxidized tungsten wire. The resistance of this ionizer is constant during the measurements; therefore, it is possible to first obtain the dependence of the surface temperature, measured from the ion distribution over the velocity projection, on the filament current, and then to obtain the same dependence using an optical pyrometer and to compare the data. The pyrometric measurements are carried out in a separate system in a vacuum of $1 \cdot 10^{-5}$ torr. During the optical measurements the temperature of the wire is increased from 1200 to 1600°K in order to obtain the dependence of its radiant emittance on the filament current before and after evaporation of the oxides. In the temperature interval under investigation this dependence is represented by two parallel segments of a straight line shifted according to the measured value of the temperature by 10±5° at a temperature of 1488°K, where evaporation of the tungsten oxides evidently terminates, and it corresponds to the best emissivity of an oxidized surface compared to a purely metallic surface. This correction was taken into account when correcting the pyrometer readings.[10] The values of the temperature determined using a Ribaud optical pyrometer are shown in Fig. 4 at points corresponding to the same value of the filament current of the ionizer in measurements using both methods.

RESULTS AND DISCUSSION

As indicated by control measurements of the temperature of the ionizer surface using the optical method, the true temperature and the values obtained from the distribution of silver ions over the velocity projection coincide to within ±10° (Fig. 4). The value of $J - \varphi^*$ obtained for the pair silver–oxidized tungsten, 0.91±0.10 eV, also agrees well with the literature value[6] of 0.81 eV.

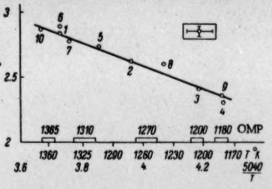

Fig. 4. Dependence of Ag$^+$ ion current on the temperature of the surface ionizer (oxidized tungsten). The values obtained using an optical pyrometer are shown in the upper row above the abscissa. The temperature values in the lower row are obtained from the ion distribution over the velocity projection. On the upper right, the limits of experimental error are shown and they are the same on the average for all the points.

The results confirm Eq. (8). The equality of the measured values of $J - \varphi^*$ and the published values corresponds to thermal equilibrium on the surface. We have used this method of analysis to investigate equilibrium in the case of silver and lead ions produced on different surfaces at temperatures up to 2600°K (see Part II). Under equilibrium the recorded distribution should be the same for all ions. Actually, in all such cases, some of which are shown in Fig. 3 for illustration, agreement between the distribution curves is observed within the experimental error ±0.001 eV. In these experiments beams of different atoms are ionized along with silver, which serves as a standard of comparison. Points calculated from Eq. (8) are plotted on this graph and they coincide with the experimental curve. It can be seen from Fig. 3 that the distribution over V_y obtained for thermionic ions of the ionizer material and the potassium and sodium impurities in them is somewhat broadened. The absolute value of the broadening is different for each ribbon and varies from 2 to 15%. However, the distribution of ions obtained during surface ionization of beams is stable over time and independent of the material and geometry of the ionizer; this has been checked by numerous determinations of the value of $J - \varphi^*$.

The presence of errors together with the poor discrimination with respect to the velocity V_z ($E_{z_0} = 0.017$ eV) means that the recorded function has a form very similar to that of $\sim \exp[-\varkappa^2 U^2/kT^*]$ where an incorrect interpretation of the experimental data can cause the temperature T^* to differ appreciably from the true temperature. For this reason, an experimental check of the method should be based not only on a comparison of the shape of the ion distribution curve, but also on the agreement between it and the temperature of the ionizing surface.

The distribution over the velocity projection of ions produced during surface ionization was first studied in ref. 11. The curves obtained have a form $I = I_0 \exp[-\alpha^2 U^2]$ and are evidently an integral distribution over two or several variables in velocity and coordinate space or an indication that distortions of type (8) are present.

In principle, analysis of the kinetic energies of ions can be a fairly precise method for measuring any surface temperature, including the range where optical pyrometry is not applicable. In particular, this method is promising for measurements where the emission properties of the surface are unknown or vary, for example, due to the interaction with the incident particle flux. The same applies to the determination of the work function of heated surfaces.

In combination with an independent method for measuring the temperature, the distribution of ions over the velocity projection allows us to obtain data on the spatial distribution of particles from the surface. With ionization of molecules, comparison of the distributions of molecular and atomic fragment ions with the temperature of the ionizing surface can give information on details of thermal equilibrium in a gas–surface system.

In conclusion, the author thanks M. V. Gur'ev, Yu. N. Lyubitov, and V. S. Senashenko for discussion.

The temperature measurements using an optical pyrometer were carried out by the author at the High-Temperature Institute of the Academy of Sciences of the USSR in the L. N. Gorokhov laboratory; the author thanks Yu. S. Khodeev for his help.

Dielectric strength of spark gaps following strong current pulses

E. P. Bel'kov

M. I. Kalinin Polytechnical Institute, Leningrad

(Submitted August 2, 1972; resubmitted January 22, 1974)
Zh. Tekh. Fiz., 44, 1946-1951 (September 1974)

The dielectric strength of various gases is determined when the spark channel undergoes natural cooling.

The restoration of the dielectric strength following a spark discharge (or an arc discharge) is closely associated with the cooling of both the gas in the gap and the electrodes. Restoration of the dielectric strength begins when the temperature of the gas in the gap falls to 3000–4500°K. Below ~ 2000–2500°K the breakdown voltage of the gap depends on the density of the gas. The breakdown voltage obeys a generalized Paschen law and the deviations from the Paschen law[1,2] do not exceed ~ 15–20%.

A theoretical analysis of the cooling of the gas in the discharge gap is given in refs. 2-7 for the time following spark or arc discharges. It is proposed in refs. 2-4 that cooling in the cylindrical column of hot gas which remains after a discharge results from heat conduction due to thermal currents from the hot gas to the cold electrodes. Another hypothesis is developed in refs. 5-7, where it is assumed that the heat is removed from the channel in the radial direction toward the surrounding cold gas. Heat is transferred by molecular heat conduction and the influx of a mass of cold gas into the channel. As has been shown by the author in ref. 8, turbulent heat conduction is also of importance in addition to the above factors. Turbulent motion of the gas develops during the cooling of the channel. This detail of the gas cooling has not been considered in the earlier work. The present work therefore deals, in further detail, with the cooling of a gas and the restoration of the dielectric strength after a spark discharge. Another problem is that of determining the basic relationships of these processes in various gases and for various gap lengths.

The cooling of a gas has been qualitatively studied with a shadow setup similar to that described in ref. 9.

Restoration of the dielectric strength has been investigated in air, elegaz, hydrogen, argon ($p = 1$ atm), and in compressed air ($p = 2.5$ atm) after the passage of current pulses whose parameters are listed in Table 1.

The electrodes of the tested gaps are hemispherical and 30 mm in diameter; St-3 steel and copper are used. In the tests in air the spark gaps are inserted into a chamber with a volume of ~ 0.25 m^3 and weak exhaust ventilation (0.05 m^3/min); in the tests involving other gases the spark gap is placed in a hermetically sealed chamber with a volume of ~ 1 dm^3. In all cases the gap tested received a bias illumination from a mercury lamp located at a distance of 10 cm from the electrodes. The bias illumination passes through a quartz window in the tests made with the hermetically sealed chamber.

The restoration of the dielectric strength is investigated at a repetition rate of 1 Hz for the current pulses. The probing voltage pulses have a form of 1.5/500 μsec. For a given exposure time the curves representing the probability of breakdown of the gap as a function of the probing voltage are recorded at the end of the current pulse, with the probability of breakdown varying between 3 and 97%. The results are used to plot the curves representing the restoration of the dielectric strength of the spark gaps for the breakdown probability 50% and to calculate the mean-square spread σ of the breakdown voltages.

After a spark discharge the gaps have zero dielectric strength for 200–300 μsec (Figs. 1–3). The length of this time interval depends weakly upon the magnitude of the current pulse, the type of the gas, the distance between the electrodes (for $S > 2$ mm), and the electrode material. The gas temperature in the gap exceeds ~ 5000–6000°K in this time period; hence, the electrical conductivity of the gas is high. After a spark discharge involving a quantity of electricity $Q < 0.1$ C (I_3, I_4), the dielectric strength is restored to $(0.85–0.9)U_0$ according to an exponential law. The time required for restoring the dielectric strength $0.9\,U_0$ is 3-5 msec in hydrogen, 4-7 msec in air and argon, and 10-12 msec in elegaz and compressed air (Fig. 1). This time is independent of the material used for the electrodes and increases slightly when the length of the gap is increased.

After a powerful spark discharge involving a quantity of electricity $Q > 0.25$ C (I_1, I_2), the dielectric strength is initially restored at the same rate as after current pulses of a spark discharge with $Q < 0.1$ C (Fig. 1). Then the restoration of the dielectric strength is retarded. Accordingly, the curves representing the restoration of the dielectric strength, which are plotted on a semilog scale, have two sections of greatly different curvature. The first curved section is characterized by a restoration rate which is independent of the material of the electrodes and which

I_m (kA): 1) 90; 2) 60; 3) 20; 4) 4; 5) 0.65; t_p (μsec): 1) 40; 2) 15; 3) 10; 4) 3; and 5) 1500.

changes only slightly when the parameters of the current pulses are varied. In the flat section of the curves, the restoration rate of the dielectric strength depends, though only weakly upon the thermal conductivity of the electrode material. When the amplitude and the length of the current pulses increase these sections of the curves are shifted downward.

After an arc discharge the dielectric strength is restored more slowly than after a spark discharge. Except for elegaz, the gaps have (2.5-5 msec after the end of a discharge) low dielectric strength in all gases on the level of 300-500 V (Fig. 2). The dielectric strength of elegaz is restored much earlier than in the other gases, 100-200 μsec after the end of the pulse. The dielectric strength is most rapidly restored to its full extent in elegaz and hydrogen. The time required for complete restoration of the dielectric strength depends upon the heat conductivity of the electrode material and the spacing of the electrodes (Figs. 1 and 3).

The laws governing the restoration of the dielectric strength after spark and arc discharges can be explained by gas cooling in the gap. As can be inferred from the shadow photographs (Fig. 4), the gas volume which is heated by the discharge continues to expand after the current pulse. This is not a consequence of the adiabatic expansion of the gas, because the pressure in the channel is approximately equal to the atmospheric pressure at the end of the current pulse for both a spark discharge, or an arc discharge. The expansion of the volume of the hot gas during its cooling under constant pressure indicates that the energy of the hot gas gradually propagates to the adjacent layers of the cold gas, heating the latter. The mass of the hot gas increases and its volume increases. The boundary of the hot gas with the cold undisturbed gas remains sharp for a long time because the relation between the heat conductivity of a gas (air) and the temperature is nonlinear. This means that a high temperature (density) gradient exists at the boundary.

Intense turbulent motion is observed inside the hot gas volume. The processes leading to the development of this motion can be envisaged as follows. After the current pulse, the discharge channel is cooled by heat conduction, and, to some extent, by radiation. Since the density of a gas decreases during cooling, gas moves from the periphery to the center inside the channel. The motion develops under the influence of the external pressure forces. Gas particles which are far from the center of the channel acquire a particularly high radial velocity. The velocity of the radial motion of the gas decreases toward the center of the channel and vanishes at the center proper. Therefore, the gas particles which are accelerated far from the center of the channel must necessarily reduce their radial velocity component in proportion to the approach to the center. Moving by inertia, these gas particles form eddy currents. Thus, turbulent motion develops in the cooling discharge channel.

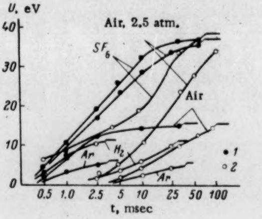

Fig. 2. Restoration of the dielectric strength of a 5 mm spark gap in various gases after current pulses. 1) I_m (kA): 1) 20; 2) 0.65; t_p(μsec): 1) 10; 2) 1500. Steel was the material of the electrodes.

Heat is transferred in the turbulent motion. The equation of energy transfer for a cylindrical model of the channel (the removal of heat onto the electrodes is ignored[8]) can be written in the following form when the turbulent transfer is taken into account:[10]

$$\rho\frac{\partial\bar{\varepsilon}}{\partial t}=\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{\lambda}{C_p}(1+\mathrm{Pe})\frac{\partial\bar{\varepsilon}}{\partial r}\right]-\frac{\partial\bar{\varepsilon}}{\partial r}\frac{1}{r}\int_0^r r\frac{\partial\rho}{\partial\bar{\varepsilon}}\frac{\partial\bar{\varepsilon}}{\partial t}dr, \tag{1}$$

where $\bar{\varepsilon}$ denotes the enthalpy of the gas; a bar on top of a symbol denotes an average over time; ρ, λ, and C_p denote the density, the heat conductivity, and the specific heat of the gas, respectively, i.e., quantities which depend upon $\bar{\varepsilon}$; Pe denotes the average Peclet criterion for the entire volume of the hot gas (independent of the coordinates).

The Peclet criterion is defined as

$$\mathrm{Pe}=\frac{\rho_{\mathrm{av}}Lv'_{\mathrm{av}}}{\left(\frac{\lambda}{C_p}\right)_{\mathrm{av}}}.$$

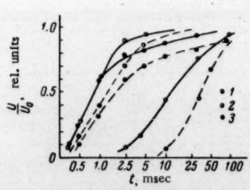

Fig. 3. Restoration of the dielectric strength of air gaps S = 2 mm (U_0 = 7.8 kV) and S = 15 mm (U_0 = 43 kV) after current pulses. I_m (kA): 1) 60; 2) 20; 3) 0.65; t_p (μsec): 1) 15; 2) 10; 3) 1500. The electrodes are steel. S = 2 mm is indicated by the solid lines; S = 15 mm is indicated by the dashed lines.

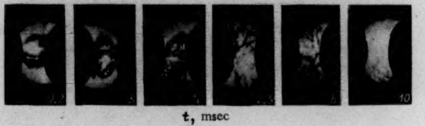

Fig. 4. Shadow photographs of the gas heated by a discharge channel through which a current pulse with $I_m = 20$ kA and $t_p = 10$ μsec passes. The photographs were taken at various times t after the termination of the discharge current.

where ρ_{av} denotes the average density of the gas in the volume; L denotes the scale of turbulence; $(\lambda/C_p)_{av}$ denotes a function of the average enthalpy of the gas in the volume; ε_{av}; and v'_{av} denotes the average velocity of the pulsating motion of the gas. This average velocity is given by the energy of the turbulent motion of the gas in the volume:

$$v'_{av} = \sqrt{\frac{2W_t}{M}},$$

where M denotes the mass of the gas in the volume. The energy of the turbulent motion of a gas can be obtained by integrating the product of the decelerating force exerted upon the gas times path over both time and the volume bounded by the radius r_m (Fig. 6):

$$W_t = \int_0^t \int_0^{r_m} 2\pi r\rho v_r^2 \frac{\partial v_r}{\partial t}\, dr\, dt. \tag{2}$$

While turbulent energy is generated in the gas volume, this energy is also spent by friction. We use an equation of ref. 11 to calculate the dissipation of the turbulent energy:

$$\frac{dv'}{dt} = -10\mu \left(\frac{v'}{L}\right)^2,$$

where μ denotes the coefficient of kinematic viscosity.

The boundary conditions of the problem are as follows:

$$\left.\begin{array}{l} r > r_0,\ \varepsilon(r,\ t) = \varepsilon_0, \\ r < r_0,\ \varepsilon(r,\ t) = \varepsilon_1(r,\ t) + \varepsilon_0, \end{array}\right\} \tag{3}$$

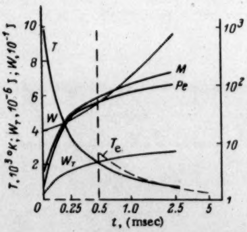

Fig. 5. Results of a calculation of the gas cooling after a current pulse with $I_m = 4$ kA and $t_p = 3$ μsec. T denotes the temperature on the axis of the cooling channel; M denotes the mass, W, the thermal energy, and W_t, the energy of turbulent motion of the gas calculated per centimeter channel length; Pe denotes the Peclet criterion; and T_e denotes the temperature deduced from the experimental results.

for

$$t = 0,\ \varepsilon(r,\ 0) = \varepsilon_{01}\left(1 - \frac{r}{r_0}\right)^{1/m} + \varepsilon_0$$

$$W_t = W_{t0}.$$

A cylindrical model of the cooling of a channel is developed in refs. 5-7, where turbulent transfer is disregarded [Pe = 0 in Eq. (1)]. The solution of Eq. (1) then produces a very slow cooling of the channel, particularly at temperatures below ~ 4500°K where the heat conductivity of air decreases sharply. Equation (1) is solved numerically when we include the turbulent transfer in the present work. The results of the calculation of the gas cooling are shown in Figs. 5 and 6 for a spark channel with a radius of 0.4 cm at the end of the current pulse (which corresponds to a current pulse with $J_m = 4$ kA and $t_p = 3$ μsec). It is assumed that removal of heat by radiation is the dominant process when the channel cools to ~ 10,000°K. In this case, an energy of turbulent motion

$$W_{t0} = \frac{\pi}{64} \frac{(\Delta\rho)^3}{(\rho_{av}\Delta t)^2} r_0^4,$$

accumulates in the channel, where Δt denotes the time within which, the gas cools to 10,000°K; $\Delta\rho$ denotes the density change corresponding to this cooling.

It follows from calculations that turbulent heat transfer Pe > 2 is of great importance in the cooling of the channel as early as 10-20 μsec after the end of the discharge, with the importance of turbulent heat transfer increasing continuously (Pe reaches the value 10^2 in the calculation). This behavior results from the fact that W_t the energy of the turbulent gas motion in the volume increases with time. A particularly fast increase in turbulent energy occurs at the beginning of the cooling process 200-250 msec after the end of the current pulse. The gas cools rapidly in this time interval and the velocity of directed radial gas motion in the volume reaches high values (Fig. 6). The gas is accelerated far from the center of the channel. The kinetic energy of the gas is converted into energy of turbulent motion when the gas approaches the center of the channel. About 2/3 of the turbulent energy of the gas in the volume is accumulated when the gas has cooled to 5000-6000°K. The turbulent energy greatly increases the turbulent heat conductivity of the gas and, hence, the gas volume continues to cool rapidly despite the fact that molecular heat conduction of the gas is low at low temperatures.

Calculations have shown that the rate of gas cooling is essentially independent of the channel radius after a spark

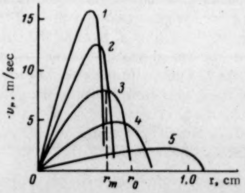

Fig. 6. Velocity of radial gas motion in the cooling of the channel. $I_m = 4$ kA, $t_p = 3$ μsec, $r_m = r_m(t)$ and $r_0 = r_0(t)$. Time (msec) after the end of the discharge: 1) 0.05; 2) 0.1; 3) 0.2; 4) 0.5; and 5) 1.0.

discharge. This is explained by the fact that at a certain initial rate of gas cooling by radiation the energy of turbulent motion developing in the volume is proportional to r_0^4, whereas the coefficient of turbulent transfer is $A_q \sim r_0^2$. Since the thermal energy of the gas in the channel is also proportional to r_0^2, the constant of the cooling time of the gas, $\tau \sim r_0^2/A_q$, is independent of the channal radius. This detail accounts for the fact that the rate at which the dielectric strength is restored after a spark discharge is almost independent of both magnitude and duration of the current pulses even when the parameters are varied over very wide limits.

After an arc discharge the gas begins to cool from a temperature of 7000-8000°K. There is no fast initial cooling of the gas. Turbulent energy accumulates slowly in the gas volume and, accordingly, the gas also cools slowly.

The observed experimental relationships in the restoration of the dielectric strength after both spark and arc discharges can be explained by gas cooling in the spark gap. Shortly after the end of the current pulse, turbulent gas motion develops in the cooling channel and the turbulent motion stimulates the entire subsequent gas cooling in the gap.

The author thanks P. I. Shkuropat for valuable comments.

Electrical conductivity of a pseudoliquefied layer in an electric field

V. V. Gal', V. I. Konov, and K. A. Nikitin

Institute of High Temperatures, Academy of Sciences of the USSR, Moscow

(Submitted October 8, 1973)
Zh. Tekh. Fiz., 44, 1952-1954 (September 1974)

The electrical conductivity of pseudoliquefied layers of graphite, niobium, and zirconium oxycarbonitride is investigated in a weak electric field, i.e., below 1 V/cm. It is shown that an electric current can flow through pseudoliquefied zirconium oxycarbonitride and niobium layers only above a threshold voltage, the breakdown voltage. The dependence of the breakdown voltage on the experimental parameters is investigated. The results are evaluated in connection with contact conductivity and the breakdown of thin dielectric oxide layers on particle surfaces.

Heating a pseudoliquefied layer of particles through which an electric current flows is one of the promising methods of generating high temperatures. Carbon-containing materials which are electrical conductors are usually employed as pseudoliquefied layers.[1-6] However, this technique of heating pseudoliquefied layers has not been thoroughly investigated, particularly in regard to materials which do not contain carbon. When a current passes through a pseudoliquefied layer, its structure obviously differs from that of a layer through which no current flows.

It is important to investigate the electrical conductivity of pseudoliquefied layers of various materials (graphite, oxycarbonitride of zirconium, niobium), when an electric field which does not change the layer structure is applied.

Suspended layers are produced in a cylindrical reaction vessel 40 mm in diameter (one electrode); a central electrode is inserted into the reaction vessel in a coaxial position. Gas is admitted to the pseudoliquefied layers through a diffusor situated in the lower section of the reaction vessel. A voltage from a dc source is applied to the electrodes and the voltage–current characteristics of the pseudoliquefied layers are recorded. Figure 1 shows a typical voltage–current characteristic. The measurements are used to determine the smallest potential difference U_{appl} for a stable, fixed current in the layer. The sensitivity of the voltage measurements is $5 \cdot 10^{-5}$ V.

The quantity U_{appl} has the meaning of the breakdown voltage of the pseudoliquefied layer. This quantity depends upon several factors. The most important of these factors are the electrophysical properties of the solid and the gaseous phases, and the structure of the suspended layer. With $U_{appl} = 0$ a number of contacts sufficient to produce an electrical conductivity exists in the pseudoliquefied layer, and these extend from one electrode to the other. When $U_{appl} > 0$ (more precisely, when U_{appl} is greater than the sensitivity threshold of the voltage measurements), no contacts with purely resistive conductivity are present in the pseudoliquefied layers. The quantity U_{appl} is therefore an indicator of the contact circuits of the conductivity of pseudoliquefied layers and is characteristic of the layer structure. The homogeneity of a pseudoliquefied layer through which an electric current flows increases with decreasing U_{appl}.

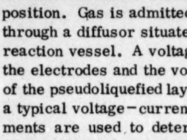

Fig. 1. Voltage–current characteristic of a pseudoliquefied layer of zirconium oxycarbonitride (at an Ar consumption of 12 liter/min).

We investigate the dependence of U_{appl} upon the solid phase and the consumption of liquefied gas. The basic results of the U_{appl} measurements are given in Table 1 (the distance between the electrodes is kept constant at 16 mm).

In a pseudoliquefied graphite layer, $U_{appl} = 0$ when the parameters of the experiment are varied over wide limits. This means that a large number of contact loops exist in the layer.

In niobium and zirconium oxycarbonitride, U_{appl} is nonvanishing even for fixed layers. This result can be explained by the fact that the contact points of the particles are nonconductive.

The possible reasons for the increase in U_{appl} with increasing layer porosity are: The formation of longer loops of contact conductivity is characteristic of increasing porosity (this results in an increase in the number of nonconductive contacts); furthermore, when the porosity increases the number of conductive loops with gas-filled inclusions also increases.

We note that the specific resistivity of pseudoliquefied layers is greater by several orders of magnitude than that of the compact material (six to seven orders of magnitude in graphite). The increased specific resistivities of pseudoliquefied layers apparently originate from the small contact areas of the particles and the high resistance of the contacts. The higher value of U_{appl} at higher porosity is due to a reduction of the number of conductivity in loops per unit of layer cross section.

The dependence of U_{appl} upon the electrode spacing has been investigated (see Table 2). In niobium, whose particles, when in contact with air, are covered by a thin film of lower oxides, U_{appl} increases in proportion to the increase in the length of the contact circuits (i.e., with the increasing effective thickness of the dielectric). U_{appl} of graphite is always equal to zero. The specific resistivity of the pseudoliquefied layer is essentially independent of the electrode spacing.

A significant dependence of the specific resistivity of the pseudoliquefied layers upon the current density should be noted (fraction 315-500 μ; see Table 3).

It is interesting to compare the electrical conductivity of pseudoliquefied layers with electrical phenomena

TABLE 1. Basic Results of the Experiments

Material	Fraction (μ)	Electrode materials	Gas	Flow of liquefied gas (liter/mm)	Porosity of pseudoliquefied layer	U_{appl}, (mV)	$\rho(\Omega \cdot cm)$
Graphite	315—500	Graphite—graphite	—	Fixed layer	0.62	0	$2 \cdot 10^{-4}$

in suspensions of electrically conductive powders. The electric breakdown of suspensions of Al and soot in dielectric liquid is studied in refs. 6 and 7. It is shown that the electric breakdown in suspensions with concentrations of about 1% of the conductive particles results in a structuring of the suspensions at fields of 10^3-10^4 V/cm The effects of aggregation and the interactions of the conducting chains with the electrodes are considered.

The similarity in the behavior of suspensions and pseudoliquefied layers in an electric field is noteworthy. The similarity resides in the fact that electric breakdown occurs in pseudoliquefied layers, as in suspensions with the breakdown voltage increasing in direct proportion to the distance between the electrodes. However, in addition to the similarities between pseudoliquefied layers and suspensions, there is an important difference: In pseudoliquefied layers the average field is about four orders of magnitude lower and the concentration of the particles is one order of magnitude greater than that in suspensions. The circuits for contact conductivity formed in suspensions are stable during the entire time in which an electric field is applied because the circuits are maintained by the forces generated by the electric field. In pseudoliquefied layers, the circuits of the contact conductivity, which are formed by the much weaker applied field, exist for a short time, which depends upon the porosity fluctuations in the layer, and disintegrate. New circuits are formed at the same time, i.e., a stationary equilibrium exists between the number of circuits being created and destroyed. A description of electrical phenomena in pseudoliquefied layers in an electric field which changes the layer structure will be communicated in subsequent publications.

Multiple scattering of a focused beam of monoenergetic electrons

G. N. Vyalov

(Submitted October 12, 1973; resubmitted January 10, 1974)
Zh. Tekh. Fiz., 44, 1955-1960 (September 1974)

The mean-square dimensions of an axisymmetric focused beam of monoenergetic electrons subject to multiple scattering are determined. The mean-square dimensions in a longitudinal magnetic field are calculated for arbitrary total scattering angles. The scattering of a magnetically self-focused charge-neutralized beam is also calculated. An approximate expression valid for small total scattering angles is obtained for the mean-square dimensions. The beam current is estimated by assuming that the beam propagates without significant change in the transverse dimension. The calculation is performed by determining the trajectory of a single electron, taking account of random forces, and then averaging over the trajectories.

1. In a number of applications of an electron beam related to its propagation in a gaseous medium it is important to take account of the effect of electron scattering on the properties of the beam.[1)] In particular, the scattering leads to an increase in the transverse dimensions of the beam, and to a reduction in its specific power. Extreme broadening of the beam at distances less than the slowing-down length can be inhibited by external focusing, for example, by a longitudinal magnetic field. For small total angles of deflection of the electrons from their initial direction the mean-square dimensions of the beam can be estimated, for example, by the method used by Vyalov and Fiks.[1] We show below that the similar problem of finding the shape of a scattered beam in a uniform longitudinal magnetic field can be solved without restricting the size of the total scattering angles. An approximate equation is derived for the transverse dimensions of a self-focused weakly divergent electron beam.

2. In order to simplify the problem we assume that the energy lost by electrons in slowing down in the medium is negligibly small. This means that the propagation distance of the beam in the medium is less than the slowing-down length.

It can be shown that to an accuracy sufficient for the calculation of the mean-square dimensions of the beam the change in direction of the momentum **p** of a single electron with a given energy in a scattering medium without a magnetic field is

$$\frac{d\mathbf{p}}{dt}=\frac{1}{\tau}(-A\mathbf{p}+Bp\mathbf{n}),\quad p=|\mathbf{p}|,\tag{1}$$

where τ is the average time between collisions, **n** is a random unit vector quasiorthogonal to **p**, i.e., orthogonal to **p** to order A/B; $B\approx\bar{\theta}$ is the average angle of deflection of the momentum in a single collision, $A\approx\bar{\theta}^2/2\approx\overline{\theta^2}/2$. We assume multiple Coulomb scattering, with small average and mean-square scattering angles in a simple interaction. The quantity $\theta_i=\theta(t_i)$, where i is the number of the scatter, varies randomly from collision to collision. Assuming that the collisions are sufficiently frequent we use the quasicontinuous collision approximation to replace the functions $\theta(t_i)$ and $\theta^2(t_i)$ by their average values determined by the Rutherford equation for small-angle scattering. The characteristics of the beam can be calculated up to the second moments by supplementing the above assumptions with the following rules for averaging over the directions of the random vector **n**(t):

$$\left.\begin{aligned}&\langle\mathbf{n}(t)\rangle\simeq 0,\\&\langle n_i(t)\,n_k(t')\rangle\simeq\frac{1}{2}\left[\delta_{ik}-\langle\pi_i(t)\,\pi_k(t)\rangle\right]\delta(t-t'),\end{aligned}\right\}\tag{2}$$

where $\boldsymbol{\pi}=\mathbf{p}/p$, with the usual notation for the unit tensor δ_{ik} and the Dirac delta function $\delta(t-t')$.

If it is assumed that initially all the electrons have the same direction described by the unit vector $\boldsymbol{\pi}_0$, then by averaging Eq. (1) and solving the averaged equation we obtain the change of the average longitudinal momentum in the beam

$$\langle\pi_{\parallel}\rangle=\langle\boldsymbol{\pi}\boldsymbol{\pi}_0\rangle=e^{-At/\tau}=e^{-t/\tau_s},\tag{3}$$

where

$$\tau_s=\left(\frac{\tau}{A}\right)=\frac{2\tau}{\overline{\theta^2}},\tag{4}$$

which agrees with Eq. (14.9) of ref. 2 obtained using the Boltzmann equation. It follows that the average longitudinal displacement of monoenergetic electrons in a scattering medium is limited by the value of $v\tau_s$, where v is the velocity of the electrons.

Similarly, using the formal solution of Eq. (1) in the form

$$\mathbf{p}=\mathbf{p}_0e^{-\frac{At}{\tau}}+\frac{Bp}{\tau}\int\limits_0^t e^{-\frac{A(t-t')}{\tau}}\mathbf{n}(t')\,dt',\tag{5}$$

we obtain an integral equation for the mean-square longitudinal momentum $T=\langle\pi_{\parallel}^2\rangle$:

$$T=e^{-\frac{2At}{\tau}}+\frac{B^2}{2\tau}\int\limits_0^t e^{-\frac{2A}{\tau}(t-t')}(1-T')\,dt'\tag{6}$$

where T' denotes the value of T at time t'. The integral equation (6) is equivalent to the differential equation

$$\frac{dT}{dt}\equiv\dot{T}=\frac{B^2}{2\tau}-\frac{T}{\tau}\left(\frac{B^2}{2}+2A\right)\rightarrow\frac{B^2}{2\tau}-\frac{3B^2}{2\tau}T\ \text{for}\ A=\frac{B^2}{2},\tag{7}$$

which has the solution

$$T=\frac{B^2+4Ae^{-\frac{t}{\tau}\left(\frac{B^2}{2}+2A\right)}}{B^2+4A}\rightarrow\frac{1}{3}\left(1+e^{-\frac{3B^2t}{\tau}}\right)\ \text{for}\ A=\frac{B^2}{2},\tag{8}$$

agreeing with Eq. (14.9) of ref. 2 for $A=B^2/2=\overline{\theta^2}/2$, written for the average of the square of the transverse momentum $\langle\pi_{\perp}^2\rangle=1-T$, obtained by using the Boltzmann equation.

The mean-square dimensions of the beam can be calculated by using Eqs. (5) and (8). We note also that according to Eq. (5) the mean-square momentum of an electron in the beam is conserved $\langle \overline{p}^2 \rangle = p_0^2$, in accord with the assumption that slowing down can be neglected.

3. The equations of motion of an electron in a scattering medium in the presence of a magnetic field H can be written in the form

$$\frac{d\mathbf{p}}{dt}=\frac{1}{\tau}(-A\mathbf{p}+Bp\mathbf{n})-\frac{e}{\gamma mc}[\mathbf{pH}], \tag{9}$$

where $\mathbf{p} = \gamma m\mathbf{v}$ is the momentum of the electron, γ is the relativistic factor, $-e$ is the charge of the electron, and c is the velocity of light.

For the motion of a beam in a uniform longitudinal magnetic field along the z axis p_x, p_y and n_x, n_y are replaced by the complex quantities

$$\Pi=p_x+ip_y;\quad n=n_x+in_y. \tag{10}$$

The vector equation (9) is equivalent to the system

$$\left.\begin{aligned}\dot{\Pi}&=-\left(\frac{A}{\tau}-i\omega\right)+\frac{pB}{\tau}n,\\ \dot{p}_z&=-\frac{A}{\tau}p_z+\frac{pB}{\tau}n_z.\end{aligned}\right\}. \tag{11}$$

The formal solution of system (11) with the initial conditions

$$\Pi(0)=\Pi_0;\quad p_z(0)=p_{z0}$$

is

$$\left.\begin{aligned}\Pi&=\Pi_0e^{-t\left(\frac{A}{\tau}-i\omega\right)}+\frac{pB}{\tau}\int_0^t e^{\left(\frac{A}{\tau}-i\omega\right)(t'-t)}n(t')\,dt',\\ p_z&=p_{z0}e^{-\frac{At}{\tau}}+\frac{pB}{\tau}\int_0^t e^{\frac{A}{\tau}(t'-t)}n_z(t')\,dt'.\end{aligned}\right| \tag{12}$$

The complex transverse displacement w = x + iy and the longitudinal displacement z are

$$\left.\begin{aligned}w&=w_0+\frac{\Pi_0}{\gamma m\left(\frac{A}{\tau}-i\omega\right)}\left[1-e^{-t\left(\frac{A}{\tau}-i\omega\right)}\right]\\ &+\frac{vB}{\tau}\int_0^t\frac{dt'n(t')}{\frac{A}{\tau}-i\omega}\left[1-e^{\left(\frac{A}{\tau}-i\omega\right)(t'-t)}\right],\\ z&=z_0+\frac{p_{z0}\tau}{\gamma mA}\left(1-e^{-\frac{At}{\tau}}\right)+\frac{vB}{A}\int_0^t dt'n_z(t')\left[1-e^{\frac{A}{\tau}(t'-t)}\right].\end{aligned}\right\} \tag{13}$$

We note that the equation for the longitudinal momentum does not contain the field H. Therefore the mean-square longitudinal momentum is determined by Eq. (8).

The mean-square dispersions of the displacement due to multiple scattering are

$$\left.\begin{aligned}\langle\Delta w\Delta w^*\rangle&=\frac{v^2B^2}{A^2+\omega^2\tau^2}\int_0^t\int_0^t dt'dt''\langle n(t')n^*(t'')\rangle\\ &\times\left[1-e^{\left(\frac{A}{\tau}-i\omega\right)(t'-t)}\right]\left[1-e^{\left(\frac{A}{\tau}+i\omega\right)(t-t'')}\right],\\ \langle\Delta z^2\rangle&=\frac{v^2B^2}{A^2}\int_0^t\int_0^t dt'dt''\langle n_z(t')n_z(t'')\rangle\\ &\times\left[1-e^{\frac{A}{\tau}(t'-t)}\right]\left[1-e^{\frac{A}{\tau}(t''-t)}\right],\end{aligned}\right\} \tag{14}$$

where the asterisk denotes the complex conjugate.

According to rules (2) for averaging we have

$$\left.\begin{aligned}\langle n(t')n^*(t'')\rangle&=\frac{1}{2}\delta(t'-t'')[1+T(t')],\\ \langle n_z(t')n_z(t'')\rangle&=\frac{1}{2}\delta(t'-t'')[1-T(t')].\end{aligned}\right\} \tag{15}$$

By taking account of (8) we obtain for T(t):

$$\left.\begin{aligned}\langle\Delta w\Delta w^*\rangle&=\frac{v^2B^2\tau}{3(A^2+\omega^2\tau^2)}\int_0^t dt'\left(2+e^{-\frac{3At'}{\tau}}\right)\\ &\left[1-2e^{\frac{A(t'-t)}{\tau}}\cos\omega(t'-t)+e^{\frac{2A(t'-t)}{\tau}}\right],\\ \langle\Delta z^2\rangle&=\frac{v^2B^2\tau}{3A^2}\int_0^t dt'\left(1-e^{-\frac{3At'}{\tau}}\right)\left[1-2e^{\frac{A(t'-t)}{\tau}}+e^{\frac{2A(t'-t)}{\tau}}\right].\end{aligned}\right\} \tag{16}$$

Integrating gives the form

$$\left.\begin{aligned}\langle\Delta w\Delta w^*\rangle&=\frac{v^2B^2\tau}{3(A^2+\omega^2\tau^2)}\left\{2\left[t-\frac{2\tau^2}{A^2+\omega^2\tau^2}\left(e^{-\frac{At}{\tau}}\left(\omega\sin\omega t\right.\right.\right.\right.\\ &\left.\left.\left.-\frac{A}{\tau}\cos\omega t\right)+\frac{A}{\tau}\right)+\frac{\tau}{2A}\left(1-e^{-\frac{2At}{\tau}}\right)\right]\\ &+e^{-\frac{3At}{\tau}}\left[\frac{\tau}{A}\left(\frac{1}{3}e^{\frac{3At}{\tau}}+e^{\frac{At}{\tau}}-\frac{4}{3}\right)\right.\\ &\left.\left.-\frac{4A\tau}{4A^2+\omega^2\tau^2}\left(e^{\frac{2At}{\tau}}\left(\cos\omega t+\frac{\omega\tau}{2A}\sin\omega t\right)-1\right)\right]\right\},\\ \langle\Delta z^2\rangle&=\frac{v^2B^2\tau}{3A^2}\left[t+\frac{\tau}{A}\left(-\frac{11}{6}+3e^{-\frac{At}{\tau}}-\frac{3}{2}e^{-\frac{2At}{\tau}}+\frac{1}{3}e^{-\frac{3At}{\tau}}\right)\right].\end{aligned}\right\} \tag{17}$$

Strong magnetic fields, for which

$$\omega\tau\gg 2A=\theta^2\quad\text{or}\quad H\gg\frac{m\gamma c}{e\tau}\theta^2=\frac{1700\beta\gamma}{Z_p}\,[\text{Oe}], \tag{18}$$

are of particular interest.

In this case we have

$$\begin{aligned}\langle\Delta w\Delta w^*\rangle&\simeq\frac{v^2B^2}{3\omega^2\tau}\left\{2\left[t-\frac{2}{\omega}\sin\omega te^{-\frac{At}{\tau}}+\frac{\tau}{2A}\left(1-e^{-\frac{2At}{\tau}}\right)\right]\right.\\ &\left.+e^{-\frac{3At}{\tau}}\left[\frac{\tau}{A}\left(\frac{1}{3}e^{\frac{3At}{\tau}}+e^{\frac{At}{\tau}}-\frac{4}{3}\right)-\frac{2}{\omega}e^{\frac{2At}{\tau}}\sin\omega t\right]\right\}.\end{aligned}$$

In the limiting case of small times, $3At/\tau \ll 1$, or $z \ll 2z_p/3$, where $z_p = v\tau/\theta^2$ is the scattering length, we obtain the simple expressions

$$\left.\begin{aligned}\langle\Delta w\Delta w^*\rangle&\simeq\frac{2v^2B^2}{\omega^2\tau}\left(t-\frac{1}{\omega}\sin\omega t\right)=\frac{2\rho^2}{z_p}\left(z-\rho\sin\frac{z}{\rho}\right)\simeq\frac{2\rho^2z}{z_p},\\ \langle\Delta z^2\rangle&\simeq\frac{v^2B^2At^4}{12\tau^2}=\frac{z^4}{24z_p^2};\quad\rho=\frac{v}{\omega}.\end{aligned}\right\} \tag{19}$$

Thus in a strong magnetic field the transverse diffusion of the beam electrons is established rather rapidly. The square of the transverse dimensions increases linearly with the time. In the absence of a magnetic field the beam spreads much more rapidly, the square of the dimensions increasing as the cube of the time.

The longitudinal diffusion of the beam can be established only after a time $t \gg \tau/A = 2\tau/\theta^2$. For small times the law for the change of the longitudinal dispersion ($\Delta Z^2 \sim t^4$) differs markedly from the diffusion law.

4. The equations of motion of an electron in a scattering medium in the form (9) can, in principle, also be applied for a magnetic field of arbitrary configuration, or for other force fields. It is also possible to take account of slowing down, for example by ionization, by introducing an appropriate retarding force on the right-hand side of (9). The equations obtained in this way are generally quite complicated and can only be solved numerically.

Because of the complexity of the problem of the motion of a high-current electron beam in a scattering medium (self-focused by its self-magnetic field) it is difficult to obtain the change of the mean-square dimensions of the beam for any time from the instant of emission of the electron. Simplification of the problem of motion of a beam in an axisymmetric transverse magnetic field which increases linearly with the radius by assuming that the deflection from the initial direction is small and the longitudinal momentum is constant gives an answer identical with that of ref. 3 obtained by the Boltzmann equation (cf. also ref. 4). In the approximation of constant longitudinal momentum p_z it is relatively simple to take account also of the decrease in the transverse momentum related to the factor A of Eq. (9). If necessary the correction to the change in p_z can be calculated by perturbation theory.

In a similar way, the average of the square of the radius a^2 of a self-focused electron beam for relatively small total scattering angles can be estimated by assuming that the transverse dimensions change slowly and that the self-magnetic field inside a charge-neutralized beam can be written in the form

$$H = \frac{2Jr}{ca^2}. \qquad (20)$$

In this case the mean-square dimensions of the beam can be estimated by the equation

$$a^2 \simeq a_0^2\left(\cos\frac{\varkappa z}{a} + \frac{a}{\varkappa f}\sin\frac{\varkappa z}{a}\right)^2 + \frac{a^2\Gamma^2}{\varkappa^2}\sin^2\left(\frac{\varkappa z}{a}\right) + \frac{a^2}{2\varkappa^2 z_p}\left(z - \frac{a}{2\varkappa}\sin\frac{2\varkappa z}{a}\right), \qquad (21)$$

which is valid when

$$\frac{d\ln a}{d\ln z} \ll 1, \qquad (22)$$

where a_0 and Γ are respectively the initial mean-square dimensions of the beam and the angular spread; $\varkappa^2 = 2I/I_0\beta\gamma$; $I_0 = mc^3/e$ is a universal current, equal to 17,000 A; f is the focal length, i.e., the distance at which a beam with a zero current and $\Gamma = 0$ would converge to a point if there were no scattering. For a sufficiently large current and $\Gamma^2 \approx (\varkappa^2/a^2)a_0^2 \approx \varkappa^2$ the beam dimensions can be estimated by the simple relation

$$a^2 \approx \frac{a_0^2}{\dfrac{z}{1-(2\varkappa^2 z_p)}}. \qquad (23)$$

The expression is satisfied approximately when its value is close to unity. By requiring that this condition be satisfied at least at distances $Z \leqslant (1/2)\, z_p$ we obtain a restriction on the current ensuring the propagation of a self-focused beam the indicated distance, $\varkappa^2 > 1/4$ or $I > (1/8)\, I_0\beta\gamma$. In general it is necessary that

$$J > \frac{1}{4} J_0\beta\gamma\frac{z}{z_p}. \qquad (24)$$

This estimate assumes also that in a distance z an electron performs a large number of transverse oscillations in the self-field of the beam, i.e., $2\varkappa z/a \gg 1$.

[1)] The role of scattering in the propagation of a relativistic electron beam in a dense gas is discussed, for example, in an experimental paper by Miller and Gerardo.[5]

Double focusing in a system of 1/r electric and magnetic fields

V. V. Zashkvara and V. N. Demin

Institute of Nuclear Physics,
Academy of Sciences of the Kazakh SSR, Alma-Ata

(Submitted October 11, 1973; resubmitted March 18, 1974)
Zh. Tekh. Fiz., 44, 1961-1963 (September 1974)

We discuss an ion-optical mass spectrometer in which spatial focusing and energy focusing of a beam of charged particles are accomplished simultaneously (double focusing). The spectrometer consists of two analyzing elements in tandem: a cylindrical electrostatic mirror and a magnetic analyzer with a 1/r field.

Electrostatic energy analyzers of the cylindrical mirror type[1-4] have been widely used in the spectroscopy of charged-particle beams because of their good ion-optical characteristics and simple construction. It is tempting to consider the possibility of using a cylindrical mirror in combination with a magnetic field in a double-focusing mass spectrometer to increase the transmission. A magnetic field varying as 1/r, where r is the distance from the axis of symmetry, corresponds most closely to a cylindrical mirror in the character of its spatial focusing of a beam. This field has been known for a long time in the spectroscopy of charged-particle beams and is the basis for high-transmission beta spectrometers.[5-8] A magnetic field varying as 1/r surrounds a straight wire carrying a current or, according to ref. 5, can be obtained between two inclined pole faces of a magnet as shown in Fig. 1. In a cylindrical coordinate system the field components are: $H_r = 0$, $H_\theta = h/r$, $H_z = 0$, where h is a constant characterizing the field intensity. Far from the edges of the magnet the lines of force are concentric circles and the equipotential lines are radii. There is a close analogy between the ion-optical properties of a cylindrical electrostatic field and a 1/r magnetic field. We assume that a point source at point 0 on the axis of symmetry of the magnetic field (Fig. 1) emits particles of mass m, charge q, and velocity v which enter the magnetic analyzer in a beam with an angular divergence of $2\Delta\alpha$ in an axial plane, and $2\theta_0$ in a plane perpendicular to the axis of symmetry. The boundaries of the pole faces of the magnet are rectilinear, and we assume that the axis of the beam is perpendicular to the boundary of the analyzer. The spatial focusing of a beam in a 1/r magnetic field with rectilinear boundaries (Fig. 1) and in a cylindrical electrostatic mirror are very similar. Neglecting edge effects it can be shown that the 1/r magnetic field, like the electrostatic field of a cylindrical mirror, focuses a beam of charged particles on the axis of symmetry z to second order in $\Delta\alpha$ and exactly with respect to the azimuthal angle θ. If the 1/r magnetic field is sharply defined at the edges of the pole faces and the boundary where the beam enters and leaves the field is a cylindrical surface of radius r_m passing through the edges of the poles (Fig. 1), then the resolution of the focal length L in terms of the small perturbations $\Delta\alpha$ and $\delta p = \Delta(mv)/mv$ the relative momentum spread in the beam of charged particles, is

$$L = r_m \{l_0 + B_1\Delta\alpha + B_2\delta p + B_{11}(\Delta\alpha)^2 + B_{12}\Delta\alpha\delta p + B_{22}(\delta p)^2 + B_{111}(\Delta\alpha)^3 + \ldots,\} \quad (1)$$

under conditions of angular focusing with respect to $\Delta\alpha$

$$l_0 = 2.71,\quad B_1 = 0,\quad B_2 = 4.31,\quad B_{11} = 0,\quad B_{12} = 5.22,\quad B_{22} = 4.30,\quad B_{111} = -1.0, \quad (2)$$

where B_2 is the linear momentum dispersion in the direction of the z axis. The numerical values of B_{111}, B_{12}, and B_{22} characterize the relative aberrations of the third order in $\Delta\alpha$ and the second order in $\Delta\alpha$ and δp in the direction of the dispersion. It should also be added that the condition for second-order angular focusing occurs at $mv/qh = 0.74$ and $r_{max} = 2.10\ r_m$ (Fig. 1). These are the optical characteristics of a magnetic analyzer if we neglect fringing fields. Actually the fringing field is the cause of the extra aberrational spread of the image in the direction of the dispersion, an effect which increases with the azimuthal divergence of the beam $2\theta_0$. Henceforth we assume that θ_0 is chosen to achieve a compromise between the aberrations due to the effect of fringing and the loss of transmission produced by the decrease in those aberrations, so that in the first approximation the expansion coefficients (1) and (2) shown above give a good description of the ion-optical properties of the magnetic analyzer. Unfortunately the value of θ_0 corresponding to these conditions cannot be estimated without knowing the actual trajectories.

We now consider a double-focusing mass spectrometer. Figure 2 shows the ion-optical scheme of such

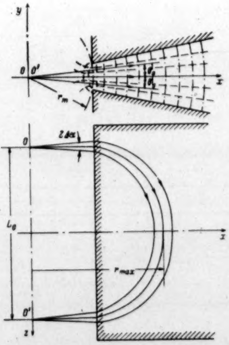

Fig. 1. Analyzer with a magnetic field varying as 1/r.

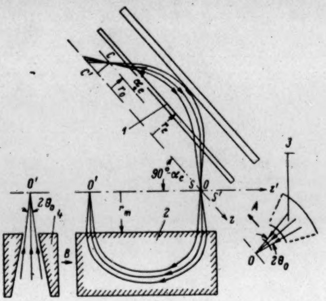

Fig. 2. Ion-optical scheme of a double-focusing mass spectrometer. 1) Electrostatic analyzer of the cylindrical mirror type; 2) magnetic analyzer with a 1/r field; 3) view of electrostatic analyzer along arrow A; 4) view of magnetic analyzer along arrow B.

an instrument consisting of a cylindrical electrostatic mirror 1 and a matching magnetic analyzer 2 with a 1/r field. We assume that the cylindrical mirror is adjusted for second-order focusing by one of the schemes of the annulus-axis type.[9] CC' is an annular slit of radius r_0 serving as the ion-optical source. The entrance angle α_e satisfies the condition of second-order angular focusing in the cylindrical mirror and, according to ref. 9, can take on values from 42°18', when the ion-optical source is a point and $r_0/r_e = 0$, to 38°50', when the ion-optical source is a narrow annular slit on the surface of the mirror z and the axis of symmetry of the magnetic field z' in the plane of Fig. 2 and the angle between them is $90° - \alpha_e$. Angular focusing is achieved in the system of fields by the coincidence of the foci of the component elements at point 0. The narrow slit SS' is located on the axis of symmetry of the cylindrical mirror; its extension along the z axis determines the energy range of ions in the beam entering the magnetic field, and the slit width determines the separation of the nonaxial trajectories leaving the source.[4] Energy focusing in this scheme is achieved if the characteristic dimensions of the analyzer r_e and r_m satisfy a relation which follows from the requirement that the linear energy dispersions of the cylindrical mirror and the magnetic analyzer be equal:

$$\frac{r_m}{r_e} = 2\frac{A_2}{B_2}\sin\alpha_e. \tag{3}$$

Data on the linear dispersion coefficient A_2 and the other parameters characterizing the ion-optical properties of a cylindrical mirror are given in ref. 9.

The proposed mass spectrometer should be useful in measuring mass spectra of low-intensity ion beams when the mass resolution requirements are not so rigid and an increase in transmission is necessary, for example in ion microanalyzers.

Numerical experiments on electron bombardment in crossed fields

P. V. Romanov and A. S. Roshal'

Moscow Physical Engineering Institute

(Submitted October 5, 1973)
Zh. Tekh. Fiz., 44, 1964-1968 (September 1974)

The statistical characteristics of electron bombardment in magnetrons are obtained by numerical experiments using the giant particle method. Cylindrical and planar electrodes are considered. The effects of the anode potential and of an rf voltage on the distributions of thermal losses, energy, velocity, and electron incidence angle are considered. Nonequilibrium distributions of mean electron energies of incidence at the cathode are enhanced with increasing dc and rf potentials. The distribution of incident electron energies lies in the low-energy region (100-200 eV). The electron distribution over an incidence angle is also a nonequilibrium distribution and has a noticeable maximum in the negative angle region, indicating the cycloidal nature of the electron motion in the immediate neighborhood of the cathode. The nonequilibrium nature of the thermal loss distribution is much stronger at the anode than the cathode. The results lead to better development on design requirements for cathodes and anodes, cathode emission characteristics, and cooling for given performance characteristics.

1. STATEMENT OF THE PROBLEM

The cathode and anode of a magnetron undergo intense electron bombardment which affects the lifetime and performance.[1-4] A study of electron bombardment in magnetron devices is necessary to understand physical phenomena in the electron cloud and to improve construction and operation characteristics. Experimental studies of electron bombardment are difficult.[1,2] It is therefore fruitful to use numerical methods, **i.e., computer simulation** of magnetron devices with an appropriate statistical formulation of stochastic processes such as electron collisions with electrodes.

Electron bombardment in an amplitron has been evaluated[4] in the adiabatic approximation. In this paper we characterize electron bombardment in magnetrons statistically, performing numerical experiments by means of the giant particle method.[5,6] Processes are simulated in 3 cm magnetrons region with secondary-emission cathodes. The region corresponding to one pair of magnetron resonators is considered.

Let P be one of the parameters characterizing electron bombardment, and let $0 \le x \le 96$ be the dimensionless coordinate along the electrode surface (cathode or anode). The origin of coordinates is chosen so that the maximum rf anode potential is located at $x = 24$. In the simulation the expectation values are found:

$$P(x) \equiv M[P[x]] = \int_{-\infty}^{\infty} P \frac{w(P,\ x)}{w_P(x)}\, dP, \tag{1}$$

where the one-dimensional distribution function

$$w_P(x) = \int_{-\infty}^{\infty} w(P,\ x)\, dP$$

and the distribution function

$$w(P) = \int_0^{96} w(P,\ x)\, dx. \tag{2}$$

The quantity P(x) characterizes the distribution of the parameter P along the electrode, and w(P) the spread in P for the electrode as a whole. In addition, the average parameter value

$$\bar{P} = \int_{-\infty}^{\infty} \int_0^{96} P w(P,\ x)\, dP dx \tag{3}$$

is calculated for the electrode as a whole.

As parameters we take the current density j, thermal losses P_l, the incident electron kinetic energy E_p, the incidence angle θ_p measured from the normal to the electrode surface, the velocity components, their squares, and the electron temperature T_e, i.e., the velocity spread of the incident electrons.[6] Calculations by Eqs. (1)-(3) are performed by averaging simulation results of stationary magnetron results over 8-15 cyclotron periods. The average number of particles in the region selected is 1800-2300. The sample volume, i.e., the number of particles arriving at the electrode in the average time, is 3500-7500 for the cathode and 300-1700 for the anode.

The results of the numerical experiment are given in Figs. 1-7. The curves 1-3 are calculated for cylindrical electrode configurations, and curves 4-6 for planar electrodes. The constant anode potential U_a and the peak rf voltage at the anode U_{st} for curves 1-6 are, respectively (in kV): 1) 15.0, 4.71; 2) 15.0, 0.67; 3) 14.0, 4.71; 4) 25.3, 6.90; 5) 15.9, 6.90; 6) 15.9, 8.68. Curve 2 is calculated for the case when the anode current and the generated power are small, and the other curves for external generation.

2. CATHODE BOMBARDMENT

The nonequilibrium distribution of incident energy $E_p(x)$ at the cathode increases with both the dc U_a and rf

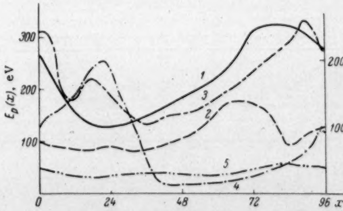

Fig. 1. Energy distribution of incident electrons $E_p(x)$. For curves 1-3 the ordinate axis is on the left, and for 4, 5 on the right.

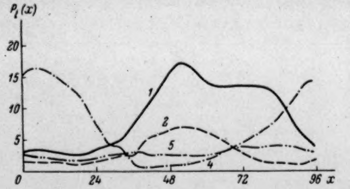

Fig. 2. Distribution of thermal losses $P_l(x)$ (in dimensionless units).

U_{st} potentials (Fig. 1). As seen from Fig. 1, the maximum position of $E_p(x)$ depends on the electrode geometry and on the operational region. The distribution of thermal losses $P_l(x)$ along the cathode (Fig. 2) is also nonequilibrium. The nonequilibrium distribution $P_l(x)$ is enhanced with increasing anode potential U_a and rf potential amplitude U_{st}. The total thermal loss at the cathode in oscillation is 5-8% of the input power, which is in good agreement with experimental data.

Strong space charge close to the cathode reduces the potential significantly. Figure 3 shows the total potential $U_1(x)$ at the first grid close to the cathode (at a distance 0.02 mm from it), which is used in solving the Poisson equation numerically. In the absence of a space charge the total potential in this region is about 300 V. The location of the potential minimum coincides with the maximum position of the current density j of the returning electrons (not shown in the figure).

The electron distribution over incidence angle $w(\theta_p)$ has a noticeable maximum (mode) $\tilde{\theta}_p$ in the negative angle region: $\tilde{\theta}_p \simeq -(0.3\text{-}0.4)\pi$, which indicates the cycloidal nature of electron motion in the immediate neighborhood of the cathode (Fig. 4). The rise of the curves close to $\theta_p \simeq \pi/2$ is due to the same emitted electrons which enter the retarding field and returns to the cathode. For these values the cycloid is restricted to a point and the incidence angle is $\pi/2$. With increasing rf field amplitude the mode position $\tilde{\theta}_p$ is somewhat displaced to the positive side (curves 1 and 2). The average incidence angle $\bar{\theta}_p = -(0.16\text{-}0.23)\pi$, the halfwidth of the curve $\omega(\theta p)$ around the mode $\bar{\theta}_p$, is about $\pi/4$.

The mode $\tilde{E}_p$ of the distribution $w(E_p)$ of incident electron energy is also strongly expressed and located in the low energy region: $\tilde{E}_p \simeq 100\text{-}200$ eV (Fig. 5), with E_p increasing with the constant potential U_a. This indicates that in the region of space-charge limiting a significant number of electrons return to the cathode. The energy of these electrons is of the order of their initial energy, i.e., it is low. For the secondary emission used the most probable initial energy is about 3.5 eV. With increasing constant potential U_a the field is enhanced in the interaction space and the space-charge limiting is reduced, i.e., a small part of the emitted electrons returns to the cathode and E_p increases. The average incidence energy is $\tilde{E}_p \cong 100\text{-}200$ eV, and the halfwidth of the curve $w(E_p)$ is 500-600 eV. The calculated incidence energies are in good agreement with the results of refs. 1 and 4.

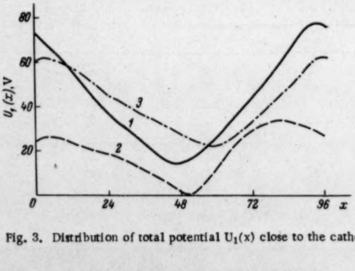

Fig. 3. Distribution of total potential $U_1(x)$ close to the cathode.

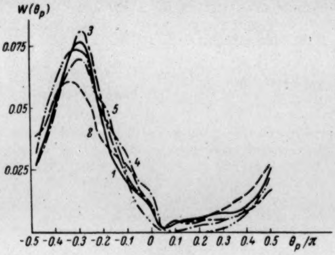

Fig. 4. Electron distribution in the incidence angle θ_p.

For the platinum emitter used the secondary emission coefficient $\sigma(E_p)$ becomes larger than unity at $E_p > E_{p1} \simeq 70$ eV and reaches a maximum $\sigma_m = 1.8$ at $E_p = E_{pm}$ 850 eV. The secondary emission coefficient $\sigma(\tilde{E}_p)$ at $\tilde{E}_p = 100\text{-}200$ eV is located at the rising branch of the curve $\sigma(E_p)$ close to $\sigma(E_{p1}) = 1$. In the regions calculated the average value is $\bar{\sigma} \simeq 1.00\text{-}1.35$. The behavior of the curve $\sigma(E_p)$ in the region $E_{p1} \leq E_p \leq E_{pm}$ requires most careful experimental investigation, as it determines the complete space charge in the interaction region and is related to the device characteristics.

The electron temperature of the current that bombards the cathode is $(0.6\text{-}1.5) \cdot 10^6$ deg K.

3. ANODE BOMBARDMENT

In the region considered the anode current I_a is less than the current I_c of electrons returning to the cathode. This is seen from the quantity $\bar{\sigma}$; for secondary emission cathodes we have $\bar{\sigma} \simeq 1 + I_a/I_c$ by the conservation of the average charge. The energy and incidence angle of the electrons hitting the anode are determined by the cycloidal

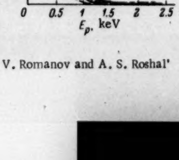

Fig. 5. Electron distribution in the incidence energy E_p.

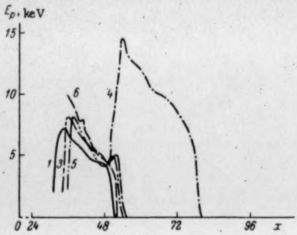

Fig. 6. Distribution of electron incidence energy $E_p(x)$.

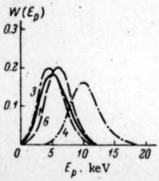

Fig. 7. Electron distribution in the incidence energy E_p.

motion in the immediate neighborhood of the anode and therefore depend strongly on the constant and rf voltages. Thus, for example, for the regions 4-6 (Fig. 4) the most probable incidence angle $\tilde{\theta}_p$ is, respectively, 0.1 π, 0.14 π, and π/4, and the halfwidth of the density distribution of $w(\theta_p) \simeq 0.08\pi$, 0.12π, and 0.20π. In the anode region (in the "spoke") the electrons regroup, with the degree of regrouping also dependent on the rf potential amplitude.

The nonequilibrium **energy distribution $E_p(x)$ enhanced** with increasing constant anode potential U_a **and with the rf** potential amplitude U_{st} (Fig. 6). The nonequilibrium nature of the distribution of thermal losses $P_l(x)$ along the anode is considerably stronger than at the cathode due to the small area the electrons hit with a large velocity spread. The total power of anode **thermal losses is 35% of** the input power, exceeding cathode losses by a factor of 4-7. The most probable electron incidence energy at the anode is $\tilde{E}_p \simeq \bar{E}_p \simeq 5$-11 keV (Fig. 7), which is 30-40% of the potential energy eU_a. The halfwidth of the distribution $w(E_p)$ is about 4.5-6 keV.

The electron temperature of the current hitting the anode is $(2-4)\cdot 10^6$ deg K.

The results of the numerical experiment provide important information on the distribution of thermal losses, energy, velocity and angle of electron incidence along the cathode and anode, and also on their dependence on the electrode geometry and on the operational region. Since the difficulties in carrying out similar physical experiments are obvious, numerical simulation is a very useful method of reproducing "ideal," i.e., unperturbed, physical observation. The data are useful in evaluating electrode design, cathode emission characteristics, and cooling requirements.

Zh. Tekh. Fiz., 44, 1969-1972 (September 1974)

Samples of stainless steel and M-1 copper are irradiated with 55 nsec pulses of 0.8 MeV electrons. The beam current is $\leqslant 25$ kA. For current densities appreciably larger than 1 kA/cm^2 a shock wave is produced in the sample, and splitting is observed on the rear surface. For current densities ~ 1 kA/cm^2 microcavities $\sim 10^{-4}$ cm across are observed in the samples. In the copper samples these are in the form of elongated chains or filaments. The distance between filaments is $\sim 10^{-2}$ cm. Possible causes of the observed phenomena are discussed.

High-current beams of relativistic electrons with a total energy $\leqslant 10^5$ J and intensities up to 10^9–10^{11} W/cm^2 incident on a solid surface for times $< 10^{-7}$ sec should produce pronounced structural changes. The effects of pure radiation damage to the crystal lattice by the beam electrons described in refs. 1 and 2 appear to be significantly masked by the consequences of strong heating and the production of high pressures in the material.[3] The pressure in the irradiated material after termination of energy transfer from the beam to the crystal lattice is determined by the heating and the elastic properties of the material and by the depth and uniformity of the penetration of the electrons. For a high enough pressure shock waves can develop in the sample, as observed by Zelenskii et al.,[4] in addition to elastic waves.

It has been shown in a number of papers[5–8] that the pressure and the directly related depth of penetration of the beam electrons, determined by the form and amplitude of the compression wave, are in satisfactory agreement with the values calculated by the single-particle theory of the interaction of electrons with matter. Honnold et al.[9] have obtained the unexpected result that a torsional wave is produced by the uniform irradiation of a sample. Apparently the torsion of the sample is related to the nonuniform penetration of the beam due to collective effects. The possibility of collective processes at large current density is confirmed by the observation of the self-focusing of a beam in a dielectric and the anomalous damage to ionic crystals.[10,11] One method of studying the way a beam penetrates matter is to investigate the uniformity and depth of structural changes in the material irradiated by the beam. In the work described below we present the first results of such studies of samples of stainless steel and copper.

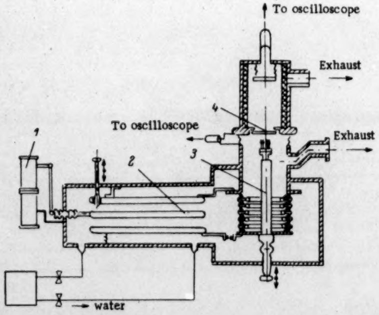

Fig. 1. 1) Voltage pulse generator; 2) shaping line; 3) cathode holder; 4) anode.

The experiments were performed at the Neptune accelerator,[12] shown schematically in Fig. 1. The double shaping line of the accelerator is charged from the voltage pulse generator for 0.5 μsec to $V_0 \approx 0.8$ Mv. During charging a prepulse of $0.15\ V_0$ appears at the cathode of the accelerator. In a number of experiments the size of the prepulse has been substantially reduced by using a special sparkgap.[12] The main voltage pulse with height $\leqslant 0.8$ MV and length 55 nsec is applied to a disk plasma cathode 4 cm in diameter. A plasma sheath is produced at the cathode by a discharge over the surface of epoxy resin filling holes 1.2 mm in diameter and 2 mm deep in the metal disk. Up to 200 holes are drilled in the cathode surface. In the matching mode the beam current is 25 kA. The distribution of current density at the exit foil, averaged over the time of a pulse and over an area of ~ 4 mm^2, is determined by the luminescence of scintillators and the blackening of glass. Under typical conditions it is nearly uniform over a circle 5 cm in diameter. As the pressure of the neutral gas in the accelerator gap is increased to $\sim 3 \cdot 10^{-4}$ torr pronounced inhomogeneities ≤ 5 mm in diameter appear in the current density. These are recorded by the luminescence of a scintillator and are typically ≤ 5 mm in diameter. The inhomogeneities are explained by the appearance of a plasma in the accelerator gap as a result of the prepulse. In this case, as is shown in ref. 13, the beam current density is increased appreciably.

This feature permits the irradiation of samples by beams which are either uniform or nonuniform over the cross section. A disk-shaped sample 1.2 mm thick and 120 mm in diameter is used as the anode of the accelerator. In a number of cases the sample is placed behind a titanium foil 50 μ thick to eliminate the possibility of the residual gas discharge in the accelerator gap acting on the surface of the target. The targets are made of 1Kh18N9T stainless steel and M-1 copper. The surface and volume of the samples are examined before and after irradiation using metallographic and profilometric analyses and a scanning electron microscope having a spatial resolution no better than $2 \cdot 10^{-5}$ cm.

A nonuniform beam causes significant metal failure including splitting on the rear surface of the disk. Figure 2 shows a microsection through one such region of failure on a stainless steel disk. A layer of metal 200 μ thick is peeled off the rear surface. Part of the layer, about 3 mm^2 in area, is completely separated from the base material, as is confirmed by the character of the

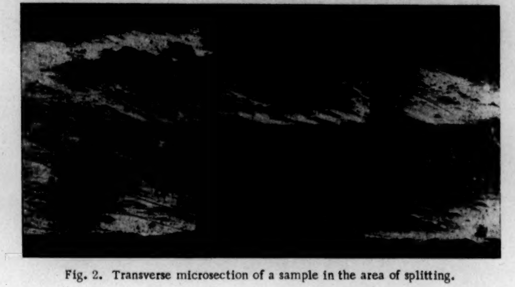

Fig. 2. Transverse microsection of a sample in the area of splitting.

surface where the splitting occurs. Close to the splitting region there are many cavities typically ~ 40 μ in size stretched out parallel to the plane of cleavage. Similar failures are recorded on the copper samples. After a hundred irradiations by a beam having a uniform current density a transverse section of a stainless steel target shows microcavities $1\text{-}2\cdot10^{-4}$ cm long and $3\cdot10^{-5}$ cm wide. The microcavities are distributed at random over the section. This effect is studied in more detail on the copper disk. Figure 3 shows a transverse section of a copper sample after five irradiations. The microcavities form filaments drawn out along the direction of propagation of the beam with typical widths of 10^{-4} cm. The average angle between a filament and the axis of the beam is a few degrees, and this prevents the observation of longer filaments. The filaments are uniformly distributed both over the cross section of the beam and over its depth, and are separated from one another by distances of a few tens to a few hundreds of microns. A rough estimate on one exposure indicates ~ 10^5 filaments in the target.

The splitting observed in these experiments is explained by the production of shock waves in the metal as a result of heating by the electron beam.[4] The appearance of the filaments is harder to understand. We note that microcavities are observed up to a depth four times the mean free path of 0.8 MeV electrons. Evidently the formation of microcavities cannot be explained by the characteristics of the metal structure.

It is possible that the formation of filaments is related to the small-scale inhomogeneities of the beam current density in the accelerator gap, or to the separation of the beam into individual filaments in the sample under study.

Fig. 3. Microcavities in a copper sample. Typical width of a cavity is ~ 10^{-4} cm.

In conclusion the authors thank E. K. Zavoiskii and L. I. Rudakov for helpful discussions, and E. S. Trekhov and E. D. Titov for help in studying the samples.

Explosion driven magnetic generator with a matched inductive load

L. S. Gerasimov

(Submitted July 10, 1973; resubmitted January 9, 1974)
Zh. Tekh. Fiz., 44, 1973-1980 (September 1974)

The conditions for maximum energy transfer and peak power from an explosion-driven magnetic generator (EMG) acting on an inductive load are considered for three circuits: transformerless, with transformer outside the explosion chamber, and transformer inside the explosion chamber. Optimum regimes are described. The parameter ranges are determined for which one of the circuits is preferable to the other two.

Explosion-driven magnetic generators (EMG) are gaining wider application in experimental physics as a means of obtaining powerful current pulses. It is well-known[1] that such pulses can also be obtained from condenser banks; however, the specific energy obtained from an EMG is greater by more than an order of magnitude. Clearly, a laboratory device for the conversion of the energy of an explosion into electromagnetic energy (explosion chamber and necessary equipment) is only justified when the energy supplied to the load is considerably greater than that which can be stored in a condenser bank. Often (for example, in plasma experiments), the more important property is not the energy, but the power of the electromagnetic pulse.[2] In any case, the EMG or condenser bank must be matched to the load to ensure optimum results.

TRANSFORMERLESS CIRCUITS

In order to simplify the analysis, we neglect the resistance of the condenser bank, generator, and connectors. We then obtain the electric circuit shown in Fig. 1a. We denote the working inductance of the generator by

$$L(t)=L_0 \text{ for } t=0,$$
$$L(t)=0 \text{ for } t=T$$

where T is the cycle length, the inductance of the connection between generator and load (output from the chamber) by L_{out}, the bank inductance by L_c, and the stored energy by E_0. If the magnetic field is trapped (dotted line in Fig. 1a) when the current is a maximum (zero bank voltage), then

$$E_0=\frac{1}{2}(L_0+L_b+L_{out}+L_L)\,i_0^2,$$

where $i_0 = i(0)$ is the feed current to the generator and the energy delivered to the load is

$$E_{\text{н.}}=E_0\left(\frac{L_0+L_{out}+L_L}{L_{out}+L_L}\right)^2\frac{L_L}{L_0+L_b+L_{out}+L_L}.$$

a) Condition for maximum energy transfer. We can estimate the efficiency of the system as

$$\frac{E_L}{E_0}=\frac{\left(1+\frac{1}{l_{out}+l_L}\right)^2}{1+\frac{1+l_b+l_{out}}{l_L}}, \tag{1}$$

where, for convenience, the dimensionless inductances

$$l_b=\frac{L_b}{L_0},\ l_{out}=\frac{L_{out}}{L_0},\ l_L=\frac{L_L}{L_0}.$$

are used.

In order to have $E_L/E_0 \geq 1.5$ it is necessary that

$$l_b \ll 1,\ l_{out} \ll 1,\ l_L \leqslant 1.$$

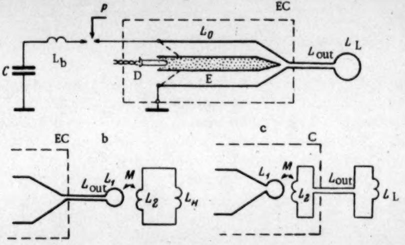

Fig. 1. Electric circuits for an explosion-driven magnetic generator with an inductive load. a) Transformerless; b) with transformer outside explosion chamber; c) with transformer inside explosion chamber; C) condenser bank; L_b) inductance of connector between bank and generator; P) spark gap switch; EC) explosion chamber; E) explosive; D) detonator; L_{out}) output inductance of EC; L_L) load inductance; L_1) inductance of transformer primary; L_2) inductance of secondary; M) mutual inductance of windings.

For example, for $l_b = l_{out} = l_L = 0.2$, $E_L/E_0 \simeq 1.5$, and for $l_b = l_{out} = l_L = 0.1$, $E_L/E_0 \simeq 2.8$. If L_L is greater than L_b and L_{out} by an order of magnitude or more, then

$$\frac{E_L}{E_0}\cong 1+\frac{1}{l_L},$$

i.e., the efficiency of energy transfer is limited by the value of l_L. Evidently, the output from the explosion chamber should be such that its inductance is two to three times less than the load inductance (further reduction has little effect). Thus, for $l_b = l_L = 0.1$ and $l_{out} = 0.05$, $E_L/E_0 = 4.7$ (as opposed to 2.8 in the second example). It is desirable to have a value $l_b = 0.2$-0.1 for the bank inductance (further reduction also has no effect). If L_L is reduced with fixed L_b and L_{out} then E_L/E_0 will begin to grow at first and then fall. The optimum value of L_{out} depends on L_b and L_{out} in a complicated manner; however, in the most interesting practical case, $l_b \ll 1$ and $l_{out} \ll 1$, we may assume that $(l_L)_{opt} = l_{out}$ to a sufficient degree of accuracy. In this case the efficiency is a maximum, given by

$$\frac{E_L}{E_0}=\frac{\left(1+\frac{1}{2l}\right)^2}{2+\frac{1}{l_{out}}},$$

which is shown in Fig. 2 (curve 1). Thus, the limiting

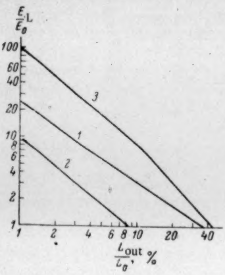

Fig. 2. Generator efficiency E_L/E_0 as a function of L_{out}/L_0. 1) Transformerless circuit under optimum conditions ($L_b/L_0 \ll 1$, $L_{out}/L_0 \ll 1$, $L_L/L_0 = L_{out}/L_0$); 2) apparatus with optimized transformer outside the explosion chamber with $k = 0.9$ and $L_b/L_0 = 0$; 3) apparatus with transformer inside the explosion chamber with $k = 0.9$, $L_b/L_0 = 0$, $L_1/L_{out} = 1$, $L_L/L_0 = 1$.

values of E_L/E_0 can be attained for $l_{out} \ll 1$ and $l_L \ll 1$.

b) Condition for maximum generated power. The energy delivered to the load up to time t is

$$E_L(t) = E_0\left[\frac{L_0 + L_{out} + L_L}{L(t) + L_{out} + L_L}\right]^2 \frac{L_L}{L_0 + L_b + L_{out} + L_L}.$$

Assuming a linear variation of the inductance of the generator, we find that the power $P = dE_L/dt$ is a maximum at the end of the cycle (for $t = T$), being equal to

$$P = \frac{2E_0(L_0 + L_{out} + L_L)^2 L_0 L_L}{(L_0 + L_b + L_{out} + L_L)(L_{out} + L_L)^3 T}.$$

We estimate the efficiency of a system with an EMG by the ratio of P to the limiting power which is delivered to an optimum load when it is directly connected to the condenser bank. In this case the power is

$$P_1 = L_L i \frac{di}{dt},$$

where

$$i = i_m \sin\omega_0 t,\quad i_m^2 = \frac{2E_0}{L_b + L_L},\quad \omega_0^2 = \frac{1}{(L_b + L_L)C}.$$

Expressing ω_0 as a function of the energy[1] and charging voltage, u_0, we have

$$\omega_0 = \frac{u_0}{\sqrt{2(L_b + L_L)E_0}},$$

and the peak power amplitude is

$$P_{1m} = \frac{u_0\sqrt{E_0}L_L}{\sqrt{2}(L_b + L_L)^{3/2}}.$$

Taking the optimum value $(L_L)_{opt.} = 2L_0$, we obtain the limiting power of the bank,

$$P_b = 0.272u_0\sqrt{\frac{E_0}{L_b}}$$

and the power efficiency of the EMG is

$$\frac{P}{P_b} = 7.36\frac{\sqrt{L_0E_0}}{u_0T}\frac{\left(1 + \frac{1}{l_{out} + l_L}\right)^2\sqrt{l_b}}{\left(1 + \frac{1 + l_b + l_{out}}{l_L}\right)(l_{out} + l_L)}. \qquad (2)$$

It is clear that P/P_b depends on two factors: One is determined by the basic parameters of the bank (u_0, E_0) and the generator (L_0, T) and the other by the parasitic parameters and the load inductance. For condenser banks with $E_0 = 10^4$–10^6 J and $u_0 = 5\cdot10^3$–$5\cdot10^4$ V and generators with $L_0 = 10^{-4}$–$5\cdot10^{-7}$ H and $T = 2\cdot10^{-5}$–10^{-4} sec, the first factor lies between 0.1 and 736. In order that the second factor be greater than unity it is necessary [as for Eq. (1)] that the conditions

$$l_b \ll 1,\ l_{out} \ll 1,\ l_L \leqslant 1$$

hold.

Thus, as an example, for $l_b = l_{out} = l_L = 0.2$ we obtain 1.7 and for $l_b = l_{out} = l_L = 0.1$ we obtain 4.4. For fixed l_b and l_{out}, as l_L increases this factor at first rises, but later falls. The optimum value of l_L for $l_b \ll 1$ and $l_{out} \ll 1$ is equal to $(l_L)_{opt} \simeq l_{out}/2$ and corresponds to a maximum of the factor equal to

$$\frac{4}{27}\frac{\sqrt{l_b}}{l_{out}^2}.$$

The limiting power, like the limiting energy, is obtained with $l_{out} \ll 1$ and $l_L \ll 1$. Both these conditions are troublesome as the first is difficult to ensure in practice and the second means that the dimensions of the generator must be significantly larger than those of the load coil.

In several cases it is possible to avoid these limitations by connecting the load through a pulse transformer. Then two approaches can be used: placing the transformer outside (Fig. 1b) and inside (Fig. 1c) the explosion chamber. With the first variant it is possible to relax the limitations on the value of the load inductance since L_{out} does not change. In the second case, the generator coil in which the magnetic flux is displaced serves as the first winding of a transformer; thus, the inductance of the connectors to the primary can be reduced to zero. The output of the chamber is through the secondary winding. The effect of L_b on the efficiency of the system is greatly reduced. In this variant high efficiencies, E_L/E_0 and P/P_b, can be obtained with reduced demands on L_{out} and L_L. However, the transformer will be destroyed in each experiment.

ARRANGEMENT WITH A TRANSFORMER OUTSIDE THE EXPLOSION CHAMBER

We now consider the first variant (Fig. 1b). Using the known solution[1] for this circuit it is easy to show that for flux trapping at the current maximum we have

$$i_L = \frac{k\sqrt{L_1L_2}}{L_2 + L_L}\frac{L_0 + L_{out} + L_1\left(1 - k^2\frac{L_2}{L_2 + L_L}\right)}{L(t) + L_{out} + L_1\left(1 - k^2\frac{L_2}{L_2 + L_L}\right)} \times\sqrt{\frac{2E_0}{L_0 + L_b + L_{out} + L_1\left(1 + 3k^2\frac{L_2}{L_2 + L_L}\right)}}, \qquad (3)$$

where $k \leq 1$ is the coupling coefficient of the transformer winding.

a) Condition for maximum energy. In Eq. (3) we set L(t) = 0, and write it as a product of three factors:

$$i_{\mathrm{L}} = k\sqrt{\frac{2E_0}{L_{\mathrm{L}}}}\,\frac{\sqrt{\frac{L_1}{L_{\mathrm{out}}}\frac{L_2}{L_{\mathrm{L}}}}}{\left(1+\frac{L_1}{L_{\mathrm{out}}}\right)\left(1+\frac{L_2}{L_{\mathrm{L}}}\right)-k^2\frac{L_1}{L_{\mathrm{out}}}\frac{L_2}{L_{\mathrm{L}}}}$$

$$\times\frac{1+\frac{L_0}{L_{\mathrm{out}}}+\frac{L_1}{L_{\mathrm{out}}}\left(1-k^2\frac{\frac{L_2}{L_{\mathrm{L}}}}{1+\frac{L_2}{L_{\mathrm{L}}}}\right)}{\sqrt{1+\frac{L_0}{L_{\mathrm{out}}}+\frac{L_{\mathrm{b}}}{L_{\mathrm{out}}}+\frac{L_1}{L_{\mathrm{out}}}\left(1+3k^2\frac{\frac{L_2}{L_{\mathrm{L}}}}{1+\frac{L_2}{L_{\mathrm{L}}}}\right)}}.$$

The first of these factors is independent of L_1 and L_2; the third depends on them weakly. Actually, for efficient operation it is necessary that $L_0/L_{\mathrm{out}} \geq 10$; thus, for variation of L_1/L_{out} and L_2/L_{L} in the range 1 to 3 (which corresponds to the maximum energy in the load, as will be shown below) the third factor changes insignificantly. Therefore, we treat the L_1 and L_2 dependence of the second factor only:

$$f(L_1, L_2) = \frac{\sqrt{\frac{L_1}{L_{\mathrm{out}}}\frac{L_2}{L_{\mathrm{L}}}}}{\left(1+\frac{L_1}{L_{\mathrm{out}}}\right)\left(1+\frac{L_2}{L_{\mathrm{L}}}\right)-k^2\frac{L_1}{L_{\mathrm{out}}}\frac{L_2}{L_{\mathrm{L}}}},$$

For arbitrary fixed L_2 = const the optimum values are

$$\left(\frac{L_1}{L_{\mathrm{out}}}\right)_{\mathrm{opt}} = \frac{1}{1-k^2\frac{\frac{L_2}{L_{\mathrm{L}}}}{1+\frac{L_2}{L_{\mathrm{L}}}}}, \tag{4}$$

and the corresponding maximum is equal to

$$f_1 = \frac{1}{2\left(1+\frac{L_2}{L_{\mathrm{L}}}\right)}\sqrt{\frac{L_2/L_{\mathrm{L}}}{1-k^2\frac{L_2/L_{\mathrm{L}}}{1+L_2/L_{\mathrm{L}}}}}. \tag{5}$$

For arbitrary L_1 = const the optimum for L_2 is given by

$$\left(\frac{L_2}{L_{\mathrm{L}}}\right)_{\mathrm{opt}} = \frac{1}{1-k^2\frac{L_1/L_{\mathrm{out}}}{1+L_1/L_{\mathrm{b}}}} \tag{6}$$

and the corresponding maximum is

$$f_2 = \frac{1}{2\left(1+\frac{L_1}{L_{\mathrm{out}}}\right)}\sqrt{\frac{L_1/L_{\mathrm{out}}}{1-k^2\frac{L_1/L_{\mathrm{out}}}{1+L_1/L_{\mathrm{out}}}}}. \tag{7}$$

Equations (4) and (5) are the same functions of L_2/L_{L} as (5) and (6) are of L_1/L_{out}. These functions are shown in Fig. 3. It is clear that this function has a mildly sloping maximum: When the winding inductance changes from 0.5 to 5 times its optimum, i_{L} is reduced from its maximum by less than 25%. The global maximum, f_{max}, corresponding to simultaneous optimization for both windings, is reached when

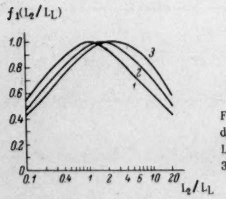

Fig. 3. The function $f_1(L_2/L_L)$, which defines the load current for optimum L_1 and arbitrary L_2. k: 1) 0.4; 2) 0.8; 3) 0.9.

$$\frac{L_1}{L_{\mathrm{out}}} = \frac{L_2}{L_{\mathrm{L}}} = \frac{1}{\sqrt{1-k^2}}.$$

being

$$f_{\mathrm{max}} = \frac{1}{2}\,\frac{1}{1+\sqrt{1-k^2}}.$$

For k = 0.95, $L_1/L_{\mathrm{out}} = L_2/L_{\mathrm{L}} = 3.16$, while for k = 0.4, $L_1/L_{\mathrm{out}} = L_2/L_{\mathrm{L}} = 1.1$. Thus, it is almost always true that $1 < L_1/L_{\mathrm{out}} < 3$. In view of the last two expressions we find

$$\left(\frac{E_{\mathrm{L}}}{E_0}\right)_{\mathrm{max}} = \frac{1}{4}\left(\frac{k}{1+\sqrt{1-k^2}}\right)^2\frac{\left(2+\frac{1}{l_{\mathrm{out}}}\right)^2}{\frac{1}{l_{\mathrm{out}}}+\frac{l_{\mathrm{b}}}{l_{\mathrm{out}}}+\frac{4}{\sqrt{1-k^2}}-2}. \tag{8}$$

From this it is clear that use of a transformer actually removes the limitation on l_{L}. The efficiency of the system does not depend on the load if both transformers are optimized. In this case, however, the efficiency depends strongly on the coupling coefficient. A high efficiency of energy transfer to the load is possible only for very small values of l_{out} (for k = 0.9 and $l_{\mathrm{b}} = 0$, $E_{\mathrm{L}}/E_0 \geq 1$ if $l_{\mathrm{out}} \leq 8\%$). The dependence of $(E_{\mathrm{L}}/E_0)_{\mathrm{max}}$ on l_{out} for k = 0.9 and $l_{\mathrm{b}} = 0$ is shown in Fig. 2 (curve 2). A comparison of this variant with the transformerless circuit can be carried out as follows. We equate the right-hand sides of Eqs. (1) and (8) and determine l_{L} from this equation. For $(E_{\mathrm{L}}/E_0)_{\mathrm{max}} > 1$, two values of l_{L} (see Table 1) correspond to each value of l_{out}. If l_{L} lies between these two values, then for the corresponding value of l_{out} the transformerless circuit has the greater efficiency. For l_{L} outside this region the opposite holds. Thus, the table indicates the region of l_{out} and l_{L} over which the use of a circuit with a transformer in the first variant is reasonable.

The ratio of the number of turns (W_1, W_2) in the windings of an optimized transformer is found from the ratio $L_2/L_1 = L_{\mathrm{L}}/L_{\mathrm{out}}$. For $k \simeq 1$, we have

$$\frac{W_2}{W_1} \simeq \sqrt{\frac{L_2}{L_1}} = \frac{L_{\mathrm{L}}}{L_{\mathrm{out}}}$$

b) Condition for maximum power. Using a linear dependence of generator inductance on time we find from Eq. (3) that the power $P = L_{\mathrm{L}} i_{\mathrm{L}} di_{\mathrm{L}}/dt$ is maximum for t = T and L(t) = 0. Dividing this quantity by P_{b}, we have

$$\frac{P}{P_{\mathrm{b}}} = 7.36\,\frac{\sqrt{L_0 E_0}}{u_0 T}k^2\sqrt{\frac{L_{\mathrm{b}}}{L_0}}\,\frac{L_0}{L_{\mathrm{out}}}\,\frac{\frac{L_1}{L_{\mathrm{out}}}\frac{L_2}{L_{\mathrm{L}}}\left(1+\frac{L_2}{L_{\mathrm{L}}}\right)}{\left[\left(1+\frac{L_1}{L_{\mathrm{out}}}\right)\left(1+\frac{L_2}{L_{\mathrm{L}}}\right)-k^2\frac{L_1}{L_{\mathrm{out}}}\frac{L_2}{L_{\mathrm{L}}}\right]^3}$$

$$\times\frac{\left[1+\frac{L_0}{L_{\mathrm{out}}}+\frac{L_1}{L_{\mathrm{out}}}\left(1-k^2\frac{L_2/L_{\mathrm{L}}}{1+L_2/L_{\mathrm{L}}}\right)\right]^2}{1+\frac{L_0}{L_{\mathrm{out}}}+\frac{L_{\mathrm{b}}}{L_{\mathrm{out}}}+\frac{L_1}{L_{\mathrm{out}}}\left(1+3k^2\frac{L_2/L_{\mathrm{L}}}{1+L_2/L_{\mathrm{L}}}\right)}.$$

TABLE 1. Values of l_L for Equal Efficiencies, E_L/E_0, of Transformer and Transformerless EMG Circuits (for k = 0.9 and l_b = 0 in both circuits).

	l_{out}							
	0.01	0.02	0.03	0.04	0.05	0.06	0.07	0.08
l_L 1	0.096	0.220	0.405	0.680	1.11	1.97	4.20	15.1
l_L 2	0.0012	0.0023	0.0033	0.0043	0.0050	0.0059	0.0069	0.0075
E_{out}/E_0	9.70	4.75	3.06	2.26	1.78	1.45	1.23	1.06

Only the second term depends significantly on the parameters L_1 and L_2. Optimizing this term simultaneously for both transformer windings we find

$$\left(\frac{L_1}{L_{out}}\right)_{opt}=\frac{1}{2\sqrt{1-k^2}},\quad \left(\frac{L_2}{L_L}\right)_{opt}=\frac{1}{\sqrt{1-k^2}},$$

for which

$$k^2\sqrt{\frac{L_b}{L_0}\frac{L_0}{L_{out}}}\frac{\frac{L_1}{L_{out}}\frac{L_2}{L_L}\left(1+\frac{L_2}{L_L}\right)}{\left[\left(1+\frac{L_1}{L_{out}}\right)\left(1+\frac{L_2}{L_L}\right)-k^2\frac{L_1}{L_{out}}\frac{L_2}{L_L}\right]^3}=\frac{4}{27}\frac{\sqrt{l_b}}{l_{out}}\left(\frac{k}{1+\sqrt{1-k^2}}\right)^2.$$

We note that the optimum values of the inductance of the secondary winding obtained from the conditions for maximum energy and maximum power agree and that for the primary winding they differ only by a factor of 2. It then follows that by choosing some average value for L_1/L_{out} it is possible to ensure both conditions in practice, since the maxima of the power and energy curves are weakly defined.

ARRANGEMENT WITH A TRANSFORMER INSIDE THE EXPLOSION CHAMBER

We define the load current using Eq. (3), setting L(t) = 0 and L_{out} = 0, and replacing $(L_L + L_{out})$ by L_L to obtain

$$i_L=k\sqrt{\frac{2E_0}{L_L}}\frac{\sqrt{\frac{L_{out}}{L_1}\frac{L_2}{L_L}}}{1+(1-k^2)\frac{L_2}{L_L}+\frac{L_{out}}{L_L}}\frac{\frac{L_0}{L_{out}}+\frac{L_1}{L_{out}}\left(1-k^2\frac{L_2/L_L}{1+L_2/L_L+L_{out}/L_L}\right)}{\sqrt{\frac{L_0}{L_{out}}+\frac{L_b}{L_{out}}\frac{L_1}{L_{out}}\left(1+3k^2\frac{L_2/L_L}{1+L_2/L_L+L_{out}/L_L}\right)}}.$$

As before, we only take account of the dependence of the second factor on L_1/L_{out} and L_2/L_L; we note that i_L increases without bound as L_1/L_{out} decreases. Thus, in using a pulse transformer in a self-destructive assembly it is necessary to obtain the lowest possible values of L_1 provided this does not lead to a reduction in the coupling coefficient. The maximum efficiency of energy transfer obtains when

$$\left(\frac{L_2}{L_L}\right)_{opt}=\frac{1+\frac{L_{out}}{L_L}}{1-k^2} \tag{9}$$

and is equal to

$$\left(\frac{E_L}{E_0}\right)_{max}=\frac{1}{4}\frac{k^2}{1-k^2}\frac{\left[\frac{L_0}{L_{out}}+\frac{L_1}{L_{out}}\left(1-\frac{k^2}{2-k^2}\right)\right]^2}{\frac{L_1}{L_{out}}\left(1+\frac{L_{out}/L_0}{L_L/L_0}\right)\left[\frac{L_0}{L_{out}}+\frac{L_b}{L_{out}}+\frac{L_1}{L_{out}}\left(1+\frac{3k^2}{2-k^2}\right)\right]}.$$

The first variant depends on k, L_{out}/L_0, L_b/L_0 and on L_1/L_{out} and L_L/L_0. We take k = 0.9, L_b/L_0 = 0, L_1/L_{out} = 1, and L_L/L_0 = 1. Then

$$\left(\frac{E_L}{E_0}\right)_{max}=1.06\frac{\left(\frac{L_0}{L}+0.32\right)^2}{\left(1+\frac{L_{out}}{L_0}\right)\left(\frac{L_0}{L_{out}}+3.04\right)}.$$

This relation is shown in Fig. 2 (curve 3). It is clear that this circuit has an energy-transfer efficiency which exceeds that of the variant with a transformer outside the chamber by an order of magnitude and that of the transformerless variant by two to five times.

The power efficiency of this system,

$$\frac{P}{P_b}=7.36\frac{\sqrt{L_0E_0}}{u_0T}k^2\sqrt{\frac{L_b}{L_0}\frac{L_0}{L_{out}}}\frac{\frac{L_2}{L_L}\left(1+\frac{L_{out}}{L_L}+\frac{L_2}{L_L}\right)}{\left(\frac{L_1}{L_{out}}\right)^2\left[1+\frac{L_{out}}{L_L}+(1-k^2)\frac{L_2}{L_L}\right]^3}$$

$$\times\frac{\left[\frac{L_0}{L_{out}}+\frac{L_1}{L_{out}}\left(1-k^2\frac{L_2/L_L}{1+L_{out}/L_L+L_2/L_L}\right)\right]^2}{\frac{L_0}{L_{out}}+\frac{L_b}{L_{out}}+\frac{L_1}{L_{out}}\left(1+3k^2\frac{L_2/L_L}{1+L_{out}/L_L+L_2/L_L}\right)}$$

increases without bound as L_1/L_{out} decreases (as does the energy efficiency). The optimum value for L_2/L_L,

$$\left(\frac{L_2}{L_L}\right)_{opt}=\frac{1+\frac{L_{out}}{L_L}}{1-k^2}k^2\left(1+\sqrt{1+\frac{1-k^2}{k^4}}\right)$$

differs somewhat from the corresponding condition, Eq. (9), for the maximum energy. For k = 0.7-0.9 this difference is not more than 1.75 times bigger. Thus even in this case, it is possible to choose a regime which is simultaneously near the optimum for both power and energy.

CONCLUSIONS

1. The energy transferred to an inductive load from an explosion-driven magnetic generator without a transformer can exceed the energy of the condenser bank by several times only when the inductance of the bank, the chamber output connection, and the load are considerably less than that of the generator. Thus for transfer of three times the energy to the load it is necessary that these inductances not exceed 10% of the generator inductance.

2. An arrangement with a transformer outside the explosion chamber will transfer more energy (compared to a transformerless circuit) to a load only when the out-

put inductance does not exceed 8% of the generator inductance and the load inductance lies outside a given range (see Table 1). The coupling coefficient of the windings must be near unity and the inductances of the windings must not differ from the optimum by more than two times.

3. An arrangement with a transformer inside the explosion chamber has an energy transfer efficiency which exceeds that of the arrangement with a transformer outside the chamber by an order of magnitude and exceeds that of an optimum transformerless circuit by two to five times. In this case the transformer primary must have as low an inductance as possible and there is an optimum inductance for the secondary.

4. The power efficiency of an EMG is defined in terms of the basic parameters of the bank (E_0, u_0) and generator (L_0, T) and also by the parasitic circuit parameters.

5. The conditions for optimization of the circuit with respect to power and energy differ for the three cases by more than a factor of 2. The power efficiency depends significantly more on L_b than does the energy efficiency.

The author is grateful to A. E. Voitenko and E. P. Matochkin for useful comments.

Impurities and crystal dimensions in zone refining

V. G. Glebovskii and B. M. Shipilevskii

(Submitted September 18, 1973; resubmitted January 21, 1974)
Zh. Tekh. Fiz., 44, 1981-1989 (September 1974)

Equations describing the radius of a growing crystal and the impurity concentration in the liquid zone are derived and solved for the first pass in zone refining. The results are used to determine the characteristic distributions of relatively volatile and nonvolatile impurities in the crystal. The limiting radius is found for crystals of several elements over a broad range of crystallization rates. Experimental data which support the calculated results are reported.

Vacuum refining is one of the most promising methods for growing especially pure metal single crystals. A fundamental feature of this method is that the recrystallization is accompanied by rapid evaporation of impurities and the host material from the surface of the liquid zone as well as by a redistribution of the components at the crystal–liquid interface. This evaporation introduces a serious difficulty in the calculations, but if we assume the vapor pressure of the host to be negligible we can solve the problem rigorously for an arbitrary number of zone passes.[1] This simplification is justified at high crystallization rates; at low and intermediate rates ($1\text{-}10^{-1}$ mm · min^{-1}) there is an appreciable depletion of the amount of molten host component so that the radius of the growing crystal is smaller than that of the original sample. In this work we evaluate the influence of these factors on the impurity distribution after a single pass. This problem has been treated in ref. 2, but there the linear approximation is used for the functional dependence of the radius of the growing crystal on the distance, and this approximation is too crude. Also, the steady-state impurity concentration is calculated on the basis of the unjustified assertion that the dimensions of the growing crystal and the concentrations of each impurity in the melt reach steady-state values simultaneously. The changes in the impurity concentration in the zone due to changes in both the amount of impurity and the amount of host material are neglected altogether.[2]

To obtain kinetic equations for the mass balance of the crystal–liquid system in vacuum we start from an obvious equation for the total differential of the concentration of impurity i in the zone:

$$dC_i = \sum_k \frac{\partial C_i}{\partial N_k} dN_k, \tag{1}$$

where C_i is the concentration of impurity i in the liquid zone (atomic fraction), and N_k is the number of gram-atoms (or moles) of each component in the liquid zone.

Then, assuming, $\sum\limits_{k\neq 0} N_k \ll N_0$, we can write1)

$$\frac{\partial C_i}{\partial N_i} = \frac{1}{N_0}; \quad \left(\frac{\partial C_i}{\partial N_k}\right)_{k\neq i,\,0} \simeq 0; \quad \frac{\partial C_i}{\partial N_0} = -\frac{C_i}{N_0}$$

or, after substituting the derivatives into (1),

$$dC_i = \frac{dN_i - C_i dN_0}{N_0}. \tag{2}$$

We assume that the following are valid under the condition prevailing in vacuum refining: 1) The solutions of the impurities in the host component obey Henry's law (γ_i = const); 2) evaporation occurs only from the lateral surface of the liquid zone; 3) convective diffusion of impurity atoms from the interior of the zone to its surface does not limit evaporation; 4) the evaporation regime is approximately molecular, and the evaporation rate is given by the Knudsen–Langmuir equation: $dN_0/dt = -\alpha_0 S/\tau_0$ (moles/sec) for the host component and $dN_i/dT = (-\alpha_i S/\tau_i) \cdot \gamma_i C_i$ (moles/sec) for an impurity. Here, $\tau = (17.16/P^0) \cdot \sqrt{\mu T/\nu}$ [moles/(cm^2 · sec)] is the molar evaporation time for the substance in its pure state, tabulated in ref. 1 for the metallic elements; t is the evaporation time (seconds); α is the accommodation coefficient; S is the evaporation surface area (square centimeters); P^0 is the saturation vapor pressure of the substance in its pure state at the Kelvin temperature (torr); μ is the atomic weight of the evaporating substance in the condensed phase; ν is the number of atoms in the vapor molecule; and γ is the activity coefficient of the impurity; 5) the liquid–crystal interface is planar.

We write the linear dimensions of the zone, l, and the average temperature at its surface ($\tilde{T}$°K), to which the molar evaporation time of the substance, τ, is referred, in the form $l = l_0 + \varkappa(\nu - r_0)$ and $\tilde{T} = \tilde{T}_0 + p(r - r_0)$, where $\varkappa$ and p are certain numerical factors, l_0 and T_0 are the original length and average surface temperature of the zone, and r_0 and r are the initial and instantaneous radii of the zone at the crystallization front. We assume the crystallization $\varkappa(r - r_0) \ll l_0$ and $p(r - r_0) \ll \tilde{T}_0$, i.e., we assume that changes in the linear dimension and average surface temperature of the zone are negligible.

Under these assumptions we can describe the change in the impurity content in the zone in time $dt = dx/f$ by

$$dN_i = \sum_{k=1}^{3} dN_i^{(k)}, \tag{3}$$

where

$$dN_i^{(1)} = -\frac{\alpha_i \gamma_i C_i S}{\tau_i f} dx, \quad dN_i^{(2)} = -\frac{\pi r^2 \rho_0 k_i C_i}{\mu_0} dx, \quad dN_i^{(3)} = \frac{\pi r_0^2 \rho_0 C_i^0}{\mu_0} dx$$

are the amount of evaporating impurity, the amount of impurity which has left the zone containing the solidified part of the crystal, and the amount of impurity supplied from the other end of the zone, respectively.

Here we have adopted the following notation: ρ_0 is the density of the host component (grams per cubic centimeter) (we assume the densities in the liquid and solid phases to be equal), f is the zone velocity (centimeters per second), k_i is the effective coefficient for the Burton–Prim–Slichter distribution of the impurity, and C_i^0 is the impurity concentration in the initial sample.

Similarly, for the host component:

$$dN_0 = \sum_{k=1}^{3} dN_0^{(k)}, \tag{4}$$

where

$$dN_0^{(1)} = -\frac{\alpha_0 S}{\tau_0 f}\,dx,\quad dN_0^{(2)} = -\frac{\pi r^2 \rho_0}{\mu_0}\,dx,\quad dN_0^{(3)} = \frac{\pi r_0^2 \rho_0}{\mu_0}\,dx.$$

For our purposes it is convenient to write the area of the lateral surface and the volume of the liquid zone as

$$S = 2\pi r l \theta,\quad \Omega = \pi r^2 l \omega. \tag{5}$$

The functions θ and ω in Eqs. (5) take account of the deviations of S and Ω for the zone from the area of the lateral surface and the volume of a regular cylinder of length l and radius r.

Substituting Eqs. (3) and (4) into (2), and using

$$N_0 = \frac{\Omega \rho_0}{\mu_0} = \frac{\pi r^2 l \rho_0}{\mu_0}\,\omega,$$

we find the desired differential equation for C_i:

$$\omega \frac{dC_i}{d\xi} = \left[1 + \frac{(g_0 - g_i)\,\theta}{\eta} - \left(k_i + \frac{1}{\eta^2}\right)\right] C_i + \frac{C_i^0}{\eta^2}, \tag{6}$$

where g_0 is the reduced evaporation coefficient of the host component, equal to $2\mu_0\alpha_0 l/f\tau_0\rho_0 r_0$; g_i is the reduced evaporation coefficient of the impurity, equal to $(2\mu_0\alpha_i l/f\tau_i\rho_0 r_0)\cdot\gamma_i$; ξ is the dimensionless instantaneous coordinate of the crystal in units of the zone length, equal to x/l; and η is the dimensionless zone radius at the crystallization front in units of the original radius, equal to r/r_0.

A relationship among the functions η, ω, and θ is established by differential equation (4); using the substitution $dn_0 = (\pi l \rho_0/\mu_0)d[r^2\omega]$, we write this relationship explicitly as

$$\frac{d\,[\eta\omega]}{d\xi} + \omega \frac{d\eta}{d\xi} = \frac{1}{\eta} - \eta - g_0\theta. \tag{7}$$

Below we distinguish between quasisteady-state recrystallization, in which the impurity concentration and crystal dimensions become essentially constant as the zone moves, and nonsteady-state recrystallization, in which these quantities change more or less rapidly as they approach their constant values.

Quasisteady-state refining. In this case, in which the derivatives $(C_i)'_\xi$, $(C_i)''_\xi$, $(\eta)'_\xi$, $(\omega)'_\xi$, and $(\theta)'_\xi$ tend to zero, and the zone parameters (ω, θ), the radius of the growing crystal, and the impurity concentration in the melt tend toward the limiting values ω_*, θ_*, η_*, and C_i^*, we can reduce system of differential equations (6), (7) to the algebraic system

$$\left\{\omega \frac{dC_i}{d\xi}\right\}^* = \left[1 + \frac{(g_0 - g_i)\,\theta_*}{\eta_*} - \left(k_i + \frac{1}{\eta_*^2}\right)\right] C_i^* + \frac{C_i^0}{\eta_*^2} = 0, \tag{8}$$

$$\left\{\frac{d\,[\eta\omega]}{d\xi} + \omega \frac{d\eta}{d\xi}\right\}^* = \frac{1}{\eta_*} - \eta_* \cdot \quad \xi_0\theta_* = 0, \tag{9}$$

from which we find

$$C_i^* = \frac{C_i^0}{1 + (k_i - 1)\,\eta_*^2 + (g_i - g_0)\,\theta_*\eta_*}, \tag{10}$$

$$g_0\theta_* = \frac{1 - \eta_*^2}{\eta_*}. \tag{11}$$

Strictly, speaking, the limits ω_*, θ_*, η_*, and C_i^* are reached only at infinity ($\xi \to \infty$). In practice, it is useful to assume that the quasisteady-state changes in the zone dimensions begin at the characteristic distance ξ_s, and that the quasisteady-state change in the value of C_i in the melt begins at the characteristic distance ξ_i^*; at these characteristic distances, we have the inequalities

$$|\eta - \eta_*| \leqslant 0.01,\quad \xi \geqslant \xi_s, \tag{12}$$

$$\left|\frac{C_i - C_i^*}{C_i^*}\right| \leqslant 0.1,\quad \xi \geqslant \xi_i^*. \tag{13}$$

Equation (10) holds if both inequalities (12) and (13) are satisfied. For convenience we write

$$\beta_i^* = \frac{C_i^* k_i}{C_i^0} = \frac{C_i^*\ (SO)}{C_i^0}.$$

After some manipulation, we find from (10) and (11)

$$\beta_i^* = [1 + g_0\theta_*\eta_*(\lambda_i - 1)]^{-1} \quad \text{or} \quad \beta_i^* = [\eta_*^2 + \lambda_i(1 - \eta_*^2)]^{-1}, \tag{14}$$

where $\lambda_i = g_i/g_0 k = \tau_0\gamma_i\alpha_i/\tau_i k_i \alpha_0$ is the directionality criterion for the process, which incorporates the basic parameters of the vacuum zone recrystallization. If $\lambda_i > 1$, then $\beta_i^* < 1$, and the evaporation facilitates the removal of impurity; if $\lambda_i = 1$, then $\beta_i^* = 1$, and the evaporation does not affect the limiting impurity distribution; finally, if $\lambda_i < 1$, then $\beta_i^* > 1$, and the evaporation favors the accumulation of impurity. Accordingly, whether the crystal is depleted of or enriched in the impurity can be largely determined from the magnitude of the zone effect, and not only on the basis of the ratio of vapor pressures of the host and impurity, as was assumed in refs. 2 and 3. In fact, even in the case $g_0 > g_i$ with $k_i \ll 1$, according to Eq. (14), a significant removal of impurity can be achieved, and vice versa. In the case $\lambda_i \ll 1$, in which the impurity is relatively nonvolatile, Eq. (14) takes the extremely simple form

$$\beta_i^* = (\eta_*)^{-2},\quad \lambda_i \ll 1. \tag{15}$$

It follows from (15) that the limiting concentration of any relatively nonvolatile, impurity is governed solely by the conditions prevailing in the refining of the host.

Let us compare the changes in the limiting radius η_* for certain crystals as the crystallization rate is varied over a range of two orders of magnitude. For this purpose we rewrite (11) as

$$\eta_* = \sqrt{1 + s^2} - s, \tag{11'}$$

where

$$s = \frac{\alpha_0 \mu_0 l \theta_*}{f \tau_0 r_0 \rho_0}.$$

Figure 1 shows plots of the function $\eta_* = \eta_*(f)$ calculated from Eq. (11') for several metals and silicon. The

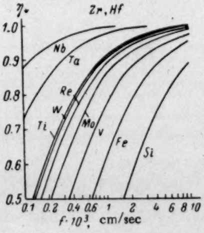

Fig. 1. Limiting crystal radius as a function of the crystallization rate for various elements. Here the zone parameters are $\widetilde{\Delta}T$ = 100°C, θ_* = 1, l/r = 2.

calculations apply for the most common zone parameters: $l/v_0 = 2$ and $\widetilde{\Delta T} = \widetilde{T} - T_{me} = 100°C$. The values of $\tau_0(\widetilde{T})$ are taken from the tables of $\log \tau = \varphi(1/T)$ in ref. 1. We also use the approximation $\rho_0(\widetilde{T}) \simeq 0.9\, \rho_0$ (273°K) and assume $\theta_* = 1$ (the calculations are continued until the values $\eta_* = 0.5$ are reached, since the zone becomes unstable[2] at $\eta_* \leqslant 0.5$). We see that the refining at rates $f < 10^{-2}$ cm/sec for many metals (Fe, V, Mo, Re, Ti, W) is accompanied by an appreciable change in the crystal radius in comparison with its initial value; the change is particularly marked at rates in the range $f \leqslant 10^{-3}$ cm/sec. In practice, the rates most frequently used are $f < 10^{-2}$ cm/sec, so that the limiting impurity concentration for these elements should be determined on the basis of (10). At higher rates, i.e., at $f > 10^{-2}$ cm/sec, the change from the initial radius is small, and the calculation method proposed in ref. 1 is completely justified. We note that at any concrete values of the zone parameters l/r_0, $\widetilde{\Delta T}$, and θ_* the limiting radius η_* can be easily determined by means of Fig. 1, through a direct replacement of f by the reduced rate $f_{li} = f\Delta_{li}$, where

$$\Delta_{li} = \frac{2r_0\tau_0(\widetilde{\Delta T})}{l\tau_0(100°\,C)\theta_*}. \qquad (16)$$

The changes in the crystal radius in vacuum refining have been studied for molybdenum and vanadium in a vacuum of 10^{-6} torr. The initial samples, 10 mm in diameter, are refined at a rate of about 10 mm/min to eliminate metal spray; then a single pass of the zone is carried out for each sample at rates of 0.2, 0.4, 0.6, 1.2, and 3.0 mm/min. The average heating of the zone surface, $\widetilde{\Delta T}_{Mo} = 110 \pm 20°C$ for molybdenum and $\widetilde{\Delta T}_V = 50 \pm 10°C$ for vanadium, is determined with an optical pyrometer and a special optical system. The zone length and the radius ratio r_*/r_0 in the steady-state region are determined by measuring the parameters of the liquid zone from a photograph. It is found that the zone length is essentially independent of the rate, amounting to $l_{Mo} = 1.7r_0$ for molybdenum and $l_V = 1.8r_0$ for vanadium. Figure 2 shows a photograph of the liquid zone of vanadium in the final stage of the formation of the quasisteady-state radius for a crystallization rate of 0.4 mm/min. Table 1 shows the measured limiting radius $\eta_* = r_*/r_0$ for the various crystallization rates studied.

Using the results, we check (11) for the refining of vanadium and molybdenum. According to this equation, the functional dependence $\eta_* = \eta_*(f)$ should become linear when plotted as $\eta_*/(1-\eta_*^2)$ vs f, since the parameters θ_* and τ_0 are weak functions of the crystallization rate. We see from Fig. 3 that the experimental points agree with the straight lines calculated from (10) with the zone parameters $l/r_0 = 1.7$, $\widetilde{\Delta T}_{Mo} = 120°C$ for molybdenum and $l/v_0 = 1.8$, $\widetilde{\Delta T} = 40°C$ for vanadium; the values of $\widetilde{\Delta T}$ agree with the experimental values within the corresponding errors. Accordingly, Eq. (11) holds satisfactorily over a broad range of crystallization rates.

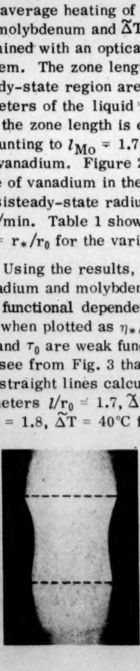

Fig. 2. Photograph of the liquid zone of vanadium when the quasisteady-state radius is established at a crystallization rate of 0.4 mm/min. The upper line is the melting front, and the lower dashed line is the crystallization front.

TABLE 1

	f, mm/min				
	3	12	0.6	0.4	0.2
η_*^{Mo}	0.97	0.93	0.87	0.82	0.66
η_*^{V}	0.98	0.95	0.9	0.86	0.73

The applicability of Eq. (14) can be demonstrated on the basis of data[4] on the zirconium distribution after a single-pass refining of molybdenum. The zone refining and growth of the molybdenum, 10 mm in diameter, are carried out at rates of 0.3 and 1.0 mm/min, with the sample rotating at 60 rpm, in a vacuum 10^{-5} torr. According to precision analysis of samples from the steady-state part of the crystal, the values of β^*_{Zr} are 0.61 and 0.44 for rates of 1.0 and 0.3 mm/min, respectively. The coefficients of the zirconium distribution in molybdenum, K_{Zr}, calculated by the method of ref. 1 for these rates are 0.31 and 0.52 at rates of 1.0 and 0.3 mm/min, respectively, i.e., the ratio of these coefficients is $k^{(0.3)}_{Zr}/k^{(1)}_{Zr} \simeq 1.7$. On the other hand, it is known[5] that as the crystallization rate is reduced the processes occurring at the crystal–liquid interface approach equilibrium, so that k_{Zr} should decrease. On the basis of the high temperatures and intense mixing in the zone, we assume that $k^{(0.3)}_{Zr}/k^{(1)}_{Zr} \simeq 1$ is near equilibrium even at a rate of 1 mm/min, so that we expect $k^{(0.3)}_{Zr} \cdot (k^{(1)}_{Zr})^{-1} \simeq 1$. Calculations based on Eq. (14) taking account of the evaporation of the molybdenum host lead to a ratio $k^{(0.3)}_{Zr}/k^{(1)}_{Zr}$ close to the expected value: According to the experimental conditions, we have $\Delta_{li} \simeq 2$, so that for molybdenum (Fig. 4)

$$\eta_*^{(0.3)} = 0.87, \quad \eta_*^{(1)} = 0.95.$$

It has been pointed out previously[4] that the weight loss of molybdenum after a single pass at 1.0 mm/min is about 10%. This value agrees with the value found above. If we rewrite Eq. (14) as

$$\lambda_{Zr} = \frac{\frac{1}{\beta^*_{Zr}} - \eta_*^2}{1 - \eta_*^2}$$

and substitute the corresponding values of β^*_{Zr} and η_* into the result, we find $\lambda^{(0.3)}_{Zr} \simeq 6.4$ and $\lambda^{(1)}_{Zr} \simeq 7.4$, so that the

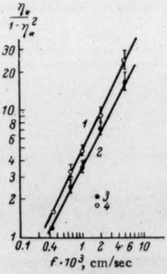

Fig. 3. Limiting radius of molybdenum and vanadium crystals as a function of the crystallization rate. Lines) calculated; points) experimental. $\widetilde{\Delta T}$, °C: 1) 40, 2) 120; 3) Mo, 4) V.

ratio of distribution coefficients is

$$\frac{k_{\mathrm{Zr}}^{(0.3)}}{k_{\mathrm{Zr}}^{(1)}} = \frac{\lambda_{\mathrm{Zr}}^{(1)}}{\lambda_{\mathrm{Zr}}^{(0.3)}} \simeq 1.15.$$

Transient regime. To evaluate the periods of the transient behavior, ξ_s and ξ_i^*, we note that in the region $\xi \geq \xi_s$ differential equation (6) becomes

$$\omega_* \frac{dC_i}{d\xi} = \left[1 + \frac{(g_0 - g_i)\theta_*}{\eta_*} - \left(k_i + \frac{1}{\eta_*^2}\right)\right] C_i + \frac{C_i^0}{\eta_*^2}. \tag{17}$$

Integrating (17), using the initial condition $C_i|_{\xi=\xi_s} = C_i^s$, we find

$$C_i - C_i^* = (C_i^s - C_i^*) \exp\left\{-\frac{k_i(\xi - \xi_s)}{\beta_i^* \eta_*^2 \omega_*}\right\},$$

from which we then find, using (13),

$$\xi_i^* - \xi_s = \frac{2.3\beta_i^* \eta_*^2 \omega_*}{k_i}\left\{1 + \lg\left|\frac{\Delta C_i^s}{C_i^*}\right|\right\}, \tag{18}$$

where $\Delta C_i^s = C_i^s - C_i^*$.

Then using the obvious inequality

$$\left|\frac{\Delta C_i^s}{C_i^*}\right| \leqslant \left|\frac{k_i - \beta_i^*}{\beta_i^*}\right|$$

we find the rough estimate

$$\frac{\xi_i^* - \xi_s}{\omega_*} \leqslant 2.3(k_i + g_i)^{-1}. \tag{19}$$

To evaluate ξ_s, we set $\omega \equiv \omega_*$ and $\theta \equiv \theta_*$ in Eq. (7) as a first approximation. Then introducing the variable $\zeta = \eta - \eta_*$ and integrating (7) with the initial condition $\zeta_0 = \zeta|_{\xi=0} = 1 - \eta_*$, we find

$$\xi = \frac{2\omega_*}{1 + \eta_*^2}\left\{\ln\left(\frac{\zeta_0 + \varepsilon}{\zeta + \varepsilon}\right) + \eta_*^2 \ln\frac{\zeta_0}{\zeta}\right\}, \tag{20}$$

where $\varepsilon = (1 + \eta_*^2)/\eta_*$.

Using (12), we easily find from (20) an equation for ξ_s:

$$\xi_s \simeq \frac{2\omega_*}{1 + \eta_*^2}\left\{\ln\left(\frac{1 + \eta_*}{1 + \eta_*^2}\right) + \eta_*^2\left(\frac{1 - \eta_*}{0.01}\right)\right\}. \tag{21}$$

Figure 4 shows a plot of the function $\xi_s/\omega_* = f(\eta_*)$. Usually, we would have $\omega_* \lessdot 1$, so that, as we see from Fig. 4, we would have $\xi_s \lessdot 2.5$, in agreement with the experimental data available.

Accordingly, when $k_i + g_i \gtrdot 1$ we have $\xi_i^* \lessdot 5$, i.e., the impurity concentration along the crystal is essentially steady-state, given by (14), since the total length of the crystal is usually equal to some 30-100 zone lengths. Under the condition $k_i + g_i < 1$ the region in which the concentration is not in a steady state can span a large part of the crystal. In this case Eq. (6) can be integrated. As before, we assume $\omega \equiv \omega_*$ and $\theta \equiv \theta_*$ in a first approximation. Then eliminating ξ from (6) by means of (7), we find

$$\frac{dC_i}{d\eta} + z(\eta)\{(1 - k_i)\eta^2 + g_0\theta_*\eta(1 - \lambda_i k_i) - 1\} C_i + z(\eta) C_i^0 = 0,$$
$$z(\eta) = \frac{2}{\eta(\eta^2 + g_0\theta_*\eta - 1)}. \tag{23}$$

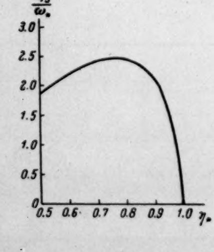

Fig. 4. Distance over which a quasi-steady-state crystal radius is established as a function of the limiting value of this radius.

Using ζ to replace η in (23) [see (20)], and integrating, using the initial condition $C_i|_{\zeta=\zeta_0} = C_i^0$, we find[3)]

$$\frac{C_i(\mathrm{SO})}{C_i^0} = \frac{[k_i - \beta_i^*\eta_*^2\Gamma(\zeta_0)]}{(\zeta + \eta_*)^2}\left(\frac{\zeta}{\zeta_0}\right)^{\nu_1}\frac{\varepsilon + \nu_2\zeta}{\varepsilon + \nu_2\zeta_0} + \frac{\beta_i^*\eta_*^2\Gamma(\zeta)}{(\zeta + \eta_*)^2}, \tag{24}$$

where

$$\Gamma(\zeta) = \left(1 + \frac{\nu_2\zeta}{\varepsilon}\right)(1 + \sigma\zeta + \delta\zeta^2), \quad \sigma = \frac{\nu_1}{\nu_1 - 1}\left(\frac{1}{\eta_*} - \frac{\nu_2 + 1}{\varepsilon}\right),$$
$$\delta = \frac{\nu_1}{1 + \eta_*^2}\left(\frac{\nu_2 + 1}{2 - \nu_1}\right), \quad \nu_1 = \frac{2k_i}{(1 + \eta_*^2)\beta_i^*}, \quad \nu_2 = \frac{2k_i}{1 + \eta_*^2}\left(\frac{\beta_i^* - 1}{\beta_i^*} + \eta_*^2\right).$$

Using system (20), (24) we can find the impurity distribution in the crystal for the case in which the transient period ξ_i^* becomes large. To illustrate this point, we show in Fig. 5 some results calculated for the distribution of a relatively nonvolatile impurity ($\lambda_i \ll 1$) along a crystal for $\eta^* = 0.7$, $\beta^* \equiv 2$, and $\omega_* = 0.9$. We see that the concentration of such an impurity tends monotonically toward a steady-state value over this range of distribution coefficients k_i. A shift of the quantity $k_i + g_i$ toward higher values leads to the appearance of an extremum at some point $\xi_i^M < \xi_s$ on the plot of the impurity concentration against the crystal coordinate. This extremum occurs because the impurity concentration in the zone changes faster than the radius of the solidified crystal can change. This conclusion follows directly from (2), according to which there are two ways in which the first derivative of the impurity concentration with respect to coordinate ξ can vanish: a) $(C_i)'_\xi \to 0$ as $\xi \to \infty$, in which case the derivatives $(N_i)'_\xi$, $(N_0)'_\xi$, and $(C_i)''_\xi$ tend toward zero; b) $(C_i)'_\xi = 0$ at the point $\xi = \xi_i^M$, at which we have $(N_i)'_\xi = C_i(N_0)'_\xi$, but at which the derivatives $(N_0)'_\xi$ and $(C_i)''_\xi$ are nonvanishing.

The situation is illustrated in Fig. 6, which shows the impurity concentration as a function of the crystal coordinate according to Eqs. (20) and (24) with the values $\eta_* = 0.5$, $\beta^* \equiv 0.8$, and $\omega_* = 0.9$. [in this case $\nu_2 = 0$, so series (25) contains only a single term, and Eq. (24) holds for any k and g.] It is evident that when $k/\beta^* < 1$ the im-

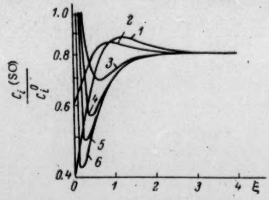

Fig. 6. Distribution of impurities having distribution coefficients in the range 0.4-10 along a semiinfinite crystal. $\eta_* = 0.5$, $\beta_* \equiv 0.8$, $\omega_* = 0.9$. k: 1) 0.4; 2) 0.6; 3) 1.5; 4) 3; 5) 5; 6) 10.

purity concentration passes through a **maximum; with** $k/\beta^* > 1$ it **through a minimum.**

A phenomenon of this type is apparently observed experimentally in ref. 4 in a study of the distribution of a Zr impurity in Mo after a single pass of the zone at rates of 0.3 and 1.0 mm/min. For both rates $(k/\beta^*)_{Zr} < 1$, and the zirconium concentration in the first part of the crystal ($\xi \sim 0.5$-1.0) is higher than the steady-state value.

In conclusion we note that, first, although we **originally assumed the length** of the zone and the average temperature of the zone surface to remain relatively constant over the course of the recrystallization, this assumption of course does not restrict the applicability of Eqs. (14) and (11). All the quantities which appear in these equations refer to the quasisteady-state region and can be easily measured, regardless of their history. Furthermore, Eq. (14) can be used for estimates simply by measuring the average heating in the zone and the limiting crystal radius for known values of k and γ; in this regard, Eq. (14) is particularly convenient.

Second, in large-diameter crystals ($d \geqslant 20$-25 mm) the elimination of relatively volatile impurities apparently becomes limited by the convective supply of atoms from the interior of the zone to its surface; this circumstance could be responsible for the discrepancy between the calculated and experimental data.

Finally, we mention the effect of the period in which the initial zone is formed, t_f, during which the concentration of relatively volatile impurities in the zone can decrease perceptibly. This circumstance can be taken into account by substituting the initial condition $C_i|_{\zeta=\zeta_0} = C_i(t_f) \simeq C_i^0 \exp[(g_0 - g_i)t_f]$ into (23) (see, e.g., ref. 3).

[1)] Here the subscript "0" denotes the host component.

[2)] The accommodation coefficient α_0 is approximately equal to unity for metallic elements.

[3)] In integrating (23) we use a series expansion of the coefficient $(\zeta+\varepsilon)^{\nu_2}$ in powers of

$$(\zeta+\varepsilon)^{\nu_2} = \varepsilon^{\nu_2}\left[1 + \frac{\nu_2\zeta}{\varepsilon} + \frac{\nu_2(\nu_2-1)}{2!}\left(\frac{\zeta}{\varepsilon}\right)^2 + \dots\right]. \qquad (25)$$

The condition $k_i + g_i < 1$ leads to a rapid convergence of this series, so that it is sufficient to retain only the first two terms. We note that in the case $\nu_1 = 1$ or 2, in which case σ and δ are not meaningful, Eq. (23) can be integrated directly.

Hydrogen-ion mobility in a high-pressure unipolar corona

A. G. Lyapin

G. M. Krzhizhanovskii Scientific Research Institute, Moscow

(Submitted April 2, 1973)
Zh. Tekh. Fiz., 44, 1990-1995 (September 1974)

A simplified method is proposed to determine the mobility of hydrogen ions, averaged over the interelectrode gap, over a wide pressure range in highly nonuniform fields. The experimental data show that at high pressure the mobility has a complicated dependence on p. Up to a critical pressure ($p \simeq 8$ atm) the mobility of negative ions changes by more than two orders of magnitude; the positive-ion mobility is approximately inversely proportional to the pressure. For hydrogen pressures greater than the critical value the mobilities of positive and negative ions are about the same and essentially independent of p. The drift velocity of the ions in a corona field is compared with data in the literature. The agreement with the available data confirms the assumptions made here.

In recent years there has been a rapid increase in technological applications of electric fields produced in the interelectrode gap of high voltage sources in the range 80 kV to 1.2 MV. In such sources both hydrogen and anisotropic mixtures of fluorochlorohydrocarbons with H_2 or N_2 are used as basic insulator materials.

The dielectric strength of these materials and the conditions for electrical discharges are determined chiefly by the volume charge distribution in the interelectrode gap. In refs. 1-3 it is shown that the latter is determined by the ion mobility.

We consider here the results of an experimental determination of the averaged (over the gap) ion mobility of clean, dry hydrogen in the field of a unipolar corona in a cylindrical electrode geometry with $30 \leq R/r_0 \leq 600$ at high pressures ($0.5 \leq p \leq 25$ atm).

An advantage of this electrode geometry is the fact that in the outer zone of the corona in the field of a cylindrical condenser the electric field is given by

$$E_x = \sqrt{\frac{I}{2\pi\varepsilon_0 l_k K}\left[1-\left(\frac{r_0}{r_x}\right)^2\right]+\left(E_0\frac{r_0}{r_x}\right)^2}, \tag{1}$$

where I is the corona current, r_0 and r_x are the radii of the corona electrode and of the zone in which the field gradient is evaluated, l_k is the length of the corona electrode, E_0 is the electric field at the surface of the corona electrode corresponding to the voltage, U_0, at which corona is initiated, and K is the ion mobility.

For a developed corona $I > 20$ mA/m, as is shown in ref. 4, and Eq. (1) takes the form

$$E_x = \left(\frac{I}{2\pi\varepsilon_0 K l_k}\right)^{1/2}. \tag{2}$$

For an outer corona zone with $r_x \geq 10\, r_0$ and a developed corona ($m = U/U_0 > 3$, where U is the voltage across the gap) the electric field is independent of the coordinate r_x and remains (beginning with some $r_x > r_{x_{cr}}$) constant.[5] Thus, for $r > r_{x_{cr}}$, we assume

$$K = \frac{I}{2\pi\varepsilon_0 l_k E_{x\,cr}^2} = aIE_{x\,cr}^{-2}. \tag{3}$$

If we take the volt–ampere characteristics $I = f(U)$ for a given corona electrode with two different outer cylinder dimensions R for each given value of corona current we have

$$E_x = \frac{U_2 - U_1}{R_2 - R_1} = \frac{\Delta U}{\Delta R}, \tag{4}$$

where R_1 and R_2 are the dimensions of the outer cylinders; ΔU is the difference in voltage across the gap for a fixed value of corona current (I/l_k = const) when the boundary of the outer zone is changed from R_1 to R_2.

In other words, the gradient of the electric field, E_x, depends on the voltage difference applied to two cylindrical condensers, R_1/r_0 and R_2/r_0, with the same corona current. Thus,

$$K_{av} = \frac{I_i \Delta R^2}{2\pi\varepsilon_0 l_k \Delta U_i^2} = GI_i\Delta U_i^{-2} \tag{5}$$

or

$$\bar{V} = KE = G'I_i\Delta U_i. \tag{6}$$

For a given current (corona current per unit length of corona electrode) the coefficients G and G' are determined only by the electrode dimensions.

The mobility of hydrogen (a basic insulator gas in high-voltage electrophysical apparatus) is determined from experimental volt–ampere characteristics with positively and negatively polarized inner electrodes of a cylindrical condenser. The R/r_0 geometry is varied by using three outer cylinders: R_i = 2.0, 3.0, and 5.0 cm. The inner working surface of the shielding elements of the noncorona electrode corresponded, for given R, to a Rogowski profile with $\psi = \pi/2$. Stainless steel wires $0.01 \leq r_0 \leq 0.175$ cm in diameter serve as corona electrodes.

Over the entire range of R/r_0 and p studied here the volt–ampere characteristics are obtained in the usual way (point-by-point) and with an x–y chart recorder (N359/P).

From the analyzed volt–ampere characteristics for R/r_0 it follows that the current for a negative unipolar corona is significantly higher than the analogous quantity for positive polarization for a given U, regardless.

Typical volt–ampere characteristics for positive (solid curves) and negative (dotted) polarity and for a number of pressures for r_0 = 0.025 cm are shown in Fig. 1.

The function $I = f(U)$ allows us (with an accuracy $\sigma_m \simeq 1\%$ at a certainty level $\Delta\sigma_m = 0.94$) to plot intermediate curves $\Delta U_i = \varphi(p)$ at r_0 = const for $2 \leq I_i \leq 200$ μA/m. For a positive unipolar corona this dependence has an exponential form, whose growth rate depends, for

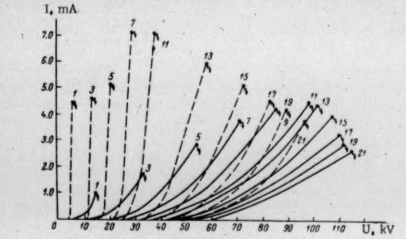

Fig. 1. Typical volt–ampere characteristics for unipolar corona in hydrogen. $R/r_0 = 100$, $R_1 = 3.0$ cm. The numbers on the curves denote pressure; the downward arrows, breakdown.

a given r_0, on the overvoltage relative to the corona threshold. That is, it is determined by the intensity with which the corona "burns." In the case of negative corona this dependence has two distinct zones: a) For $0.5 \leq p \leq 5$ atm ΔU_i is essentially proportional to the square root of the pressure; and b) for $8 \leq p \leq 15$ atm, $\Delta U_i = \varphi(p)$ is nearly exponential.

The intermediate curves $\Delta U_i = \varphi(p)$ for all R/r_0, $s = R - r_0$, p, and corona electrode polarities which were studied enable us to plot the basic dependence $\bar{K}_{av} = f(p)$, as shown in Fig. 2. Here, $\bar{K}_{av}$ means the value of K averaged over an entire series of runs (arithmetic mean). In order to simplify the analysis the average mobility of hydrogen ions is also shown as a function of lifetime [$K_{av} = \varphi(t)$] and as a function of the electric field gradient [$K_{av} = \psi(E/p)$].

The function $\bar{K}_{av} = f(p)$ for ions of both sign is qualitatively the same for the pressures and electrode distances considered here (this does not contradict the conclusions of ref. 6). Quantitatively, however, there is a substantial difference between the curves $\bar{K}^-_{av} = f(p)$ and $\bar{K}^+_{av} = f(p)$.

For positive ions over the entire range of pressure studied here $\bar{K}^+_{av}$ falls by five or six times as p increases; for negative polarity the drop is almost two orders of magnitude. Then a sharp drop in K_{av} for positive and negative ions occurs over a range up to the critical pressure for hydrogen, which at normal temperature (according to ref. 7) reaches 7 atm. Over the remaining portion of this pressure range ($8 \leq p \leq 25$ atm) the ion mobility changes insignificantly (up to 20%). In the range $0.5 \leq p \leq 7$ atm the mobility of the negative ions falls by more than 50 times.

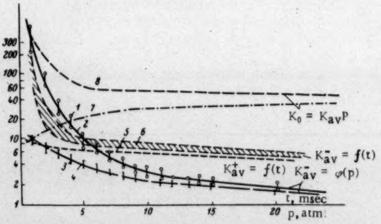

Fig. 2. Change in mobility, averaged over the interelectrode gap, of negative and positive ions with H_2 pressure or ion lifetime. 1) Spread in $\bar{K}_{av} = \varphi(p)$; 2) generalized dependence $K^- = \psi(p)$ (over the whole series of experiments); 3) spread in $K^+_{av} = \varphi(p)$; 4) generalized dependence $K^+_{av} = \varphi(p)$; 5) dependence $K^+_{av} = f(t)$; 6) spread in $K^-_{av} = f(t)$; 7, 8) K^+_0 and K^-_0, respectively, for the pressure range studied.

For p > 7-8 atm the mobility of both positive and negative ions is pressure-independent and it is assumed that $\bar{K}^-_{av} = \bar{K}^+_{av}$ in this range.

In the case of a negative unipolar corona for p < 5 atm the mobility of the ions exceeds 100 cm²/V · sec. This experimental result indicates that if clean, dry hydrogen is compressed slightly the principal charge carriers in a negative corona may be the electrons. This conclusion agrees with the data of refs. 8 and 9.

The equal positive- and negative-ion mobilities at high pressures (p > 12 atm), for which K_{av} reaches similar values to those representative of normal ions at atmospheric pressure, indicates that in this pressure range the mobility of the charge carriers is affected by the presence of chemical impurities and additives in the hydrogen. The chief impurities are water vapor (< 0.0012%) and compounds of the KOH groups (< 0.001%). The sublimation technique (freezing during pumping) used in these experiments to dry the hydrogen does not remove these additives.

Another important result is indicated by the present data. For positive hydrogen ion lifetimes, $1 \leq t \leq 30$ msec, the relation between K and t can be written in the form

$$K^+(t) = 5.9 + 2.13\exp(-0.38pt). \qquad (7)$$

We note that the ion lifetimes are calculated by the method of ref. 4 for given overvoltage m, that is,

$$t = \frac{E_0}{KI_i}\left\{\sqrt{G\frac{I_i}{\Delta U_i^2}} - 1\right\}. \qquad (8)$$

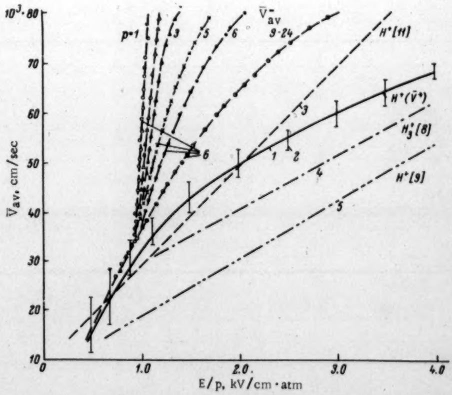

Fig. 3. Ion drift speed as a function of E/p. $R/r_0 = 60$-240, $R_1 = 3.0$ cm, $R_2 = 6.0$ cm. 1) Averaged dependence $\bar{V}^+ = f(E/p)$; 2) spread in $\bar{V}^+$; 3) $\bar{V}^+ = f \cdot (E/p)$ according to ref. 11; 4) same, from ref. 8; 5) same, from ref. 9; 6) $\bar{V}^- = f(E/p)$.

It has not been possible to obtain a unique dependence $K_{av}^{-} = \psi(t)$, whose analytic form approximates a relationship like Eq. (7), for negative ions. This difficulty can be explained only by the effect of the electron component in the corona current on the character of $K_{av}^{-} = \psi(t)$.

Attempts to isolate the ion component (using grids) in the plot of unipolar current at negative polarity have been unsuccessful.

This difficulty, in our opinion, is most fully illustrated by a curve of the ion drift speed as a function of the electric field divided by the pressure, which is plotted in Fig. 3. This curve shows that the drift speed of the hydrogen ions over the entire range of E/p and p studied here has a complicated structure due to changes in the form of the corona discharge.

For a negative unipolar corona with $0.3 \leq E/p \leq 1$ kV · (cm · atm)$^{-1}$, the drift speed is proportional to E/p and can be approximated by the analytic expression

$$\bar{V}^{+} = 1.5\left(\frac{E}{p} - 1.5\right) \cdot 10^{4}, \text{ cm/sec.} \qquad (9)$$

This expression agrees with the data of ref. 9. For high values of E/p (E/p > 1.0 kV/cm-atm) the drift speed increases much more slowly than E/p, that is, saturation is reached in the curve $\bar{V}^{-} = \varphi(E/p)$.

On the other hand, for a positive corona the drift speed is approximated by the analytic expression

$$\bar{V}^{-} = 5.6\left(\frac{E}{p} - 0.3\right) \cdot 10^{4}, \text{cm/sec.} \qquad (10)$$

only for $E/p \geq 1.5$ kV/cm · atm.

For lower values of E/p the positive ion drift speed depends on the absolute pressure, p.

All these data agree with ref. 10.

The ion mobility values obtained from volt—ampere characteristics yield another important result: The constancy of Kp, usually assumed in estimates of the dielectric strength of corona gaps, holds only at high pressures (i.e., for $K_{av}^{+} = K_{av}^{-}$). For the range of pressures of interest in the construction of apparatus ($3 \leq p \leq 16$ atm) the product of ion mobility and pressure depends on the polarity of the corona electrode and the relationship is complicated.

Optical observations of the character of the corona for given electrode geometries as the pressure is varied show not only that the latter depend on the polarity of the corona electrode but also on the form of the corona. For p > 7 atm a streamer corona in the form of separate filaments, several of which cross the entire discharge gap, is observed independent of polarity.

The data on hydrogen ion mobility obtained using the techniques described here are in good agreement with data obtained by the classical methods of determining K. Thus, it is possible to determine the mobility of the ions in analyzing the electrical characteristics of compressed gases by taking volt—ampere characteristics in the pressure range of practical interest.

Absolute-photometry determination of the rate constant of the gas-phase reaction of the radical compound C_3F_7 and $I(^2P_{3/2})$

G. A. Skorobogatov, V. S. Komarov, and V. G. Seleznev
A. A. Zhdanov Leningrad State University

(Submitted September 24, 1973)
Zh. Tekh. Fiz., 44, 1996-2001 (September 1974)

A method described elsewhere has been used to measure the differential quantum yield of the stimulated emission of a C_3F_7I laser at peak output: (140 ± 20)% and (148 ± 12)% for initial perfluorinated propyl iodide pressures of 22.3 and 74.2 torr, respectively. Calculations based on these quantum yields yield a rate constant of $k_{11}(360°K) = (1.5 \pm 0.5) \cdot 10^{-10}$ cm³/(molecule · sec) for the gas-phase reaction $C_3F_7 + I(^2P_{3/2}) \rightarrow C_3F_7I$.

INTRODUCTION

Photolysis of the perfluorinated alkyl iodides has been studied intensively in recent years because of the discovery of photodissociative iodine lasers.[1,2] In the early work[1,3-5] it was assumed that the radical R formed in the photolysis

$$RI + h\nu_1 \rightarrow R + I(^2P_{1/2}) \qquad (1)$$

recombines rapidly,

$$2R \xrightarrow{k_2} R_2 \qquad (2)$$

and has no effect on the behavior of the $I(^2P_{1/2})$ atoms. The $I(^2P_{1/2})$ atoms, on the other hand, are assumed to lose their electronic excitation in some undetermined way:

$$I(^2P_{1/2}) \rightarrow I(^2P_{3/2}) + h\nu_3, \qquad (3)$$

$$I(^2P_{1/2}) + h\nu_3 \rightarrow I(^2P_{3/2}) + 2h\nu_3, \qquad (4)$$

$$I(^2P_{1/2}) + M \rightarrow I(^2P_{3/2}) + M \quad (M \equiv RI,\ I_2)\ . \qquad (5)$$

Then they are assumed to recombine to molecular iodine:

$$2I(^2P_{3/2}) + M \rightarrow I_2 + M \quad (M \equiv RI,\ I_2). \qquad (6)$$

However, these assumptions do not explain all features of the photolysis of the perfluorinated alkyl iodides (with or without the laser effect), so it has been suggested that an important role is played in these processes by either pyrolysis of the irradiated material,[2,6]

$$RI \rightarrow R + I(^2P_{3/2}), \qquad (7)$$

or reactions involving excited photolysis products,[7-10]

$$I(^2P_{1/2}) + RI \rightarrow I_2 + R, \qquad (8)$$

$$\tilde{R} + RI \rightarrow R_2 + I(^2P_{1/2}), \qquad (9)$$

where $\tilde{R}$ is the vibrationally excited R radical. However, direct measurements[11] show that the rate constants for reactions (8) and (9) do not exceed 10^{-16}-10^{-17} cm³ · (molecule · sec)$^{-1}$. A theoretical analysis shows[12,13] that with these low values of k_8 and k_9 it would not be possible to explain fundamental features of the photolysis of the perfluorinated alkyl iodies such as the laser effect; the situation is not saved by taking process (7) into account.[14]

1. KINETIC MODEL

In accordance with the discussion in the introduction we assume that only processes (1), (3), (4), and (11) occur in the working volume of a C_3F_7I laser before peak output is reached, at t_{max}. We describe the time evolution of the concentrations [RI], $[I(^2P_{1/2})]$, $[I(^2P_{3/2})]$, and $[C_3F_7]$, and the intensity of the stimulated transitions G(t) in the approximation of Part I of ref. 18. Then for a pumping pulse

$$\varphi(t) = \varphi\Theta(t), \qquad (12)$$

where Θ(t) is the Heaviside function, and for zero critical inversion (P = 0), we find that Eqs. (20)-(28) of ref. 18 become

$$\Gamma(\tau) = y + \frac{1}{2}Kvz, \qquad (13)$$

$$\frac{dy}{d\tau} = -\frac{dz}{d\tau} = -y + Kvz \quad [y(0) = 1;\ z(0) = 0], \qquad (14)$$

$$\frac{du}{d\tau} = y - \frac{2}{3}\Gamma(\tau) = \frac{1}{3}y - \frac{1}{3}Kvz \quad [u(0) = 0], \qquad (15)$$

$$\frac{dv}{d\tau} = \frac{2}{3}\Gamma(\tau) - Kvz = \frac{2}{3}y - \frac{2}{3}Kvz \quad (v(0) = 0), \qquad (16)$$

where

$$\left.\begin{array}{c} K = \dfrac{nk_{11}}{\sigma(RI)\varphi}, \quad \Gamma(\tau) \equiv \dfrac{3G(t)}{2\sigma(RI)\varphi n}, \\ y \equiv \dfrac{1}{n}[C_3F_7I], \quad z \equiv \dfrac{1}{n}[C_3F_7], \\ u \equiv \dfrac{1}{n}[I(^2P_{1/2})], \quad v \equiv \dfrac{1}{n}[I(^2P_{3/2})], \\ \tau \equiv \sigma(RI)\varphi t, \quad n = [RI]_{t=0} \end{array}\right\} \qquad (17)$$

and σ(RI) is the cross section for photon absorption by the RI molecule averaged over the band.

The system of four equations in (14)-(16) has three independent integrals

$$u - \frac{1}{2}v = 0, \quad z = 1 - y, \quad v = \frac{2}{3}(1 - y), \qquad (18)$$

so that the solution of system (14)-(16) reduces to the solution of one equation. For example, using the last two integrals in (18) we find from (14)

$$\frac{dy}{d\tau} = \frac{2}{3}K\left[y^2 - 2\left(1 + \frac{3}{4K}\right)y + 1\right], \quad [y(0) = 1]. \qquad (19)$$

No significant process was made toward an understanding of the mechanism for the photolysis of the perfluorinated alkly iodides until Pimentel's group reported[15] experimental results indicating a decisive role in these processes of fast reactions involving the R radical:

$$\mathrm{I}(^2P_{1/2}) + R \xrightarrow{k_{10}} \mathrm{I}(^2P_{3/2}) + R, \qquad (10)$$

$$\mathrm{I}(^2P_{3/2}) + R \xrightarrow{k_{11}} R\mathrm{I}, \qquad (11)$$

for which the rate constants are comparable to k_2. For the case in which R is CF_3, e.g., the value of k_{10} increases with increasing temperature and at 300-500°C is 100 times the value of k_5 for the case $M \equiv I_2$ (ref. 16). As a result, process (10) turns out to be responsible for the quenching of the generation of a CF_3I laser at a pumping flux density of $> 10^{22}$ photons/(cm^2 • sec) in the CF_3I absorption band.[17]

In contrast, in the photolysis of perfluorinated propyl iodide, reactions (2) and (10) should play a less important role, and reaction (11) should play a more important role than in the photolysis of trifluoromethyl iodide since, according to refs. 2 and 6, the energy yield of the stimulated emission from a unit volume of the active medium of a C_3F_7I laser is twice that for a CF_3I laser.

We have evaluated the absolute value of k_{11} for the case $R \equiv C_3F_7$ by measuring the differential quantum yield of the stimulated emission of a C_3F_7I laser at peak output.

If we assume k_{11} to be independent of the temperature and thus of the time, we can write the solution of the Cauchy problem for Eq. (19) as

$$y(\tau) = 1 + \frac{3}{4K} - \frac{3}{4K} A \frac{A \operatorname{sh}\frac{1}{2}\tau A + \operatorname{ch}\frac{1}{2}\tau A}{\operatorname{sh}\frac{1}{2}\tau A + A \operatorname{ch}\frac{1}{2}\tau A} \quad \left(A = \sqrt{\frac{8}{3}K + 1}\right). \qquad (20)$$

The problem is solved completely, since from (20) and (18) we find the functional dependences of the other concentrations (u, v, z) on the time, and by substituting (18) into (13) we find the differential quantum yield of the stimulated transitions:

$$\Gamma(\tau) = y(\tau) + \frac{1}{3} K (1 - y(\tau))^2. \qquad (21)$$

From (20) and (21) we find the asymptotic values of the functions y and Γ in the case $\tau \to \infty$:

$$y(\infty) = 1 + \frac{3}{4K}\left(1 - \sqrt{\frac{8}{3}K + 1}\right), \qquad (22)$$

$$\Gamma(\infty) = 1\frac{1}{2} + \frac{3}{4K}\left(1 - \frac{3}{2}\sqrt{\frac{8}{3}K + 1}\right) \quad (K > 0), \qquad (23)$$

$$\Gamma(\infty) \simeq 1.5\left(1 - \sqrt{\frac{3}{2K}}\right) \quad (K \gg 1). \qquad (24)$$

In a real RI laser, because of the temperature increase in the working volume and because of processes (2), (5)-(7), and (10), the value of Γ sooner or later falls below the limiting value (23) before it vanishes. Accordingly, in a real RI laser Eqs. (22)-(24) hold only in the range $\tau_{\mathrm{asymp}} \leq \tau \leq \tau_{\max}$, where $\tau_{\max}$ is the time at which the output reaches its peak and where $A\tau_{\mathrm{asymp}} \gg 1$. We assume

$$\tau_{\mathrm{asymp}} = 4A^{-1}. \qquad (25)$$

If we have

$$\tau_{\mathrm{asymp}} < \tau_{\max} \qquad (26)$$

in a real laser, then there is a range of times $\tau_{\mathrm{asymp}} < \tau < \tau_{\max}$ in which the measured quantum yield $\Gamma(\tau_{\max})$ obeys (23) or (24). If, on the other hand, inequality (26) does not hold, then Eqs. (22)-(24) are not applicable for the given RI laser, and $\Gamma(\tau_{\max})$ is smaller than the limiting value in (23).

2. EXPERIMENTAL PROCEDURE AND APPARATUS

The quartz laser cell (inside diameter 5.4 mm, length 250 mm, and working volume 5.7 cm^3), with end windows making an angle of 90° with the axis of the cell, is surrounded by four IFP-5000 lamps wrapped in aluminum foil. The IFP-5000 lamps are placed inside a copper tube (100 mm in diameter and 350 mm long) so that the discharge current passes through the lamps and the copper tube to ground through a low-inductance circuit. The pumping pulses are produced by supplying the lamps a voltage of up to 30 kV through a coaxial air spark switch from two KMK-40-4 capacitors (C_{tot} = 7.6 μF, L = 15 nH). For a discharge energy of 500 J the length of the voltage pulse in the UV region is 10 μsec at half-height, and that at an energy of 3600 J is 20 μsec.

The cavity is formed by an opaque mirror and one with a dielectric coating which reflects 10% of the radiation at 1300 nm. The radius of curvature of the mirrors is 1 m, and the mirrors are 750 mm apart. Part of the stimulated emission (12-20%) is reflected by a quartz plate; after attenuation by a factor of ~100, it reaches a light guide to the pickup (a type FD9É111B photodiode) of an S1-29 storage oscilloscope. The other 80-88% of the radiation reaches the entrance of an IKT-1M calorimeter. When a cell having Brewster-angle windows is used the stimulated-emission energy per cm^3 of the working volume is not significantly increased.

The trifluoromethyl iodide (99.8% pure) is purified until the impurity peaks on the chromatograms disappear completely, by means of 8-10 vacuum distillations. The perfluorinated propyl iodide is purified in a similar manner, and the product used in the experiments contains 2-3 mole % of inert impurities of the type C_6F_{14}.

3. ABSOLUTE PHOTOMETRY

Table 1 shows, for each initial pressure n = $[RI]_0$, the pumping energy E_{pump}; the measured stimulated-emission energy per cm^3 of the working volume, E_{gen}; the time at which the generation reaches its maximum, $t_{\max}$; and the time at which generation is cut off, t_{cut}. This table also shows values of the integrated quantum yield of the stimulated emission, calculated from

$$\Gamma_{\Sigma}(\%) = \frac{(\quad 0.988 \cdot 10^{19} E_{\mathrm{gen}}(\mathrm{J/cm^3})}{n\,(\mathrm{molecules/cm^3})} \cdot 100 \qquad (27)$$

as a percentage of the maximum possible value $2/3[RI]_0$:

$$\Gamma_{\Sigma} = \frac{3}{2n} \int_0^{t_{\mathrm{cut}}} G(t)\,dt = \int_0^{\tau_{\mathrm{cut}}} \Gamma(\tau)\,d\tau. \qquad (28)$$

Then, using the measured values of E_{gen} and the shapes of the pulses (Fig. 1), we calculate the maximum

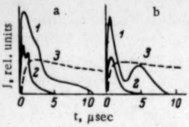

Fig. 1. Intensities J of the pumping pulses and the generation of CF_3I and C_3F_7I lasers. a) E_{pump} = 3420 J, [RI] = 22.3 torr; b) E_{pump} = 2570 J, [RI] = 74.2 torr. 1) C_3F_7I; 2) CF_3I; 3) pumping.

power per unit working volume of the stimulated emission, E_{max} (joules per cubic centimeter per second). These values are shown, in units of photons per cubic centimeter per second (G_{max}), in the ninth column of Table 1. The 10th column shows the apparent pumping radiation flux in the RI absorption band at the time of peak output, t_{peak}, calculated from

$$\varphi^{RI}_{max}[\text{photons}/(\text{cm}^2 \cdot \text{sec}) = \frac{1.5G_{max}[\text{photons}/(\text{cm}^3 \cdot \text{sec})]}{n\sigma(RI)}. \quad (29)$$

We assumed $\sigma(CF_3I) = 4 \cdot 10^{-19}$ and[3,19] $\sigma(C_3F_7I) = 6 \cdot 10^{-19}$ cm^2/molecule.

We also assert that the apparent flux $\varphi^{CF_3I}_{max}$ is equal to the actual pumping flux on the basis of four arguments used to derive fundamental equation (2) of ref. 20 [Eq. (29) with $R \equiv CF_3$ was derived from this equation]. Column 11 in Table 1 shows the ratios $\varphi^{C_3F_7I}_{max} / \varphi^{CF_3I}_{max}$ calculated from data in the 10th column, while column 12 shows the average values of these ratios, $(\varphi^{C_3F_7I}_{max} / \varphi^{CF_3I}_{max})_{av}$. Since the values of t_{max} are the same for CF_3I and C_3F_7I lasers, we can conclude from the assertion above that

$$\Gamma^{C_3F_7I}(t_{peak}) = (\varphi^{C_3F_7I}_{max} / \varphi^{CF_3I}_{max})_{av} \quad (30)$$

Furthermore, if (26) holds we can assume that the value of $\Gamma(\infty)$ for the model in Sec. 1 is equal to the experimental value $\Gamma^{C_3F_7I}(t_{max})$; then we find from (17), (24), and (30) that

$$k_{11} = \frac{3}{2}\sigma(CF_3I)\,\varphi^{CF_3I}_{max}\left\{[CF_3I]_0\left[1 - \frac{2}{3}(\varphi^{C_3F_7I}_{max} / \varphi^{CF_3I}_{max})_{av}\right]^2\right\}^{-1}. \quad (31)$$

The values of $k_{11}^{C_3F_7}$ calculated from (31) are shown in column 13 of the table. To check the legitimacy of the model in Sec. 1, we calculate τ_{asymp} and τ_{max} from Eqs. (25) and (17) (columns 14 and 15, respectively). We see from the data that Eq. (26) holds for n = 74.2 torr but does not hold for n = 22.3 torr. The value $k_{11} = 1.8 \cdot 10^{-10}$ is more reliable. Quantitative estimates show that $k_{11} \geq 10^{-10}$ for $\Gamma^{C_3F_7I}(t)$ to reach a value of 1.4 by t_{max} when n = 22.3 torr.

The relative amount of the CF_3I working medium at peak output is, in a first approximation, equal to $g(t_{max}) = \exp(-\tau_{max})$. From this equation and the data in column 15 of the table we see that the assumption[20] $[CF_3I] \simeq [CF_3I]_0$ used in deriving Eq. (29) holds within 1-2%.

We are left with the problem of evaluating the temperature of the photolyzed perfluorinated propyl iodide at time t_{max}. The absorption of one pumping photon leads to an increase of 3.6 eV in the energy of the working gas. We adopt 34 cal/(deg · mole) as the specific heat C_3F_7I. Then in the approximation of Sec. 2 of ref. 18, we find, using Eq. (45) of ref. 18, that we would have $T(t_{peak})$ = 368°K in an experiment with n = 22.3 torr and $T(t_{peak})$ = 358°K in an experiment with n = 74.2 torr. Our experimental results thus yield the value $k_{11}^{C_3F_7}(360°K) = (1.5 \pm 0.5) \cdot 10^{-10}$ cm^3/(molecule · sec).

Publisher's note: The numbering system used for the equations corresponds to the Russian original.

Optical methods for studying amplification of elastic surface waves in a stratified system

I. B. Yakovkin, V. V. Petrov, and S. V. Bogdanov

Institute of Semiconductor Physics, Siberian Branch, Academy of Sciences of the USSR, Novosibirsk

(Submitted July 3, 1973)
Zh. Tekh. Fiz., 44, 2002-2007 (September 1974)

The amplification (damping) of elastic surface waves (ESW) in a layer-type amplifier is studied using the scattering of light on ESW. The distribution of the acoustic field is determined both in the amplifying and damping regimes for various levels of acoustical input power. The resulting curves indicate a nonlinearity in density at large ESW amplitudes. A method is shown for determining the magnitude of the "mechanical" damping caused by scattering of ESW and their transformation into other types of waves.

Elastic surface waves (ESW) can be amplified in piezoelectric crystals using the drift of free charge carriers.[1] From a physical viewpoint the most interesting ESW amplifying system is a piezoelectric substrate, in which an ESW is excited, to which is clamped a layer of semiconductor in which the electrons (holes) drift due to a driving electric field, E_T. With such a system it is possible to investigate the interaction of the charge carriers with the ESW and to determine several electrophysical parameters of the semiconductor. The usual method of studying such systems,[2] which involves measuring the signal at a receiver transducer as a function of a variable parameter, only yields an integral value of those quantities which characterize the interaction of the surface wave with the moving carriers. In order to obtain the local characteristics of the interaction we can find the spatial distribution of the acoustic field of ESW in the amplifier by means of scattering of light[3] from the ESW. In particular, by this method it is possible to determine the local amplification coefficient, to determine the coordinates of points where the deviation from linearity becomes noticeable, to explain the effect of various mechanisms for ESW scattering, etc.

We shall discuss the construction of the amplifier, the experimental arrangement, the measured quantities, and the errors involved. The amplifier, which consists of an acoustic line ($LiNbO_3$, Y–Z shear plane) on which ESW are excited by means of opposed rod transducers (f_0 = 85 MHz; aperture 0.18 cm; 16 electrode pairs), is shown in Fig. 1. Charge carrier drift arises in a layer of n-type silicon (resistivity, ρ = 0.6 cm; mobility, μ = 1200 $cm^2/V \cdot sec$; equilibrium concentration in conduction zone, $n_0 = 9 \cdot 10^{15}$ cm^{-3}) epitaxially grown on a p-type silicon substrate. Light from a He–Ne laser (λ = 6328 Å; polarized along the X axis of the crystal; beam diameter 0.2 cm) passes through a lens (L_1 and L_2) and diaphragm (D) system and falls on the backing near normal incidence. Propagating into the crystal and interacting with an ESW, the light beam is split into a basic beam of intensity I_0 and a scattered beam of intensity I_1. It should be noted that the intensity of the scattered light is determined by two factors. These are the phase shift of light rays when they are reflected from periodic curved surfaces and the phase shift due to changes in the refractive index of the layer near the surface[3] due to ESW. Restricting ourselves to small arguments of the Bessel function, it is easy to obtain a simple relation between the experimentally measured ratio I_1/I_0 and the amplitude, u_0, of a surface wave for a given interaction geometry and incident polarization:

$$\frac{I_1}{I_0} = J_1^2\left[\frac{4\pi}{\lambda}\left(u_0 + \int_0^\infty \Delta n dy\right)\right] = J_1^2\left[\frac{4\pi u_0}{\lambda}(1 + 0.1\pi n_0^3)\right], \qquad (1)$$

where J_1 is the first-order Bessel function of the first kind, λ is the wavelength of the light, Δn is the change in refractive index due to the photoelastic effect, and n_0 is the refractive index of lithium niobate.

The amplitude of the ESW calculated from this equation agrees with the amplitude found by the independent technique (diffraction of light reflected from a metallized surface for constant ESW power). The measurement error of 10% in u_0 is determined by the photomultiplier and the instability of the laser.

We note here several additional distinctive features which arise in the measurements.

1. The light is scattered by a spatially damped (growing) elastic wave. This causes the scattered light inten-

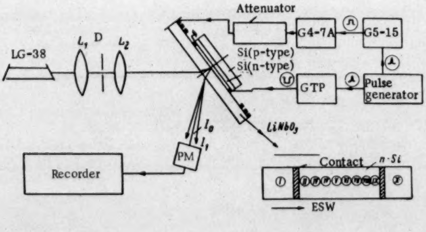

Fig. 1. Diagram of experimental apparatus.

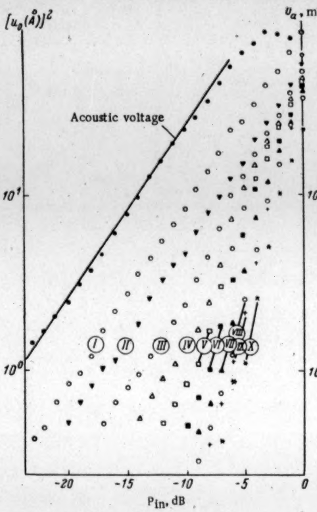

Fig. 2. Dependence of u_0^2 and the acoustic voltage, v_a, on P_{in} at various points in the amplifier for $E_T = 0$.

sity to depend not only on the amplitude of the ESW but also on the damping (amplification) coefficient, which is shown in Eq. (1) by an additional factor,[4] $\exp[(\alpha^2)/2\pi p^2]$, where α is the damping coefficient and p is the Gaussian parameter of the beam intensity distribution $[I \sim \exp\cdot(-\pi p^2 x^2)]$. This factor is of order unity in our experiments; thus, it is ignored in calculating u_0.

2. The electrophysical properties of the silicon layer change due to the light; hence, the amplification conditions change at this point. If the layer is homogeneous the mapping of the distribution of the acoustic field in the ESW amplifier obtained by means of the laser beam will be close to the true distribution. This is confirmed by a special experiment, in which the entire sample is illuminated by the same kind of laser. The form of the distribution is the same for both cases (with illumination and without) within the error limits of the experiment.

3. Measurement of the acoustic field distribution at very small ESW energies is not possible due to noise limits caused by loading of the photomultiplier by light incident on its cathode, which is scattered by inhomogeneities in the substrate.

4. In order to eliminate error in measuring the scattered light caused by shear waves,[5] the latter are eliminated by means of special absorbers of polystyrene tape dissolved in toluene attached to the ends of the acoustic line.

5. The electronic damping (amplification) and mechanical damping of the ESW are measured simultaneously by the optical method as well as by acoustoelectric measurements. The mechanical damping arises due to scattering of ESW, i.e., their transformation into other types of waves at the places of mechanical contact between the semiconductor layer and the substrate.

The goal of this experiment is to study the distribution of the acoustic field in the ESW amplifier in detail both for damping and amplifying regimes with various acoustical input power levels, to measure the amplification (damping) coefficient at each point of the amplifier, and to determine the spatial origin of nonlinear processes in the amplifier.

The relative intensity of scattered light is measured for reflection from the points I to X (Fig. 1, lower right) as a function of the acoustic power emitted by the transducer. The distance between neighboring points is 0.2 cm. This dependence is shown in Figs. 2 and 3 for damping and amplification, respectively. The 0 dB level (on the abscissa) corresponds to an acoustic power of 16 mW. It is possible to raise the maximum amplification (damping) coefficient by means of additional illumination. With the illumination chosen here the maximum amplification is observed for $E_T = 820$ V/cm. Damping is measured for the same illumination at $E_T = 0$. From the data of Figs. 2 and 3 it is possible to determine the acoustic field distribution along the amplifier for various values of input acoustical power, P_{in}. The resulting distributions are shown in Fig. 4. The damping (amplification) coefficient at every point of the amplifier for several values of P_{in} is shown in Fig. 5.

DISCUSSION OF RESULTS

In following the curves of Figs. 2 and 3 we distinguish three amplification (damping) regimes depending on the input acoustical power: a) for $P_{in} = -20$ dB and less the damping (amplification) coefficient is large and is independent of the input acoustic power (linear regime); b) for P_{in} between −15 and −7 dB the damping (amplification) coefficient decreases as the input power increases; and c) for P_{in} greater than −2 dB the electron damping (amplification) goes to zero. Only "mechanical" damping remains and its magnitude remains constant for larger P_{in}.

Apparently, the nonlinear behavior of the ESW amplitude in damping and amplification is due to a concentration effect. For $u_0 = 2.6$ Å the deviation from linearity reaches 10%.

The dependence of the acoustic voltage on P_{in} also indicates a concentration nonlinearity in ESW damping, since the deviation from linearity is observed for the same values of P_{in} both for the damping and amplification curves. It should be noted that the acoustic voltage is produced not only by the fundamental of the wave emitted in the wave transformation but also by its higher harmonics, which arise because of the nonlinearity of the system. Thus, although the coefficient of electronic damping (amplification) at the first harmonic for $P_{in} = -2$ dB is zero, the total acoustic voltage does not go to zero (cf. Fig. 2).

In order to verify this assumption of a concentration nonlinearity we calculate the nonequilibrium electron concentration due to the piezoelectric field of the ESW and compare it with the equilibrium concentration in the conduction zone. The mechanical stress is given by

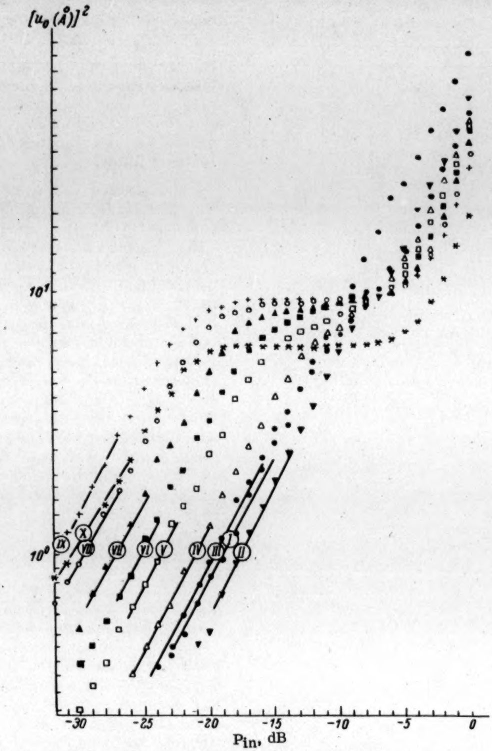

Fig. 3. Dependence of u_0^2 on P_{in} at various points in the amplifier for E_T = 820 V/cm.

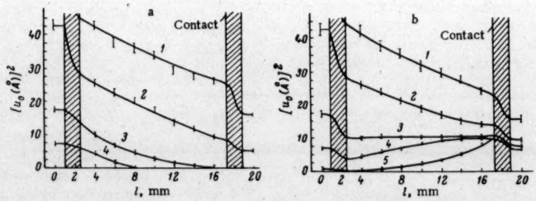

Fig. 4. Distribution of u_0^2 along the amplifier for various P_{in} with: a) E_T = 0; b) E_T = 820 V/cm. 1) −1 dB; 2) −3 dB; 3) −7 dB; 4) −11 dB; 5) −20 dB.

$$\sigma_{kl}=C_{ijkl}\zeta_{ij}-\frac{1}{4\pi}h_{nkl}D_n \qquad (2)$$

which goes to zero at a free boundary, while

$$\operatorname{div}\bar{D}=4\pi e\tilde{n}, \qquad (3)$$

where ζ_{ij} are the elastic deformations, c_{ijkl} is the matrix of elastic coefficients, h_{nkl} is the matrix of piezoelectric

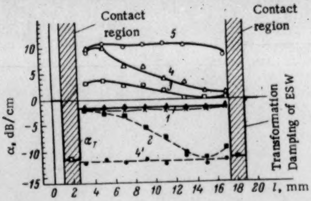

Fig. 5. Amplification (damping) coefficient in different parts of the amplifier for various values of P_{in}. 1) 0 dB; 2) −5 dB; 3) −10 dB; 4, 4')− 15; 5) −25 dB. E_T: 1, 3-5) 820 V/cm; 4) 0.

constants, $\bar{D}$ is the electric induction vector, e is the electronic charge, and $\tilde{n}$ is the nonequilibrium electron concentration.

Simulateneous solution of these equations for the semiconductor and the piezoelectric yields a relation between U_0 and $\tilde{n}$:

$$\tilde{n}=\frac{k^2u_0}{eh_{31}}\left[c_{13}+c_{11}-2\frac{h_{22}}{h_{15}}c_{44}+\left(2-\frac{h_{22}}{h_{15}}\right)c_{14}\right], \qquad (4)$$

where k is the wave vector of the ESW. Substituting the known values of constants and putting u_0 = 2.6 Å in Eq. (4) we obtain

$$\tilde{n}=9.5\cdot 10^{15}\,\mathrm{cm}^{-3}, \text{i.e., } \tilde{n}\simeq n_0.$$

These estimates confirm that when the amplitude of the displacement reaches 2.6 Å a concentration nonlinearity begins. As is known, under these conditions the second harmonic of the fundamental signal appears. We have made an attempt to measure it directly. For this, the intensity of light scattered at twice the scattering angle for the fundamental is measured (according to our estimates, second-order scattering from the ESW at the fundamental frequency is two orders of magnitude less than first-order scattering at the second harmonic of the ESW. It seems that in the nonlinear regime the second harmonic still only grows insignificantly, while the fundamental is no longer amplified. In fact, the measured amplitude of the second harmonic at the point X is three times larger than at point I.

Following the curves of Fig. 3 it is possible to calculate a dynamic amplification zone, which, when the silicon layer is strongly pressed to the acoustic line, is bounded above for an acoustic input power of 160 μW. For a weaker compression the dynamic zone widens considerably due to the nonuniform gap.

For P_{in} > 2 dB the mechanical damping is independent of the input signal magnitude and we conclude that the Hooke nonlinearity does not appears. Thus, if it is necessary to determine exactly the magnitude of the mechanical (transformation) damping, it is sufficient to take the acoustic field distribution in a known nonlinear regime. Hence, from Fig. 5 it is clear that for P_{in} = 0 dB the damping at each of the aluminum contacts of width 0.13 cm is of order 1.75 dB, while transformation damping at the silicon−lithium niobate interface of length 1.45 cm leads to mechanical losses of 2 dB.

The authors thank M. D. Levin for useful discussion.

Magnetohydrodynamic stability of a neutral current layer in a plasma

S. V. Bulanov

P. N. Lebedev Physics Institute,
Academy of Sciences of the USSR, Moscow

(Submitted February 26, 1974)
Zh. Tekh. Fiz., 44, 2008-2010 (September 1974)

The stability of a bounded plane layer of a current-carrying plasma has been investigated. The low-conductivity limit is considered, taking account of the compressibility of the medium and the thermal conductivity. The layer is found to be unstable in the long-wave limit. The characteristic decay rate is of the order of the isothermal acoustic velocity.

The investigation of the stability of a neutral current layer is of interest both for astrophysical applications,[1,2] and also for a laboratory plasma.[3] It is known that a plane current layer is stable in the infinite-conductivity limit. Taking account of the finite electrical conductivity leads to various instabilities.[4] The most interesting of these instabilities for astrophysical applications is the tearing-mode type. As a result of this instability the current layer splits into plasmoids, stretched along the current direction, and it is possible to have electric fields (in the limit of the order of the magnetic-field intensity outside the layer) and effective acceleration of charged particles. The tearing instability has been considered in many papers, both in the magnetohydrodynamic (MHD) approximation,[4] and also within the framework of the Vlasov equation.[5,6]

Below we will consider the stability of a current layer in the MHD approximation in the low-conductivity limit. This corresponds to the approximation S → 0, where $S = \sqrt{4\pi}\sigma h^2 L^2/\rho^{1/2} c^2$. Here σ is the electrical conductivity, h is the magnetic-field gradient inside the layer, L is the half-thickness of the layer, and ρ is the density. The tearing instability has been considered in this limit in the MHD approximation in an incompressible homogeneous fluid in ref. 4. However, in the low-conductivity limit in the problem being considered, it is imposible to disregard the compressibility of the medium.1) Moreover, the limit $\sigma \to 0$ indicates that the Joule dissipation of the magnetic field is large; therefore, in this case it is necessary to consider heat-transfer processes

1. We consider a plane layer of plasma of thickness 2L, located in the yz plane. The plasma is confined by the magnetic field produced by the current flowing in it. The current is directed along the oz axis. The magnetic field has only a y component H_y, equal to hx inside the layer ($|x| < L$) and hL outside the layer ($|x| > L$). The density distribution that corresponds to the equality of the magnetic and gas pressures at constant temperature (T_0 = const) is $\rho_0(x) = \rho(0)(1 - x^2/L^2)$. There is no plasma outside the layer. We neglect the viscosity. In this case the system of MHD equations can be written in the form

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v}\nabla)\mathbf{v} = -\frac{1}{\rho}\nabla p + \frac{1}{4\pi\rho}[\mathrm{curl}\,\mathbf{H}, \mathbf{H}], \tag{1}$$

$$\frac{\partial \rho}{\partial t} + \mathrm{div}\,(\rho\mathbf{v}) = 0, \tag{2}$$

$$\frac{\partial \mathbf{H}}{\partial t} = \mathrm{curl}[\mathbf{v}, \mathbf{H}] - \frac{c^2}{4\pi}\mathrm{curl}\frac{1}{\sigma}\mathrm{curl}\mathbf{H}, \tag{3}$$

$$\mathrm{div}\,\mathbf{H} = 0, \tag{4}$$

$$\rho T\left(\frac{\partial s}{\partial t} + \mathbf{v}\nabla s\right) = \mathrm{div}\,(\chi\nabla T) + \frac{c^2}{(4\pi)^2\sigma}(\mathrm{curl}\mathbf{H})^2. \tag{5}$$

A high-temperature plasma can be assumed to be an ideal gas; the pressure is then

$$p = \frac{(1+z)\varkappa}{M}\rho T = \rho v_T^2, \tag{6}$$

where z is the effective ion charge, M is the ion mass, and $v_T^2 = (1 + z)\varkappa T/M$ is the square of the isothermal acoustic velocity. The entropy per unit mass is

$$s = \frac{(1+z)\varkappa}{M}\ln\frac{T^{3/2}}{\rho}. \tag{7}$$

We neglect the weak density dependence of the coefficients of electrical and thermal conductivity. We assume that $\sigma(T_0) \sim T_0^{3/2}$ is constant inside the layer and is zero outside it. The thermal conductivity $\chi(T_0) \sim T_0^{5/2}$ is assumed to be everywhere constant.

2. We now investigate the stability of a neutral current layer with respect to small perturbations. We represent the perturbed quantities in the form $f_1(x, y, t) = f_1(x)\exp(-i\omega t + iky)$. We consider the perturbations to be homogeneous in z. Linearizing the system of equations (1)-(5) taking account of T_0 = const, we obtain

$$(\rho_0 v_{1x})'' - q_T^2\rho_0 v_{1x} = -i\omega\left(\frac{\rho_0 T_1}{T_0}\right)' - \frac{hxq_T^2}{4\pi\omega k}(H_{1x}'' - k^2 H_{1x}) + \frac{\omega h}{4\pi k v_T^2}H_{1x}' + \frac{kh}{4\pi\omega}H_{1x}(\delta(x+L) - \delta(x-L)), \tag{8}$$

$$H_{1x}'' - \left(k^2 - i\frac{4\pi\sigma_0\omega}{c^2}\right)H_{1x} = -i\frac{4\pi\sigma_0 hxk}{c^2}v_{1x} - i\frac{3}{2}\frac{kh}{T_0}T_1 + v_{1x}\frac{kh}{\omega}(\delta(x+L) - \delta(x-L)), \tag{9}$$

$$\begin{aligned} T_1'' - \left[k^2 + \frac{3c^2h^2}{2(4\pi)^2\sigma_0\chi_0 T_0} - i\omega\frac{v_T^2\rho_0\left(\frac{3}{2}q_T^2 + k^2\right)}{T_0\chi_0 q_T^2}\right]T_1 &= -i\frac{2c^2h}{(4\pi)^2\sigma_0\chi_0 k}(H_{1x}'' - k^2H_{1x}) - \frac{\omega kh}{4\pi q_T^2\chi_0}H_{1x} \\ &+ i\frac{c^2h^2}{(4\pi)^2\omega\chi_0\sigma_0}v_{1x}[\delta(x+L) - \delta(x-L)] \\ &- \frac{\omega^2}{q_T^2\chi_0}(\rho_0 v_{1x})' - \frac{v_T^2}{\chi_0}\rho_0' v_{1x}. \end{aligned} \tag{10}$$

In the low-conductivity limit (S → 0) we obtain

$$(\rho_0 v_{1x})'' - q_T^2 \rho_0 v_{1x} = -i\omega\left(\frac{\rho_0}{T_0} T_1\right)' + \frac{\omega h}{4\pi k v_T^2} H'_{1x}$$

$$+ i\frac{3}{2}\frac{h^2 x q_T^2}{4\pi\omega T_0} T_1 - \left(\frac{h^2 x q_T^2}{4\pi\omega^2} v_{1x} - \frac{kh}{4\pi\omega} H_{1x}\right)(\delta(x+L) - \delta(x-L)), \quad (11)$$

$$H''_{1x} - k^2 H_{1x} = -i\frac{3}{2}\frac{kh}{T_0} T_1 + \frac{kh}{\omega} v_{1x}(\delta(x+L) - \delta(x-L)), \quad (12)$$

$$T''_1 - Q^2 T_1 = -i\frac{c^2 h^2}{(4\pi)^2 \omega\sigma_0\chi_0} v_{1x}(\delta(x+L) - \delta(x-L)). \quad (13)$$

Here $q_T^2 = k^2 - \omega^2/v_T^2$, $Q^2 = k^2 - 3c^2h^2/(4\pi)^2 2\sigma_0\chi_0 T_0$. The boundary conditions are represented in the form of sources on the right sides of the equations. Below we consider perturbations, corresponding to tearing, that are mirror symmetric with respect to the plane x = 0, i.e., $v_{1x}(x) = -v_{1x}(-x)$, $H_{1x}(x) = H_{1x}(-x)$, $T_1(x) = T_1(-x)$. Then the solution of the system (11)-(13) will be

$$T_1(x) = -i\frac{c^2h^2 e^{-QL} v(L)}{(4\pi)^2 \sigma_0\chi_0 Q\omega} \operatorname{ch} Qx, \quad (14)$$

$$H_{1x}(x) = \left(\frac{3c^2h^2e^{-QL}}{4(4\pi)^2\sigma_0\chi_0 Q T_0}\int_{-L}^{L} e^{-k|x-x'|}\operatorname{ch}(Qx')\,dx' + e^{-kL}\operatorname{ch}(kx)\right)\frac{h}{\omega} v(L), \quad (15)$$

$$\rho_0 v_{1x}(x) = \Biggl\{\frac{-c^2e^{-QL}}{8\pi\sigma_0\chi_0 Q T_0}\int_{-L}^{L} e^{-q_T|x-x'|}\operatorname{sign}(x-x')\,\rho_0(x')\operatorname{ch} Qx'\,dx'$$

$$-\frac{3c^2h^2e^{-QL}q_T}{(4\pi)^2 4\omega^2\sigma_0\chi_0 Q T_0}\int_{-L}^{L} e^{-q_T|x-x'|}x'\operatorname{ch} Qx'\,dx'$$

$$-\frac{q_T L e^{-q_T L}}{\omega^2}\operatorname{sh} q_T x + \frac{k e^{-q_T L}}{\omega^2 q_T}\operatorname{sh} q_T x$$

$$\times\left[\frac{3c^2h^2e^{-(Q+k)L}}{4(4\pi)^2\sigma_0\chi_0 Q T_0}\left(\frac{\operatorname{sh}(k+Q)L}{(k+Q)L} + \frac{\operatorname{sh}(k-Q)L}{(k-Q)L}\right) + e^{-kL}\operatorname{ch} kL\right]$$

$$+\frac{1}{2v_T^2 q_T}\Biggl[\frac{3c^2h^2e^{-QL}}{4(4\pi)^2\sigma_0\chi_0 Q T_0}$$

$$\times\int_{-L}^{L}\int_{-L}^{L} e^{-q_T|x-x'|-k|x'-x''|}\operatorname{sign}(x'-x'')\operatorname{ch} Qx''\,dx'\,dx''$$

$$-e^{-kL}\int_{-L}^{L} e^{-q_T|x-x'|}\operatorname{sh} kx'\,dx'\Biggr\}\frac{h^2}{4\pi} v(L). \quad (16)$$

Here v (L) is the value of v_{1x} on the boundary x = +L. Taking into account that $\rho_0 v_{1x}(x = \pm L) = 0$ (the material flow through the boundary equals zero), we obtain from (16), setting x = L, a dispersion equation relating ω and k.

We consider perturbations with wavelength much greater than the layer thickness. In other words, we assume the inequalities $kL \ll 1$ and $q_T L \ll 1$ to be satisfied. In this limit we obtain the instability growth rate from (16):

$$\gamma = \frac{\sqrt{kL}}{\tau_T}$$

$$\times\left\{\frac{1 + \left(1 - \frac{k^2}{Q^2}\right)e^{-QL}\operatorname{sh} QL}{\dfrac{1 + \left(1 - \frac{k^2}{Q^2}\right)e^{-QL}\operatorname{sh} QL\left[Q^2L^2 + (1 - QL\operatorname{cth} QL)\left(3 + \frac{4}{3}\frac{\tau_A^2}{\tau_T^2}\right)\right]}{Q^2L^2}}\right\}^{1/2}. \quad (17)$$

Here,

$$\tau_T = \frac{L}{v_T}, \quad \tau_A = \frac{L}{v_A} \equiv \frac{\sqrt{4\pi\rho(0)}}{h}. \quad (18)$$

In the limit $Q^2 \to k^2$, which corresponds to $\chi_0 \to \infty$ (high thermal conductivity), we obtain $\gamma = \sqrt{kL}/\tau_T$. Low thermal conductivity ($\chi_0 \to 0$) corresponds to $L^2Q^2 \to \infty$. In this case also $\gamma = \sqrt{kL}/\tau_T$. We can show[7] that for short-wave perturbations ($kL \gg 1$) the layer is stable.

Thus, we see that in the MHD approximation in the low-conductivity limit a neutral current layer is unstable. The characteristic instability growth rate is of order τ_T and depends weakly on thermal conductivity.

In conclusion we thank A. A. Rukhadze and S. I. Syrovatskii for their interest.

Radiation of electromagnetic waves by a modulated electron beam

S. G. Pankratov

(Submitted December 24, 1973)
Zh. Tekh. Fiz., 44, 2011-2014 (September 1974)

We calculate the intensity of coherent electromagnetic radiation from a velocity-modulated beam of charged particles. The radiation field is calculated by using the velocity distribution function for the beam particles found in the first approximation in the small parameter eI/mv_0^3, where I is the beam current. We show that the spectral distribution of the radiation intensity has sharp maxima at the modulation frequency and its harmonics. The results are valid in the region in which spreading of the beam affects the radiation.

1. In the study of electron beams particular attention is focused on the interaction of beams with a plasma.[1-4] The radiation of electromagnetic waves by an electron beam itself has not been adequately investigated. Experiment shows that the electromagnetic radiation from a modulated electron beam is intense enough[5] to permit the use of a beam as a radiator. The spectral distribution of the radiation intensity has sharp maxima at the modulation frequency and its harmonics.[5-7] The use of such a radiator can be justified, for example, if it is necessary to transmit information through a dense plasma layer. Electromagnetic waves are appreciably attenuated in passing through a plasma layer of thickness l larger than $c/\omega\sqrt{\varepsilon}$. If the density of the beam remains higher than that of the plasma in the region near the injector, where the spreading of the beam can be neglected, the plasma has a negligible effect on the motion of the beam. The characteristic spreading length of a beam is of the order $amv_0^3/2eI$, where a is the initial radius of the beam, v_0 is the initial velocity of the electrons, and I is the beam current. Thus, for $l \ll amv_0^3/2eI$ electromagnetic power is transmitted beyond the limits of the plasma layer.

2. The electric and magnetic fields produced by the beam are given by

$$\left.\begin{aligned}\Delta\mathbf{E}-\frac{1}{c^2}\frac{\partial^2\mathbf{E}}{\partial t^2}&=4\pi e\int d^3v\left(\nabla f+\frac{\mathbf{v}}{c^2}\frac{\partial f}{\partial t}\right),\\ \Delta\mathbf{H}-\frac{1}{c^2}\frac{\partial^2\mathbf{H}}{\partial t^2}&=\frac{4\pi e}{c}\int d^3v\,[\mathbf{v}\nabla]\,f,\end{aligned}\right\} \tag{1}$$

where $f(\mathbf{r}, \mathbf{v}, t)$ is the distribution function for the beam electrons. This function satisfies the collisionless Boltzmann equation which, in turn, contains E and H

$$\frac{\partial f}{\partial t}+\mathbf{v}\frac{\partial f}{\partial \mathbf{r}}+\frac{e}{m}\left\{\mathbf{E}+\frac{1}{c}[\mathbf{vH}]\right\}\frac{\partial f}{\partial \mathbf{v}}=0. \tag{2}$$

Using Fourier components we can write the solution of Eq. (1) at large distances, $R \gg kL^2$, $kR \gg 1$, where $k = \omega/c$ and $L \lessdot amv_0^3/2eI$ is the effective length of the beam, in the form[8]

$$\mathbf{H}_\omega \approx \frac{ie^{ikR}}{cR}[\mathbf{kj}(\mathbf{k},\omega)];\quad \mathbf{E}_\omega=[\mathbf{H}_\omega\mathbf{n}];\quad \mathbf{n}=\frac{\mathbf{R}}{R}, \tag{3}$$

where we have used the notation

$$\mathbf{j}(\mathbf{k},\omega)=e\int d^3r\int_{-\infty}^{\infty}dt\,e^{i\omega t-i\mathbf{kr}}\int d^3v\,\mathbf{v}f(\mathbf{r},\mathbf{v},t);\quad \mathbf{k}=\frac{\omega}{c}\mathbf{n}. \tag{4}$$

The distribution function $f(\mathbf{r}, \mathbf{v}, t)$ can be found by using the fact that the velocity of the electrons is small in comparison with the velocity of light. The terms on the right-hand sides of Eq. (1) containing v/c are omitted and the effect of the magnetic field on the motion of the particles is neglected. If the effective beam dimensions are small in comparison with the wavelength, the self-consistent field is reduced to the Coulomb repulsion of the charges

$$\mathbf{E}(\mathbf{r},t)=-e\int d^3v\,d^3r'\frac{\partial}{\partial \mathbf{r}}\frac{f(\mathbf{r}',\mathbf{v},t)}{|\mathbf{r}-\mathbf{r}'|}. \tag{5}$$

The system of equations (1) and (2) must be supplemented by the boundary condition which determines the way the beam is modulated. As an example we consider velocity modulation. By taking the x axis along the initial velocity of the beam we can write

$$f(\mathbf{r},\mathbf{v},t)|_{x=0}=\Theta(a-r_\perp)\,n_0\varphi(\mathbf{v}_\perp,\ v_x-v_0-\Delta v\cos\Omega t), \tag{6}$$

where $\varphi(\mathbf{v})$ is the initial electron velocity distribution function, normalized to unity, and Ω is the modulation frequency

$$\Theta(a-r_\perp)=\begin{cases}0, & r_\perp>a,\\ 1, & r_\perp\leqslant a.\end{cases} \tag{7}$$

We solve Eq. (2) by successive approximations, using the fact that the interaction energy of the electrons is small in comparison with the kinetic energy

$$\frac{U_{\text{eff}}}{\dfrac{mv_0^2}{2}}\sim\frac{2\pi a^2n_0e^2}{mv_0^2}=\frac{2eI}{mv_0^3}\ll 1. \tag{8}$$

In the zeroth approximation in the interaction parameter the distribution function has the form

$$f^{(0)}=\Theta(a-r_\perp)\,n_0\varphi\left[v_\perp,\ v_x-v_0-\Delta v\cos\Omega\left(t-\frac{x}{v_x}\right)\right], \tag{9}$$

while the perturbation of the distribution function, including the interaction of the beam electrons, is

$$\frac{\partial f^{(1)}}{\partial t}+\mathbf{v}\frac{\partial f^{(1)}}{\partial \mathbf{r}}-\frac{e^2}{m}\left(\int d^3v'd^3r'\frac{\partial}{\partial \mathbf{r}}\frac{f^{(0)}(\mathbf{r}',\mathbf{v}',t)}{|\mathbf{r}-\mathbf{r}'|}\right)\frac{\partial f^{(1)}}{\partial \mathbf{v}}=0. \tag{10}$$

In this equation the electric field which acts on the beam particles can be written in the form

$$\mathbf{E}^0(\mathbf{r},t)=-e\frac{\partial}{\partial \mathbf{r}}\int d^3r'd^3v\frac{f^{(0)}(\mathbf{r}',\mathbf{v},t)}{|\mathbf{r}-\mathbf{r}'|}=$$

$$=-4\pi en_0a\frac{\partial}{\partial \mathbf{r}}\sum_{\nu=-\infty}^{\infty}i^\nu e^{i\nu\Omega t}\int_{-\infty}^{\infty}\frac{ds}{2\pi}g\left(\frac{s}{\Delta v}\right)J_\nu(s)\int_{-\infty}^{\infty}d\xi\,e^{-is\xi-\frac{i\nu\Omega x}{v_0+\xi\Delta v}}\times$$

$$\times \int_0^\infty \frac{dl_\perp J_0(l_\perp r_\perp) J_1(l_\perp a)}{l_\perp^2 + \left(\frac{\nu\Omega}{v_0 + \xi\Delta v}\right)^2}, \tag{11}$$

where

$$g(x) = \int_{-\infty}^{\infty} du e^{iux} \int d^2 v_\perp \varphi(\mathbf{v}_\perp, u) \tag{12}$$

is the Fourier transform of the initial longitudinal velocity distribution function, $\xi \equiv (v_\parallel - v_0)/\Delta v$, and $J_\nu(s)$ is the Bessel function.

The effective values of ξ which contribute to the integral in (11) are of the order of unity; therefore the term $\xi\Delta v$ in the denominator can be neglected in comparison with v_0. The quantity $\xi\Delta v$ in the exponent cannot be neglected. It is evident that in this case the time dependence of the field vanishes. However, using the fact that $\Delta v/v_0 \ll 1$ the exponent can be expanded in powers of $\Delta v/v_0$. If the effective values of ν in the sum are such that

$$\frac{\nu\Omega L}{v_0}\left(\frac{\Delta v}{v_0}\right)^2 \ll 1, \tag{13}$$

only the first two terms in the expansion in the exponent need be retained. Condition (13) is not too stringent since those harmonics whose wavelengths are comparable with the length of the beam, i.e., $\nu \sim c/\Omega L$, make a significant contribution to the radiation. Thus when the condition

$$\left(\frac{\Delta v}{v_0}\right)^2 \ll \frac{v_0}{c} \tag{14}$$

is satisfied, after performing the integration in (11) we have

$$\mathbf{E}^0 = 4\pi e n_0 a^2 \frac{\partial}{\partial \mathbf{r}} \sum_{\nu \neq 0} i^\nu e^{i\nu\Omega\left(t - \frac{x}{v_0}\right)} \frac{I_0\left(\frac{\nu\Omega r_\perp}{v_0}\right) K_1\left(\frac{\nu\Omega a}{v_0}\right)}{\frac{\nu\Omega a}{v_0}} \times g\left(\frac{\nu\Omega x}{v_0^2}\right) J_\nu\left(\frac{\nu\Omega x}{v_0}\frac{\Delta v}{v_0}\right), \tag{15}$$

where $I_0(x)$ is the Bessel function and $K_1(x)$ is the Macdonald function. $\mathbf{E}^0(\mathbf{r}, t)$ is the variable part of the electric field produced by the modulated beam when spreading can be neglected. In the region in which the spreading of the beam is small the Coulomb repulsion of the electrons changes the velocities of the particles by an amount which is small in comparison with the initial velocity

$$|\mathbf{v} - \mathbf{v}_0| \ll v_0. \tag{16}$$

When condition (16) is satisfied $\mathbf{v}$ can be replaced by $\mathbf{v}_0$ in Eq. (10). Then the solution of Eq. (10) can be written in the form

$$f^{(1)} = n_0 \Theta(a - r_\perp) \varphi\left\{\mathbf{v}_\perp - \frac{e}{mv_0}\int_0^x dx' \mathbf{E}_\perp^{(0)}\left(t - \frac{x - x'}{v_0}\right);\right.$$

$$\left. v_\parallel = v_0 - \Delta v \cos\Omega\left(t - \frac{x}{v_0}\right) - \frac{e}{mv_0}\int_0^x dx' \mathbf{E}_\parallel^0\left(\mathbf{r}_\perp, x', t - \frac{x - x'}{v_0}\right)\right\}. \tag{17}$$

Using (15) it is easy to see that the inequality (16) is equivalent to

$$L \ll a \frac{mv_0^2}{2eI}. \tag{18}$$

3. In calculating the radiation it is convenient to rewrite (3) in the form

$$\mathbf{E}_\omega = -\frac{ik}{cR} e^{ikR} \boldsymbol{\theta} [j_\parallel(\omega, \mathbf{k}) \cos\theta - j_\perp(\omega, \mathbf{k}) \sin\theta]$$

$$= \frac{k}{cR} e^{ikR} \int_{-\infty}^{\infty} dt e^{i\omega t} \int d^3 r e^{-i\mathbf{kr}} \left[\mathbf{n}\left[\mathbf{n}\frac{\partial}{\partial \mathbf{q}}\right]\right] f^{(1)}(\mathbf{r}, \mathbf{q} = 0, t), \tag{19}$$

where $\boldsymbol{\theta}$ is a unit vector in a spherical coordinate system with its polar axis along the x axis; the vector $\mathbf{j}(\omega, \mathbf{k})$ is given by (4), and $f(\mathbf{r}, \mathbf{q}, t) = \int d^3 v e^{-i\mathbf{qv}} f(\mathbf{r}, \mathbf{v}, t)$.

Using (15) and assuming that the radius of the beam is small in comparison with the wavelength of the radiation we obtain the following expression for the field at large distances:

$$\mathbf{E}_\omega = -\frac{ike^{ikR}}{cR} \boldsymbol{\theta} 8\pi I \sin\theta \frac{2eI}{mv_0^3} \sum_{\nu \neq 0} i^\nu D_\nu(\cos\theta) \frac{K_1\left(\frac{\nu\Omega a}{v_0}\right) I_1\left(\frac{\nu\Omega a}{v_0}\right)}{\left(\frac{\nu\Omega a}{v_0}\right)^2}, \tag{20}$$

where

$$D_\nu(\cos\theta) \equiv \int_0^\infty dx e^{-i\left(k\cos\theta + \frac{\nu\Omega}{v_0}\right)x} g\left(\frac{\nu\Omega x}{v_0^2}\right) J_\nu\left(\frac{\nu\Omega x}{v_0}\frac{\Delta v}{v_0}\right). \tag{21}$$

The upper limit of the integral in (21) is taken as infinity. This is admissible if

$$\frac{\Omega L}{v_0} \sim \frac{\Omega a}{v_0}\frac{mv_0^3}{2eI} \gg 1, \tag{22}$$

i.e., the beam is long enough to contain several bunches.

Assuming that the initial velocity distribution is Maxwellian with a longitudinal temperature T, from (12) we obtain

$$g\left(\frac{\nu\Omega x}{v_0^2}\right) = \exp\left\{-\frac{T}{2mv_0^2}\left(\frac{\nu\Omega x}{v_0}\right)^2\right\}. \tag{23}$$

We note that the condition $T \ll mv_0^2$ does not ensure that the beam is cold since the initial narrow distribution function spreads as the distance from the point of injection increases. This spreading is greater for higher modulation frequencies and for higher harmonics. The decrease in the intensity of coherent radiation due to thermal velocities can be neglected if the temperature and the effective beam length satisfy the inequality

$$\frac{T}{mv_0^2}\left(\frac{\Omega L}{v_0}\right)^2 \ll 1, \tag{24}$$

which can be rewritten in the form

$$T \ll e^2 n_0 a^2 \frac{e^2 n_0}{m\left(\frac{\Omega}{2\pi}\right)^2}. \tag{25}$$

If conditions (24) and (25) are satisfied the longitudinal velocity distribution function can be considered a delta function over the region in which spread of the beam is small. In this case $g(\nu \Omega x/v_0^2) = 1$. Using the value of integral (21) given in ref. 9 we obtain

$$D_\nu(\cos\theta) = \frac{e^{-\frac{i\pi}{2}(\nu+1)}\left(\frac{\nu\Omega}{v_0}\right)^\nu\left(\frac{\Delta v}{v_0}\right)^\nu}{\sqrt{\left(\frac{\nu\Omega}{v_0}+k\cos\theta\right)^2-\left(\frac{\nu\Omega}{v_0}\right)^2\left(\frac{\Delta v}{v_0}\right)^2}\left(\frac{\nu\Omega}{v_0}+k\cos\theta+\sqrt{\left(\frac{\nu\Omega}{v_0}+k\cos\theta\right)^2-\left(\frac{\nu\Omega}{v_0}\frac{\Delta v}{v_0}\right)^2}\right)^\nu}. \tag{26}$$

Substituting (26) into (20) and retaining only the first nonvanishing term in the expansion in v_0/c (quadrupole) we obtain the radiation field

$$\mathbf{E}_\omega \approx -\frac{ke^{ikR}}{cR}\,64\pi I\sin 2\theta\,\frac{2eI}{mv_0^3}\,\frac{ka^2}{\left(\frac{\Omega a}{v_0}\right)^4}\sum_{\nu=1}^{\infty}\frac{\nu+1}{\nu^4}\,\frac{\left(\frac{\Delta v}{v_0}\right)^\nu}{2^\nu} \times K_1\left(\frac{\nu\Omega a}{v_0}\right)I_1\left(\frac{\nu\Omega a}{v_0}\right)\delta(\omega-\nu\Omega). \tag{27}$$

Since the field decreases rapidly as the harmonic number increases, we can limit ourselves to the term with $\nu = 1$. In the limiting case of a narrow beam, $a \ll v_0/\Omega$, the energy radiated by the beam per unit time is

$$\frac{d\varepsilon(\mathbf{n},\omega)}{d\Omega d\omega} = \frac{c}{4\pi^2}|\mathbf{E}_\omega|^2 \approx \frac{I^2\sin^2 2\theta}{c}\,\frac{(ka)^4}{\left(\frac{\Omega a}{v_0}\right)^8}\left(\frac{\Delta v}{v_0}\right)^2\left(\frac{2eI}{mv_0^3}\right)^2\delta(\omega-\Omega).$$

We note that for high modulation frequencies (22) the radiation intensity decreases as the frequency increases.

Skin effect in a constant magnetic field

Z. K. Yankauskas, V. I. Chesonis, and V. G. Skripnik

(Submitted October 10, 1973)
Zh. Tekh. Fiz., 44, 2015-2017 (September 1974)

The skin effect is studied in a conducting plate in alternating and constant magnetic fields. The effective magnetic permeability is determined in the alternating magnetic field.

We consider an infinite conducting plate bounded by the planes $z = \pm a$. A conductor is wound around the plate perpendicularly to the x axis. An alternating current of frequency ω flows through the conductor producing an alternating magnetic field (Fig. 1).

$$\mathscr{H} = H\cos\omega t, \quad |z| = a. \tag{1}$$

In the classical skin effect the field $\mathscr{H}_x$ penetrates the conducting plate[1] only to the skin depth δ. For $a \gg \delta$ the alternating magnetic field inside the plate is essentially zero.

If the plate is in a sufficiently strong constant magnetic field along the z axis, helical waves (helicons) are excited in the plate,[2] and the alternating magnetic field $\mathscr{H}_x$ penetrates well beyond the skin depth. The distribution of helical waves at microwave frequencies in a waveguide is calculated in ref. 3. We consider the skin effect for a range of low and high frequencies (up to ~ 100 MHz) in the presence of helicons.

If there is no constant magnetic field the alternating magnetic field $\mathscr{H}_x$ given by Eq. (1) excites eddy currents in the plate in planes perpendicular to the x axis. When there is a constant magnetic field $H_z = H_0$ in the plate Hall currents are produced in planes perpendicular to the y axis.[4]

Since we are considering an infinite plate, i.e., one whose transverse dimensions are much greater than its thickness, we can limit ourselves to the transverse current components j_x and j_y (plane wave approximation). Assuming for simplicity that the conductivity of the plate is due to electrons with an isotropic mass, we write the equations for the current components j_x and j_y:

$$\left.\begin{aligned}\frac{d}{dt}j_x + \tau^{-1}j_x - \frac{eH_0}{mc}j_y = \frac{Ne^2}{m}E_x,\\ \frac{d}{dt}j_y + \tau^{-1}j_y + \frac{eH_0}{mc}j_x = \frac{Ne^2}{m}E_y,\end{aligned}\right\} \tag{2}$$

where e, m, N, and τ are respectively the electron charge, effective mass, density, and mean free time; E_x and E_y are the components of the alternating electric field, and H_0 is the constant magnetic field along the z axis. The effect of the alternating magnetic field is neglected in comparison with H_0.

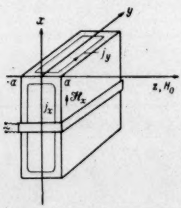

Fig. 1

Equation (2) must be considered together with Maxwell's equations

$$\left.\begin{aligned}\operatorname{curl}\mathscr{E} = -\frac{1}{c}\frac{\partial\mathscr{H}}{\partial t},\\ \operatorname{curl}\mathscr{H} = \frac{1}{c}\frac{\partial\mathscr{E}}{\partial t} + \frac{4\pi}{c}J.\end{aligned}\right\} \tag{3}$$

We seek the solution of the system of equations (2) and (3) in the form

$$\mathscr{E} = \operatorname{Re}\bar{E}\exp(-i\omega t), \quad \mathscr{H} = \operatorname{Re}\bar{H}\exp(-i\omega t), \quad J = \operatorname{Re}\bar{J}\exp(-i\omega t), \tag{4}$$

where the complex amplitudes $\bar{E}$, $\bar{H}$, and $\bar{J}$ depend only on the z coordinate and have only x and y components.

Since the frequency ω of the alternating magnetic field is appreciably smaller than the reciprocal of the mean free time $\tau^{-1} = 10^{11}$-10^{13} Hz, the time derivatives in Eq. (2) can be neglected. Expressing $\bar{E}$ and $\bar{J}$ in terms of $\bar{H}$ and neglecting the displacement currents in comparison with conduction currents, we obtain a system of equations for the complex amplitudes H_x and H_y from (2)-(4):

$$\left.\begin{aligned}c^2\frac{\partial^2}{\partial z^2}H_x + i\omega\sigma_{11}H_x + i\omega\sigma_{12}H_y = 0,\\ c^2\frac{\partial^2}{\partial z^2}H_y + i\omega\sigma_{22}H_y - i\omega\sigma_{12}H_x = 0,\end{aligned}\right\} \tag{5}$$

where the components of the conductivity tensor σ are

$$\sigma_{11} = \sigma_{22} = \sigma_0\frac{1}{1+\left(\frac{eH\tau}{mc}\right)^2}, \quad \sigma_{12} = \sigma_0\frac{\frac{eH\tau}{mc}}{1+\left(\frac{eH\tau}{mc}\right)^2}, \quad \sigma_0 = \frac{Ne^2\tau}{m}. \tag{6}$$

It follows from (1) that we must solve the system of equations for the boundary conditions

$$\left.\begin{aligned}H_x = H, \quad H_y = 0 \quad \text{for} \quad z = \pm a,\\ \frac{\partial H_x}{\partial z} = \frac{\partial H_y}{\partial z} = 0 \quad \text{for} \quad z = 0.\end{aligned}\right\} \tag{7}$$

The solutions satisfying these conditions are

$$H_x = \frac{1}{2}H\left(\frac{\cos k_- z}{\cos k_- a} + \frac{\cos k_+ z}{\cos k_+ a}\right), \tag{8a}$$

$$H_y = \frac{1}{2}iH\left(\frac{\cos k_+ z}{\cos k_+ a} - \frac{\cos k_- z}{\cos k_- a}\right), \tag{8b}$$

where $k_\pm$ are determined from the characteristic equation

$$c^2k_\pm^2 = \frac{\omega_p^2\omega}{\pm\omega_H + i\tau^{-1}}, \quad \omega_p^2 = \frac{4\pi Ne^2}{m}, \quad \omega_H = \frac{eH}{mc}. \tag{9}$$

The terms in (8) with the argument $k_- z$ are due to helicons. The magnetic fluxes per unit transverse length are

$$\Phi_x = \int_{-a}^{a} H_x dz = H\left(\frac{\operatorname{tg}k_- a}{k_-} + \frac{\operatorname{tg}k_+ a}{k_+}\right), \tag{10a}$$

$$\Phi_y = \int_{-a}^{a} H_y dz = iH\left(\frac{\operatorname{tg} k_+ a}{k_+} - \frac{\operatorname{tg} k_- a}{k_-}\right). \qquad (10b)$$

Equations (8) and (9) determine the complex field amplitudes and the flux as functions of the constant magnetic field H_0, the frequency ω, and the thickness of the plate a. As a consequence of the Hall currents an alternating magnetic field appears in the plate perpendicular to the exciting field.

From Eq. (10a) we find the effective magnetic permeability of the plate:

$$\mu_{\text{eff}} = \frac{\Phi_x}{2aH} = \frac{\operatorname{tg} k_- a}{2k_- a} + \frac{\operatorname{tg} k_+ a}{2k_+ a}. \qquad (11)$$

When $\omega_H \tau \gg 1$, from (9)

$$k_- = \sqrt{\frac{\omega_p^2 \cdot \omega}{\omega_H c^2}}\left(1 + \frac{i}{\omega_H \tau}\right), \qquad (12)$$

μ_{eff} is maximum at resonance

$$(\operatorname{Re} k_-)a = \frac{n\pi}{2}, \quad n = 1, 3, 5, \ldots \qquad (13)$$

and is equal to

$$\max \mu_{\text{eff}} \cong \frac{2i\omega_H \tau}{n^2\pi^2}, \quad n = 1, 3, 5, \ldots \qquad (14)$$

Thus at resonance the impedance Z of the induction coil with a conducting core is purely resistive

$$Z = -i\omega L_0 \mu_{\text{eff}} = \frac{2\omega_H \tau}{n^2\pi^2}\omega L_0 \qquad (15)$$

with absolute magnitude appreciably ($2\omega_H \tau/n^2\pi^2$ times) larger than the inductive reactance ωL_0 of the coil without a core, where L_0 is the inductance of the coil without a core. The intensity of the resonance peak decreases with an increase in the resonance number n = 1, 3, ...

The most suitable core material is InSb for which $\omega_H \tau = 1$ at room temperature in a magnetic field of ~ 1000 Oe.

Graphical methods for constructing trajectories of small particles in electrostatic fields

N. I. Shtepa

(Submitted October 10, 1973)
Zh. Tekh. Fiz., 44, 2017-2020 (September 1974)

Graphical methods are described for the velocity increments and radii of curvature for trajectories of small (10^{-1}-10^{-4} cm) statically charged particles in strong electrostatic fields. An example is presented.

The focusing of small (10^{-1}-10^{-4} cm) statically charged particles by strong electrostatic fields is discussed in refs. 1-4. The analysis of the focusing is based on the general form of the differential equations describing the motion of particles in the fields under study. Focusing results from the linearity of the second-order differential equations in the paraxial approximation. Analytic expressions for the focusing parameters can be obtained in general form only for the fields of so-called thin lenses.

In order to find the focusing parameters of the practically important electrostatic fields of thick lenses and to explain their special features it is necessary to know how to find particle trajectories in each particular problem.

Finding the trajectories with sufficient accuracy is generally quite difficult and requires the use of a computer.

Relatively simple graphical methods similar to the methods of electron optics[5-7] can be used to find approximate trajectories. However, in contrast with electron-optical problems the calculational equations are somewhat complicated in the cases under consideration because of the effect of dissipative forces on the motion of particles in viscous media.

We describe below graphical methods for the velocity increments and radii of curvature for the construction of trajectories of small statically charged particles in strong electrostatic fields. As in refs. 1-4, it is assumed that the particles are homogeneous, isotropic, spherical, and small enough so that the variation in the guide field is negligible, but large enough so that fluctuation phenomena can be neglected. In steady flow in a viscous medium the particle velocities are limited by Stokes' law.

VELOCITY INCREMENTS METHOD

Under the limitations assumed the differential equation of motion of a particle in an electrostatic field can be written in the form[1]

$$m\frac{d\mathbf{v}}{dt}=\mathbf{F}_q+\mathbf{F}_p+\mathbf{F}_b+\mathbf{F}_a+\mathbf{F}_c, \tag{1}$$

where $\mathbf{v}$ is the velocity of the particle

$$m=\frac{4}{3}\pi R^3\rho_1 \tag{2}$$

is the mass of the particle, R is its radius, ρ_1 is its density,

$$\mathbf{F}_q=q\mathbf{E} \tag{3}$$

is the force due to the free charge q of the particle, $\mathbf{E}$ is the intensity of the electrostatic field,[1)]

$$\mathbf{F}_p=R^3\frac{(\varepsilon-1)}{(\varepsilon+2)}(\mathbf{E}\nabla)\mathbf{E} \tag{4}$$

is the force due to the polarization of the particle, ε_1 and ε_2 are respectively the permittivities of the particle and the medium, $\varepsilon = \varepsilon_1/\varepsilon_2$,

$$\mathbf{F}_b=\frac{4}{3}\pi R^3\rho_1\mathbf{g} \tag{5}$$

is the weight, $\mathbf{g}$ is the acceleration due to gravity,

$$\mathbf{F}_a=-\frac{4}{3}\pi R^3\rho_2\mathbf{g} \tag{6}$$

is the buoyant force, ρ_2 is the density of the medium,

$$\mathbf{F}_c=-6\pi\mu R(\mathbf{v}-\mathbf{u}) \tag{7}$$

is the viscous force, μ is the coefficient of viscosity, and $\mathbf{u}$ is the velocity of the medium.

We represent the displacement Δs of a particle along its trajectory in terms of Δx, Δy, and Δz. For a sufficiently small displacement Δs the velocity increments can be written to second order as follows:

$$\Delta v_x=\frac{\Delta x}{v_x}\left[\eta E_x+aE\frac{\partial E}{\partial x}+kg_x-\lambda(v_x-u_x)\right], \tag{8}$$

$$\Delta v_y=\frac{\Delta y}{v_y}\left[\eta E_y+aE\frac{\partial E}{\partial y}+kg_y-\lambda(v_y-u_y)\right], \tag{9}$$

$$\Delta v_z=\frac{\Delta z}{v_z}\left[\eta E_z+aE\frac{\partial E}{\partial z}+kg_z-\lambda(v_z-u_z)\right], \tag{10}$$

where

$$\eta=\frac{3q}{4\pi R^3\rho_1},\quad a=\frac{3(\varepsilon-1)}{4\pi(\varepsilon+2)\rho_1},\quad k=1-\frac{\rho_2}{\rho_1},\quad \lambda=\frac{9\mu}{2R^2\rho_1}. \tag{11}$$

Equations (8)-(10) are the basic calculational equations of the velocity increments method.

In this method the trajectory is constructed step by step in two projections, for example on the xoy and xoz planes, in the following way (Fig. 1). Starting from the projections A_{u_0} and A_{w_0} of the initial point A_0 on the coordinate planes, the components v_{u_0} and v_{w_0} of the initial velocity are constructed. Replacing the true motion of a point along a small segment by its motion along a tangent, v_{u_0} and v_{w_0} are used to find the projections A_{u_1} and A_{w_1} of the next point A_1 of the trajectory corresponding to a small increment Δx_0. Equations (8)-(10) are used to calculate the increments in the velocity components Δv_{x_0}, Δv_{y_0}, Δv_{z_0} corresponding[2)] to the step of the construction, and the velocity components v_{u_1}, and v_{w_1} at point A_1 are found from $v_{x_1} = v_{x_0} + \Delta v_{x_0}$, $v_{y_1} = v_{y_0} + \Delta v_{y_0}$, $v_{z_1} = v_{z_0} + \Delta v_{z_0}$. A similar construction is then performed for the next portion, and this process is continued until the whole trajectory is constructed.

The accuracy of the method is improved if the displacement along the tangent is replaced by the displacement along the bisector of the angle between the tangents at the initial and end points of the interval. The final position of each point is recalculated after the main construction, which increases the volume of the work somewhat.

RADII OF CURVATURE METHOD

In this method a trajectory is constructed from a succession of arcs of osculating circles of projections on the coordinate planes xoy and xoz.

The radii of curvature of the projections of the trajectory are

$$R_u = \frac{(v_x^2 + v_y^2)^{3/2}}{v_y \frac{dv_x}{dt} - v_x \frac{dv_y}{dt}}, \tag{12}$$

$$R_w = \frac{(v_x^2 + v_z^2)^{3/2}}{v_z \frac{dv_x}{dt} - v_x \frac{dv_z}{dt}} \tag{13}$$

which, by taking account of (1), can be rewritten in the form

$$R_u = \frac{(v_x^2 + v_y^2)^{3/2}}{\eta\,(v_y E_x - v_x E_y) + aE\left(v_y \frac{\partial E}{\partial x} - v_x \frac{\partial E}{\partial y}\right) + k\,(v_y g_x - v_x g_y) + \lambda\,(u_x v_y - u_y v_x)}, \tag{14}$$

$$R_w = \frac{(v_x^2 + v_z^2)^{3/2}}{\eta\,(v_z E_x - v_x E_z) + aE\left(v_z \frac{\partial E}{\partial x} - v_x \frac{\partial E}{\partial z}\right) + k\,(v_z g_x - v_x g_z) + \lambda\,(u_x v_z - u_z v_x)}. \tag{15}$$

The construction of a trajectory on the coordinate planes xoy and xoz is started from the projections A_{u_0} and A_{w_0} of the initial point A_0 (Fig. 2). At this point Eqs. (14) and (15) are used to calculate the radii of curvature R_{u_0} and R_{w_0}. Using the values found for the radii the centers of curvature O_{u_0} and O_{w_0} are located along the perpendiculars to the velocity components v_{u_0} and v_{w_0} at the initial point, and the arcs $A_{u_0}A_{u_1}$ and $A_{w_0}A_{w_1}$ corresponding to the small increment Δx_0 are constructed. The end points of the arcs, A_{u_1} and A_{w_1}, determine the succeeding point of the trajectory A_1. The next part of the trajectory is then constructed from this point, etc.

The velocity components v_x, v_y, v_z needed to calculate the subsequent radii of curvature in the construction process are found by calculating their increments Δv_x, Δv_y, Δv_z from Eqs. (8)-(10).

As an example Table 1 lists the results of constructing the trajectory of an ice particle of radius $R = 0.5 \cdot 10^{-2}$ cm moving in the electrostatic field of a cylindrical capacitor with a vertical axis. The air between the capacitor plates is at rest (u = 0); the intensity of the electric field is E = A/r, the charge of the particle and its initial velocity are chosen so that

$$\eta = \lambda\sqrt{a},\quad \dot{r}_0 = \frac{A\sqrt{a}}{r_0},\quad \dot{z}_0 = \frac{kg}{\lambda},\quad \dot{\vartheta}_0 = 0$$

(r, z, ϑ are cylindrical coordinates with the z axis along the axis **g** of the cylinder). The differential equation of the trajectory can be integrated exactly:

$$z = \frac{kg}{2\lambda A\sqrt{a}}(r^2 - r_0^2),\quad \vartheta = \text{const}$$

assuming $z_0 = 0$. The construction is performed for the following values: $A = 2 \cdot 10^3$ V, $\varepsilon_1 = 2.8$, $\varepsilon_2 = 1$, $\rho = 0.9$ g/cm^3, $g = 981$ cm/sec^2, $k = 1$, $\mu = 1.8 \cdot 10^{-4}$ g/cm$\cdot$sec, and $r_0 = 1$ cm. The trajectory is constructed from $z_0 = 0$ to $z = 10$ cm in steps $\Delta z_i = 1$ cm.

Table 1 shows that the approximate trajectories found by graphical methods are close to the exact values.

In conclusion we note that the main virtue of the methods described is their relative simplicity and universality. They can be used when the guide fields are described either analytically or numerically. The latter is important since in practice the electrostatic fields of complex configurations (calculated or simulated) are ordinarily given in the form of numerical values of the potential. An important shortcoming of the methods is the lack of reliable methods of estimating accuracy. In practice the accuracy can be judged by the difference between trajectories constructed by different methods or for various partitions into segments.

Cumulative destruction of transparent dielectrics in repeated laser irradiation

L. D. Khazov, I. A. Fersman, and V. Yu. Bortniker

(Submitted June 4, 1973)
Zh. Tekh. Fiz., 44, 2020-2022 (September 1974)

We obtain a relation between the number of laser shots needed to destroy a K-8 glass surface and the energy density in the laser beam. We find that the scattering of light at the glass surface increases with the number of laser shots. This means that microdefects accumulate during repeated irradiation.

The relation between the number of laser shots needed to destroy a sample and the energy density in the laser beam (lifetime curves) has been obtained by several researchers for various materials such as nonlinear $LiNbO_3$ and $Ba_2NaNb_5O_{15}$ crystals,[1] polymers,[2] and reflecting dielectric coatings.[3]

Two explanations of the reduced destructive energy density of a laser beam have been described in the literature. Bass[4] has proposed a statistical form of destruction, i.e., he assumes that the probability of destruction depends linearly upon the intensity of the laser light.

In another explanation[1-3] for the reduced threshold, an accumulation of irreversible, residual changes in the properties of the material and an increase in the number of defects, which results in aging of the material, are assumed.

We have investigated the destruction resulting from multiple irradiations of K-8 glass which has its surface polished according to usual standards. In order to explain the reduced transparency of the surface after repeated irradiation, we record the scattering of the laser light at the surface in addition to investigations of the lifetime. Figure 1 shows the optical arrangement of the apparatus. The radiation emitted by the single-pulse ruby laser 1, which is operated in a single, transverse mode, is focused by a lens 4 with great focal length (f = 235 mm) upon sample 5.

A K-8 glass sample ϕ 30 × 4 mm is placed in a movable mounting and forms the window of the blackened housing 10. It is assumed that if microdefects are generated, scattering must occur at the defects. The forward scattering is recorded, because the scattering is a maximum in the forward direction. In order to record the scattering at small angles inside the housing a concave mirror 8 with a center opening for the basic laser beam is mounted inside the housing. The laser beam is attenuated behind the mirror with the aid of a filter 9. The scattered light, which is reflected by the mirror, is directed with a total internal reflection prism 13 onto an FÉU-14 photomultiplier 11. In order to attenuate spurious signals which reduce the sensitivity of the apparatus, all components surrounding the beam are blackened and the basic laser beam is transmitted in a blackened tube. A neutral KS-19 filter 12 is placed in front of the photomultiplier to prevent light from incandescent lamps from being recorded. In order to preclude bias illumination by the luminescence flux, an iris 3 mm in diameter is placed in front of the lens. The residual scattering signal (without sample) is reduced to half the magnitude of the scattering signal in undamaged glass by these measures. The moment at which the surface is destroyed is indicated by the formation of a plasma whose bright flash generates a strong signal in an oscilloscope.

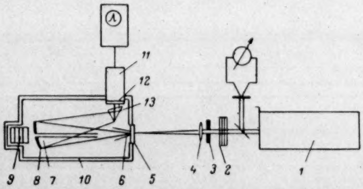

Fig. 1. Optical scheme of the recording apparatus. 1) Single-pulse single-mode ruby laser; 2) set of calibrating neutral filters; 3) diaphragm; 4) collector lens; 5) sample; 6) blackened cone; 7) tube; 8) concave mirror with center opening; 9) cassette with a set of neutral filters; 10) housing; 11) FÉU-14 photomultiplier; 12) NS-9 and KS-19 filters; 13) prism.

In order to obtain the lifetime characteristics a series of statistical tests is made. The destruction threshold obtained with the first shot is defined as the energy density at which destruction occurs with a probability of about 50%. This limit is termed "resistance of light." Since the resistance to light is inhomogeneous, the transition region near the threshold is very large (Figure 2a).

The following method is used to obtain the threshold of destruction of the surface after a series of shots. For a given adjustable energy of the shot, the irradiation shots are repeated until a large signal generated by a spark appears on the oscilloscope. After this series, the average energy of a shot and the energy spread in a series are calculated. The high inhomogeneity of the resistance to

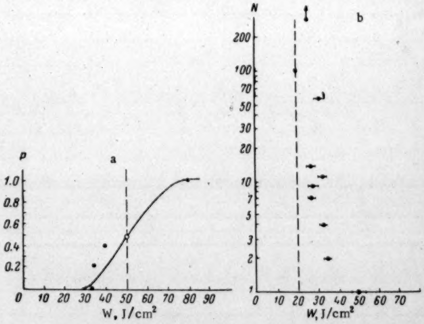

Fig. 2. a) Dependence of the probability of destruction with the first shot upon the energy density of the radiation. The diameter of the irradiated section is 126 μ. b) Dependence of the number of shots needed for destruction on the energy density in the beam. The horizontal arrows denote the spread of the radiation energy in a series. The vertical arrows indicate that after a particular number of flashes, destruction does not occur at the given energy density.

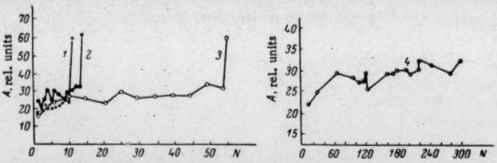

Fig. 3. Dependence of the magnitude of the scattering signal upon the number of irradiation pulses. Curves 1 and 2 are recorded with W ≈ 38 J/cm^2, curve 3, with W ≈ 33 J/cm^2, and curve 4, with W ≈ 29 J/cm^2.

light implies that for similar values of the average energy of a shot, there appear points which are destroyed after seven shots, as well as points which are not destroyed even after 300 shots (Fig. 2b). At an energy density of 29 J/cm^2 in the beam, no sample destruction takes place at seven points of a sample even after 100 irradiation pulses.

There probably exists an energy below which no destruction occurs even for $N \to \infty$ (dashed line in Fig. 2b). This energy density is termed the stability limit of a particular sample. Several thousand shots must be applied for a correct determination of the stability limit. This is not possible for technical reasons.

The dimensional effect of ref. 5 must be recalled when the quantitative data of Fig. 2 are used.

The scattering signal increases in proportion to the increasing number of radiation shots which do not yet cause destruction (Fig. 3). The slight increase in the scattering signal in the subthreshold region is followed by a sharp discontinuity of the signal, with the discontinuity resulting from the spark of a surface discharge. Values of the scattering signal obtained at constant radiation energy are used to construct the curves.

The increase in the scattering signal indicates the generation of microdefects in the surface layer of the sample in multiple shots. The microdefects accumulate from shot to shot and result in aging of the sample and reduced sample transparency.

Ion energy spectra and collective effects in a Penning ion source

V. I. Farenik, V. V. Vlasov, A. M. Rozhkov, and A. A. Kozharin

A. M. Gor'kii Khar'kov State University

(Submitted July 17, 1973; resubmitted February 12, 1974)
Zh. Tekh. Fiz., 44, 2023-2025 (September 1974)

It has been shown experimentally that the energy spectrum of an ion beam extracted along the magnetic field from a Penning source is governed by any instability which occurs in the source plasma. In the case of the ion-cyclotron instability the spectral half-width is much larger than in the case of low-frequency ($\omega_{LF} < \omega_{Hi}$) drift waves. The regimes corresponding to ion-cyclotron and drift instabilities are determined.

In many applications of ion beams from plasma sources the ions must have a small energy spread. Various methods are known for reducing this spread:[1] in general, reducing the maximum beam energy, using various types of extracting probes, choosing appropriate materials for the source electrodes, etc. It has also been pointed out[1] that oscillatory processes involving a collective interaction between the electron and ion beams with the plasma affect the conditions under which the ion beam is produced and affect the characteristics of this beam. However, these questions have not been studied adequately; in particular, an unambiguous relationship has not been established between the width of the ion energy spectrum and the characteristic waves in a Penning source.

We report here an experimental study of the energy spectra of ion beams extracted along the magnetic field from a Penning source in the case in which ion-cyclotron waves and low-frequency drift waves exist in the plasma, at frequencies ω_{Hi} and $\omega_{LF} < \omega_{Hi}$.

The experimental apparatus and the configurations of the magnetic and electric fields are described in ref. 2. The magnetic field is varied over the range H = 0-1.5 kOe, the anode voltage over the range V_a = 1-2 kV and the working-gas (air) pressure over the range P = $(0.5-2)\cdot 10^{-4}$ torr. The ion energy spectra are determined by a special electrostatic analyzer which can be used to measure the ion energy over the radial cross section of the beam. The plasma waves are detected by a system of single probes at the floating potential and a standard radio receiver.

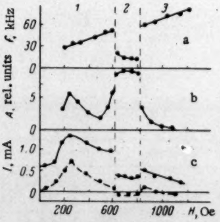

Fig. 1. Functional dependences of the magnetic field H of various quantities. a) Plasma-wave frequency f; b) plasma-wave amplitude A; c) anode current I_a (solid curve) and current to reflecting electrodes (dashed curve). It should be kept in mind that the anode current and the current to the reflecting electrodes have different polarities. Ion-cyclotron waves (regions 1 and 3) and low-frequency drift waves (region 2) occur in the discharge. V_a = 1.2 kV, P = $6\cdot 10^{-5}$ torr.

A resonant cyclotron instability, accompanied by the excitation of waves at the ion gyrofrequency (region 1 in Fig. 1) occurs in the discharge when the crossed radial electric field E_r and longitudinal magnetic field H satisfy

$$H = H_{cr} \approx \sqrt{\frac{2m_i c^2 E_r}{e_i r}} \tag{1}$$

where m_i is the mass of atomic nitrogen, c is the speed of light, e_i is the ion charge, r is the plasma radius $E_r = 0.3\cdot 10^{-2}\, V_a/\delta$, and δ is the distance between the anode and the reflecting electrode. This instability leads to an effective heating of the ion plasma component,[3] so that the ion velocity distribution becomes an equilibrium distribution (Fig. 2, curve 1). In this case the spectral half-width is a maximum at $H = H_{cr}$. At $H > H_{cr}$, a saturation region (or plateau) appears in the ion distribution, due to nonlinear effects which tend to increase the average ion energy.

At $H \approx 3\, H_{cr}$ the amplitude of the cyclotron waves falls abruptly (region 2 in Fig. 1), and large-amplitude, low-frequency waves ($f_{LF} < \omega_{Hi}/2\pi$) appear. We identify them as drift waves:[4]

$$f_{LF} \sim \frac{E_r}{H}, \quad \cos\theta = \frac{k_\parallel}{k_\perp} \ll 1,$$

where θ is the angle between the magnetic field and the wave-propagation direction, $k_\parallel$ and $k_\perp$ are the components of the wave number, and the wave propagates in the direction of the ion Larmor drift. The value of the frequency

$$f_{LF} \approx \frac{m f_{Hi}}{2\pi}\frac{\rho_i^2}{r} \approx 0.3 f_{Hi},$$

where m is the index of the azimuthal mode and ρ_i is the ion Larmor radius, agrees well with the results of ref. 4.

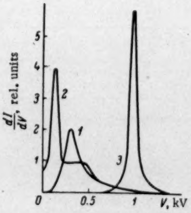

Fig. 2. Energy spectra of the ion beams. 1,2) Cyclotron instability; 3) low-frequency drift waves. V_a = 1.2 kV; P = $6\cdot 10^{-5}$ torr; dI/dV is the derivative of the function I = f(V); I is the collector current in the electrostatic analyzer, V is the retarding potential.

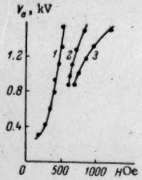

Fig. 3. Experimental dependence on the magnetic field H for the anode voltage V_a corresponding to the excitation of cyclotron (1,3) and low-frequency (2) waves in the plasma.

Under these conditions the emission of particles, particularly electrons, from the plasma is significantly lower. Figure 1c shows the abrupt decreases in the anode current and the current to the reflecting electrode. These decreases are accompanied by pronounced changes in the energy spectrum of the ion beam (Fig. 2), where the half-width falls below $0.1V_a$. It is particularly important to note that the maximum beam energy is comparable to the potential drop across the electrodes and can be changed easily by changing this potential drop. Furthermore, while in the cyclotron-instability region the beam energy and intensity are smoothly varying functions of the radius (the functional dependences are "bell-shaped"), they are concentrated near the center of the discharge in the region of low-frequency drift waves.

With a further increase in the magnetic field, at $H > (4\text{-}4.5)H_{cr}$ the ion cyclotron instability sets in (region 3 in Fig. 1), and the energy spectrum of the ion beam becomes thermal. The entire process behaves as if the anode voltage were changed at H = const. Figure 3 shows the functional dependences $V_a = f(H)$, which give the thresholds for the onset of the cyclotron (curves 1 and 3) and drift-wave (curve 2) instabilities. For values of H and V_a lying between curves 2 and 3 the ions display a minimal energy spread.

We cannot go into detail here on the nature of the excitation of the drift and cyclotron (region 3 in Fig. 1c) waves, which result from the relative azimuthal motion of the plasma components in a cylindrically symmetric system (see, e.g., ref. 5), but we note that one reason for the abrupt change in the plasma-wave frequency f as a function of **H** (Fig. 1) can be a nonlinear interaction between the strong high-frequency waves in this discharge with the low-frequency ions waves (a parametric interaction) (refs. 6, 7). The possibilities for reducing the width of the ion-beam energy spectrum are apparently not exhausted by a study of the low-frequency spectrum of collective instabilities ($\omega \nless \omega_{Hi}$), but we can conclude that an important first step in producing an ion beam having a small energy spread is to suppress the ion cyclotron instability, which leads to an effective heating of the ion component.

The authors thank K. I. Stepanov and V. A. Suprunenko for useful discussions.

Turbulent plasma heating and the Buneman instability

V. L. Sizonenko
Physicotechnical Institute,
Academy of Sciences of the Ukrainian SSR, Khar'kov

(Submitted February 25, 1974)
Zh. Tekh. Fiz., 44, 2025-2027 (September 1974)

The nonlinear stage of the kinetic Buneman instability is analyzed. The scattering of resonant electrons by fluctuations of the electric field leads to an anomalously rapid increase in the electron thermal velocity to the velocity characteristic of the current.

Kinetic wave branches as well as hydrodynamic Buneman instabilities[2-4] are excited efficiently in an unmagnetized plasma.[1] Below we analyze the nonlinear stage of these kinetic instabilities, finding that the primary nonlinear effect is a rapid electron heating.

We start from the following relations[1] for the kinetic instability in a plasma with $T_e \gg T_i$:

$$\gamma \equiv \operatorname{Im}\omega \sim \operatorname{Re}\omega \sim \omega_{pi},\ k \sim r_D^{-1},\ \cos\vartheta \sim \frac{v_{Te}}{u} \ll 1, \tag{1}$$

where **k** is the wave vector, ω is the complex frequency, **u** is the ordered velocity corresponding to the current, $r_D = (v_{Te}/\omega_{pe})$, $v_{T\alpha} = (T_\alpha/m_\alpha)^{1/2}$, $\omega_{p\alpha} = (4\pi e^2 n_0/m_\alpha)^{1/2}$, $\alpha = (e, i)$, and ϑ is the angle between **k** and **u**.

To describe the nonlinear stage of the instability we use the weak coupling kinetic model of Kadomtsev,[5] according to which

$$\varepsilon(\mathbf{k}, \omega) \equiv 1 - \frac{\omega_{pi}^2}{\omega^2} + \frac{4\pi e}{k^2}\int dv\,(\mathbf{k}\mathbf{g}_{\mathbf{k}\omega}) f_0 + \Delta\varepsilon(\mathbf{k}, \omega), \tag{2}$$

$$\eta_{\mathbf{k}\omega} P_{\mathbf{k}\omega} = \frac{\partial}{\partial v_i} A_{ij} \frac{\partial P_{\mathbf{k}\omega}}{\partial v_j},\ A_{ij} = \left(\frac{e}{m_e}\right)^2 \int d\mathbf{k}'d\omega' \frac{k_i' k_j' I_{\mathbf{k}'\omega'}}{\omega'' - \mathbf{k}''\mathbf{v} + \eta_{\mathbf{k}''\omega''}}, \tag{3}$$

$$P_{\mathbf{k}\omega} = I_{\mathbf{k}\omega}(\mathbf{k}\mathbf{g}_{\mathbf{k}\omega}) f_0 + \Delta P_{\mathbf{k}\omega},\ \mathbf{g}_{\mathbf{k}\omega} \equiv \frac{e}{m_e} \frac{1}{\omega - \mathbf{k}\mathbf{v} + \eta_{\mathbf{k}\omega}} \frac{\partial}{\partial \mathbf{v}}, \tag{4}$$

where $\mathbf{k}'' = \mathbf{k} - \mathbf{k}'$, $\omega'' = \omega - \omega'$, $I_{\mathbf{k}\omega} = \langle|\varphi_{\mathbf{k}\omega}|^2\rangle$, $P_{\mathbf{k}\omega} = \langle\varphi^*_{\mathbf{k}\omega} f_{\mathbf{k}\omega}\rangle$, and $\varphi_{\mathbf{k}\omega}$ and $f_{\mathbf{k}\omega}$ are the Fourier components of the potential φ and the electron distribution function. The background electron distribution f_0 satisfies

$$\frac{\partial f_0}{\partial t} = \frac{e}{m_e} E_0 \frac{\partial f_0}{\partial v_z} - \frac{e}{m_e} \frac{\partial}{\mathbf{v}\varrho} \int d\mathbf{k}\, d\omega\, \mathbf{k} \operatorname{Im} P_{\mathbf{k}\omega}, \tag{5}$$

where $\mathbf{E}_0$ is the external electric field. The nonlinear terms for ions are neglected [for monoenergetic ions, $(\gamma/kv_{Ti}) \sim (T_e/T_i)^{1/2} \gg 1$, this simplification is valid if $W \equiv (1/8\pi)(\nabla\varphi)^2 \ll n_0 T_e$]. The terms $\Delta\varepsilon(\mathbf{k}, \omega)$ and $\Delta P_{\mathbf{k}\omega}$ describe the nonlinear wave interaction.

The quantity $\eta_{\mathbf{k}\omega}$ gives the resonance broadening and is a complicated function of the variable $\zeta \equiv \mathbf{kv}/kv$. Under the assumption that the nonlinear wave interaction is weak $[|\Delta\varepsilon(\mathbf{k}, \omega)| \ll 1,\ |\Delta P_{\mathbf{k}\omega}| \ll |P_{\mathbf{k}\omega}|]$, taking account of the strong functional dependence on ζ of the quantities $P_{\mathbf{k}\omega}$ and $\eta_{\mathbf{k}\omega}$ in the resonance region, $|\omega - \mathbf{kv}| \lesssim |\eta_{\mathbf{k}\omega}|$, $|\zeta| \lesssim |\eta_{\mathbf{k}\omega}/kv| \ll 1$, we find from (3)

$$\eta_{\mathbf{k}\omega} P_{\mathbf{k}\omega} = A \frac{\partial^2 P_{\mathbf{k}\omega}}{\partial\zeta^2},\ A = \left(\frac{e}{m_e}\right)^2 \frac{1}{k^2 v^2} \int d\mathbf{k}'d\omega' \frac{(\mathbf{k}\mathbf{k}')^2 I_{\mathbf{k}'\omega'}}{\omega'' - \mathbf{k}''v + \eta_{\mathbf{k}''\omega''}} \approx \text{const.} \tag{6}$$

Eliminating $\eta_{\mathbf{k}\omega}$ from (4) and (6), we find an equation for $P_{\mathbf{k}\omega}$:

$$\frac{\partial^2 P_{\mathbf{k}\omega}}{\partial\zeta^2} - \left(\zeta - \frac{\omega}{kv}\right)\frac{kv}{A} P_{\mathbf{k}\omega} = \frac{e}{m_e} \frac{I_{\mathbf{k}\omega}}{A}\left(\mathbf{k}\frac{\partial f_0}{\partial \mathbf{v}}\right). \tag{7}$$

It follows from (7) that the width of the resonance region is of order $\Delta\zeta \sim |A/kv|^{1/3} \sim (W/n_0T_e)^{1/3}$. It is not difficult to show on the basis of the structure of Eq. (7) that

$$J \equiv \int_{-\infty}^{\infty} d\zeta \operatorname{Im} P_{\mathbf{k}\omega} = -\frac{\pi}{kv}\frac{e}{m_e} I_{\mathbf{k}\omega}\left(\mathbf{k}\frac{\partial f_0}{\partial \mathbf{v}}\right)\Big|_{\omega = \mathbf{kv}}, \tag{8}$$

i.e., with $W \ll n_0T_e$, the resonance broadening is negligible for the integral J, which describes the resonant interaction of the waves with the particles. We can find the quantities $\Delta\varepsilon(\mathbf{k}, \omega)$ and $\Delta P_{\mathbf{k}\omega}$ (in order of magnitude) by simplifying the problem, assuming that $\eta_{\mathbf{k}\omega}$ is independent of **v** and is a slowly varying function of **k**. Then $\eta_{\mathbf{k}\omega}$ plays the role of a complex increment in the frequency ω, and a calculation of the nonlinear wave interaction would be the same as that for the case of the ion-acoustic instability.[6] Replacing ω by $\omega + \eta_{\mathbf{k}\omega}$ in the equations of ref. 6, we can easily show that the following holds for the case of Buneman instabilities:[1]

$$\operatorname{Im}\Delta\varepsilon(\mathbf{k}, \omega) \sim \operatorname{Re}\Delta\varepsilon(\mathbf{k}, \omega) \sim \frac{W}{n_0T_e}\left[\frac{m_e}{m_i} + \left|\frac{\eta_{\mathbf{k}\omega}}{\omega_{pe}}\right|^2\right]^{-1} \sim \frac{W}{n_0T_e}\left[\frac{m_e}{m_i} + \left(\frac{W}{n_0T_e}\right)^{2/3}\right]^{-1}. \tag{9}$$

Accordingly, in the case $1 \gg (W/n_0T_e) > (m_e/m_i)^{3/2}$ the nonlinear increment $\Delta\varepsilon(\mathbf{k}, \omega)$, like $\Delta P_{\mathbf{k}\omega}$, is smaller by a factor of $(n_0T_e/W)^{1/3}$ than the linear terms[1)] $\varepsilon(\mathbf{k}, \omega)$. Also using (8) we conclude that with $W \ll n_0T_e$ for these instabilities, the scattering of electrons by the oscillations leads primarily to an increase in the transverse electron temperature $(k_\parallel/k_\perp) \sim (v_{Te}/u) \ll 1$ and is described by the diffusion equation

$$\frac{\partial f_0}{\partial t} = \frac{1}{v_\perp}\frac{\partial}{\partial v_\perp} v_\perp D_\perp \frac{\partial f_0}{\partial v_\perp},\ D_\perp \equiv \left(\frac{e}{m_e}\right)^2 \frac{1}{v_\perp^2} \int d\mathbf{k}\, d\omega \frac{(\mathbf{ku})^2 I_{\mathbf{k}\omega}}{\sqrt{k_\perp^2 v_\perp^2 - (\mathbf{ku})^2}}. \tag{10}$$

Using estimate (1), we find from (10) that $n_0(\partial T_{\perp e}/\partial t) \sim \omega_{pe} W$; we then find $n_0 T_{\perp e} \sim W(m_i/m_e)^{1/2}$.

As the electrons are heated, waves with increasingly large values of $|\cos\vartheta| \sim v_{Te}/u$ become "kinetic," so that the electron spread with respect to longitudinal energy is also accelerated; then at a noise level

$$W \sim n_0 T_e (m_e/m_i)^{1/2}, \tag{11}$$

we would obviously have $T_{\perp e} \sim T_{\parallel e}$ and $u \sim v_{Te}$. More information about the growth of the instability can be obtained by solving the equations of the quasilinear theory under the condition $u \lesssim v_{Te}$. Obviously, an anomalous plasma resistance can also appear with $u \lesssim v_{Te}$, in which case the quasilinear effects lead to $\gamma \lesssim kv_{Ti}$, and the instability is stabilized completely by nonlinear scattering of the waves by ions. This conclusion is consistent with the experimental data of refs. 9 and 10, for which the condition $u \lesssim v_{Te}$ is satisfied even when the plasma conductivity reaches the second plateau. It is also possible that the instability leads to a regime in which there is no anomalous plasma resistivity.[11]

On the basis of this analysis we can assume that hydrodynamic instabilities do not significantly affect a plasma carrying a current, since such an effect would require too high a noise level, $W \sim n_0 m_e u^2$ (ref. 12).

The author thanks K. N. Stepanov for discussion.

---

1)An analogous conclusion is reached in ref. 7 for the ion-acoustic instability.

Gas polymerization wave excited by monochromatic light

A. I. Plis and V. A. Shcheglov

Moscow Energetics Institute

(Submitted February 19, 1974)
Zh. Tekh. Fiz., 44, 2027-2030 (September 1974)

The profiles of the intensity and reactant densities are obtained in an analysis of photochemical polymerization waves in a gaseous medium. An equation for the wave velocity is derived for the general case. This velocity is found for the particular case in which the elementary steps of the polymerization chain reaction have equal rate constants. The molecular weight of the mixture is calculated.

The propagation of photodissociation waves in gaseous media is analyzed in refs. 1-3, and the photochemical waves propagating in gaseous mixtures with chain and branched-chain conversion mechanisms are analyzed in refs. 4-6. It has been shown[4-6] that secondary (with respect to the photolysis) chemical reactions involving the annihilation of the photodissociating reactant lead to an increase in the velocity of the "intensification" wave. This is an extremely important circumstance from the physical standpoint, since it yields information about the dynamics of the processes involved in photochemical conversions in a gaseous medium.

We are concerned here with photochemical polymerization waves in a gaseous medium. Polymerization waves initiated by quasimonochromatic light are of interest primarily from the practical standpoint; a point of physical interest is the unusual kinetics of the polymerization process (see, e.g. ref. 7).

The initial reactant is a monomer molecule A = B having a double bond. When light having a certain photon energy $h\nu_0$ acts on the monomer, one of the bonds is ruptured, and the active radical −A−B− is formed. The reaction of this radical with the initial monomer leads to the formation of the dimer radical −A−B−A−B−, which in turn, by interacting with the A = B monomer, forms a trimer; etc. Corresponding to this chain mechanism is the scheme

$$\left.\begin{array}{l} (AB)_1 + h\nu_0 \xrightarrow{\sigma} (AB^*)_1, \\ (AB^*)_1 + (AB)_1 \xrightarrow{k_1} (AB)_2, \\ (AB)_2 + (AB)_1 \xrightarrow{k_2} (AB)_3, \\ (AB)_3 + (AB)_1 \xrightarrow{k_3} (AB)_4, \\ \cdots\cdots\cdots\cdots \end{array}\right\} \quad (1)$$

According to (1) the photochemical polymerization wave is described by a system of equations consisting of the one-dimensional radiation-transport equation and the kinetic equations

$$\left.\begin{array}{c} \left(\frac{1}{c}\frac{\partial}{\partial t}+\frac{\partial}{\partial x}\right)I=-\sigma IN_1;\ \frac{\partial N_1}{\partial t}=-\sigma IN_1-k_1N_1^*N_1-\left(\sum_{i=2}^{\infty}k_iN_i\right)N_1, \\ \frac{\partial N_1^*}{\partial t}=\sigma IN_1-k_1N_1^*N_1;\ \frac{\partial N_2}{\partial t}=k_1N_1^*N_1-k_2N_2N_1, \\ \frac{\partial N_i}{\partial t}=k_{i-1}N_{i-1}N_1-k_iN_iN_1,\ i\geqslant 3, \end{array}\right\} \quad (2)$$

where I (photons per square centimeter per second) is the radiation flux density; σ is the photoinitiation cross section; k_i are the rate constants for the corresponding reactions; and the densities of reactants $(AB)_1$, $(AB^*)_1$, $(AB)_2$, etc., are denoted by N_1, N_1^*, N_2, etc. System (2) is to be supplemented with the initial and boundary conditions

$$\left.\begin{array}{c} t=0,\ N_1=N_0,\ N_1^*=N_2=\ldots=0,\ I=0\ (0<x<\infty), \\ x=0,\ I=I_0\ (0<t<\infty). \end{array}\right\} \quad (3)$$

We seek a solution of system (2) in the form of a stationary wave whose velocity D is to be determined. For such a wave the particle densities and radiation flux densities are functions of the argument $x' = x - Dt$ only, so we can write system (2) as

$$\left.\begin{array}{c} \frac{D^{-1}dI}{d\tau}=-\sigma IN_1;\ \frac{dN_1}{d\tau}=\sigma IN_1+k_1N_1^*N_1+\left(\sum_{i=2}^{\infty}k_iN_i\right)N_1, \\ \frac{dN_1^*}{d\tau}=-\sigma IN_1+k_1N_1^*N_1;\ \frac{dN_2}{d\tau}=-kN_1^*N_1+k_2N_2N_1, \\ \frac{dN_i}{d\tau}=-k_{i-1}\overset{\bullet}{N}_{i-1}N_1+k_iN_iN_1,\ i\geqslant 3, \end{array}\right\} \quad (4)$$

where $\tau = x'/D = (x-Dt)/D$ and where we have assumed $D/c \ll 1$ in a first approximation. System (4) describes a stationary polymerization wave propagating in the positive x direction. It is not difficult to see that system (4) has the integral

$$N_1^* + \sum_{i=2}^{\infty} N_i = \frac{I}{D}, \quad (5)$$

which expresses "photon-particle" conservation. From (4) we also find the obvious relation (conservation of elements)

$$N_0 = N_1 + N_1^* + \sum_{i=2}^{\infty} iN_i.$$

Using (3) and (4) we can find a relation between the densities of the reactants and the radiation flux density:

$$N_1^* = \frac{I}{D}\frac{1}{(1+a_1)},$$

$$N_i = \frac{I}{D}\frac{a_1a_2\ldots a_{i-1}}{(1+a_1)(1+a_2)\ldots(1+a_i)}, \quad (6)$$

where $a_i = k_i/\sigma D$. Using (6) and the first two equations in (4) we find a relation between the density of the initial monomer and the intensity:

$$N_1 + A\frac{I}{D} = C, \quad (7)$$

$$A = 1 + \frac{a_1}{1+a_1} + \frac{a_1a_2}{(1+a_1)(1+a_2))} + \ldots$$

$$+ \frac{a_1a_2\ldots a_{i-1}}{(1+a_1)(1+a_2)\ldots(1+a_i)} + \ldots. \quad (8)$$

Using $N_1 = 0$ and $I = I_0$ at $\tau = -\infty$, and then using N_1 =

N_0 and I = 0, we find

$$C = N_0 = \frac{I_0}{D} A. \tag{9}$$

Equation (9) gives the velocity of the photochemical wave. From (7) and (9) we can determine the intensity profile:

$$\frac{I}{I_0} = [1 + e^{\sigma I_0 A\tau}]^{-1}. \tag{10}$$

The profiles of the densities of the corresponding reactants are determined from (6) and (7). Equations (6)-(10) thus completely define the solution of the problem. For the profile of the total particle density we easily find

$$N = \frac{I_0}{D_0} + I\left(\frac{1}{D} - \frac{1}{D_0}\right). \tag{11}$$

Finally, we can show that the profile of the molecular weight of the reactant system, M, is

$$\frac{M}{M_0} = \frac{1}{N}\left\{\frac{1}{D_0}(I_0 - I) + \frac{I}{D}\left[\frac{1}{(1+a_1)} + \frac{2a_1}{(1+a_1)(1+a_2)} + \ldots + \frac{i a_1 a_2 \ldots a_{i-1}}{(1+a_1)(1+a_2)\ldots(1+a_i)}\right]\right\}, \tag{12}$$

where M_0 is the molecular weight of the original monomer.

In the case of equal rate constants for the elementary steps of the polymerization reaction [$k_i \equiv k$ (i = 1, 2, ...)] the analysis simplifies; in particular, Eq. (8) becomes

$$A = 1 + a = 1 + \frac{k}{\delta D},$$

so that the wave velocity is given by

$$y^2 - y - \xi = 0, \tag{13}$$

where $y = D/D_0$ and $\xi = kN_0/\sigma I_0$. From (13) we find

$$y = \frac{1}{2} + \left[\frac{1}{4} + \xi\right]^{1/2}.$$

The densities of the reactants and the radiation intensity in this case are related by

$$N_1 = N_0 - \frac{I}{D}(1 + a),$$

$$N_1^* = \frac{I}{D}\frac{1}{(1 + a)},$$

$$N_i = \frac{I}{D}\frac{a^{i-1}}{(1 + a)^i} (i \geqslant 2); \quad a = \frac{\xi}{y}.$$

The molecular weight of the mixture is given by

$$\frac{M}{M_0} = \left[1 + \frac{I}{I_0}\left(\frac{D_0}{D} - 1\right)\right]^{-1}.$$

The maximum molecular weight is obviously reached at the wave front:

$$\frac{M_{\max}}{M} = \frac{D}{D_0}.$$

As an example, we consider the case of equal rate constants for the elementary steps, with $K \sim 10^{-13}$ cm^3 · (particle · sec)$^{-1}$, $N_0 \sim 10^{18}$ particles/cm^3, $\sigma \sim 10^{-18}$ cm^2, and $I_0 \sim 10^{21}$ photons/(cm^2 · sec); we find the velocity of the photochemical polymerization wave to be $D \sim 10^4$ cm/sec, the width of the wave profile to be $\Delta x \sim 1$ cm, and the maximum molecular weight of the reactant mixture to be $M \sim 10M_0$.

We note in conclusion that we have focused primarily on questions of the propagation of photochemical polymerization waves in a gaseous medium here. We have not taken up several processes – the bond-rupture reaction, thermal effects, etc. – so that the generality of our analysis is limited. A more complete analysis, incorporating these processes, is planned for a future paper.

Luminosity of a cylindrical spectrometer with a small off-axis source

V. V. Zashkvara
Institute of Nuclear Physics,
Academy of Sciences of the Kazakh SSR, Alma-Ata

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 2030-2032 (September 1974)

Our purpose here is to calculate the luminosity of a cylindrical-mirror analyzer[1] as a function of radial position of a small source. This functional dependence is of practical interest in connection with the development of a scanning microprobe analyzer for studying the distribution of chemical elements over solid surfaces on the basis of the characteristic Auger-electron spectra. Figure 1 shows the Auger microanalyzer. Here 1 and 2 are the inner and outer electrodes of a cylindrical-mirror analyzer. The surface of the specimen, 3, is in the plane perpendicular to the symmetry axis of the mirror electrodes and intersecting the axis at point 0. This point corresponds to the position of a point source in an ion-optics system for second-order angular focusing of a beam of electrons to be analyzed. The central ray of this beam makes an angle of 42°18' with the z axis.[1] Auger electrons are excited in the atoms of the surface layer of the specimen under the influence of a beam of primary electrons brought to a sharp focus near point 0. This beam is shaped by electron gun 4. Then the Auger electrons enter the analyzer. Here 5 are annular slits at the surface of inner cylindrical electrode 1, covered by high-transmission metal grids. Receiving iris 6 has a circular aperture 7 of small radius $\Delta r_r = r_1\rho_r$ (r_1 is the radius of the inner cylindrical electrode, 1). This aperture is centered on the z axis, at a second-order focal point. Beyond the iris is some detector, which we will not discuss here. We assume that the dimension of the microprobe on the surface of the specimen is much smaller than Δr_r. In the course of a measurement, the microprobe scans the specimen surface within a certain area 8 (dashed circle) having dimensions comparable to Δr_r. To design a detection system for the microanalyzer we must determine how the signal level at the peak varies as the microprobe is moved radially away from point 0. We can find this information by calculating the luminosity of a cylindrical mirror of this type having an off-axis source of monoenergetic charged particles under conditions such that the analyzer operates in the regime of second-order angular focusing. We assume that the particle emission by the source surface obeys Lambert's law; then the luminosity of the analyzer is given by the double integral

$$L = \int dS d\Omega \cos i \tag{1}$$

over the area of the source and over the solid angle subtended by the beam to be analyzed. This integral is calculated for all the trajectories issuing from the source and intersecting the plane of the entrance aperture of the receiving iris. In Eq. (1) i is the angle between the normal to area ds and the given direction. Figure 2 shows a projection on the plane perpendicular to the symmetry axis of the analyzer of certain elements shown in Fig. 1, for assistance in understanding the calculations. The entrance aperture of the receiving iris describes a circle of radius $\Delta r_r = r_1\rho_r$. The circle of radius r_1 corresponds to the inner cylindrical electrode. Line 1 is the projection of an arbitrary ray coming from the region of the off-axis source, which has small dimensions and an area S. The deviation of this ray from the axis is characterized by the angle ψ. The dashed lines in Fig. 2 nominally bound the range of angles ψ including all trajectories emerging from source S and ending at the entrance aperture of the receiving iris.

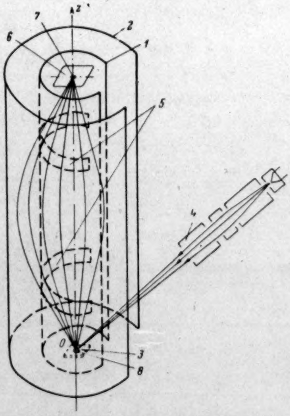

Fig. 1. The Auger microanalyzer. 1, 2) Inner and outer electrodes of the cylindrical analyzer; 3) specimen; 4) electron gun; 5) annular slits; 6) receiving iris; 7) entrance aperture of receiving iris; 8) region on the specimen surface over which the microprobe is scanned..

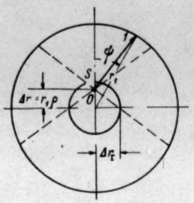

Fig. 2.

Under these conditions Eq. (1) can be rewritten as

$$L = 4S \iint\limits_{\alpha_0-\Delta\alpha}^{\alpha_0+\Delta\alpha} \cos\alpha \sin\alpha \, d\alpha d\psi \simeq 4S \cos\alpha_0 \sin\alpha_0 \int\limits_{\alpha_0-\Delta\alpha}^{\alpha_0+\Delta\alpha} \psi(\rho, \alpha - \alpha_0)\, d\alpha, \tag{2}$$

where $\alpha_0 = 42°18'$ is the angle between the z axis and the central ray in the beam to be analyzed, $\Delta\alpha$ is the divergence half-angle of the beam in the axial plane, and ρ is the relative displacement of source S from the z axis. In Eq. (2) the cos α and sin α are taken through the integral sign, since they are slowly varying functions over the integration range. A necessary condition for the evaluation of integral (2) is the condition governing the passage of the trajectories through the aperture of the receiving limiter of the cylindrical analyzer. This condition, derived in ref. 2, takes the following form for the case of second-order angular focusing:

$$\rho \sin\psi \leqslant \sqrt{\rho_r^2 - \mathrm{tg}^2\,\alpha_0 A_{III}^2 (\alpha - \alpha_0)^6}, \tag{3}$$

where A_{III} is the coefficient of cubic angular aberration.[1] Using the substitution $x = |\alpha - \alpha_0|$ in (2) we find

$$L = 8 \sin\alpha_0 \cos\alpha_0 S \int_0^{\Delta\alpha} \psi(\rho,\ x)\, dx, \tag{4}$$

where, in accordance with condition (3),

$$\psi = \begin{cases} \dfrac{\pi}{2}, & \text{if} \quad \rho \leqslant \sqrt{\rho_r^2 - \mathrm{tg}^2\alpha_0 A_{III}^2 x^6}, \\ \arcsin \dfrac{\sqrt{\rho_r^2 - \mathrm{tg}^2\alpha_0 A_{III}^2 x^6}}{\rho}, & \text{if} \quad \rho > \sqrt{\rho_r^2 - \mathrm{tg}^2\alpha_0 A_{III}^2 x^6}. \end{cases} \tag{5}$$

Let us consider several possible positions for the off-axis source.

1. $\rho = 0$. The source is on the symmetry axis. It follows from (4) and (5) that $\psi = \pi/2$ and

$$L_0 = 4\pi \sin\alpha_0 \cos\alpha_0 S\Delta\alpha. \tag{6}$$

In this case the luminosity is a maximum.

2. $\rho < \rho_r$. From (4) and (5) we find

$$\int_0^{\Delta\alpha} \psi(\rho,\ x)\, dx = \frac{\pi}{2} x_e + \int_{x_e}^{\Delta\alpha} \arcsin \frac{\sqrt{\rho_r^2 - \mathrm{tg}^2\alpha_0 A_{III}^2 x^6}}{\rho}\, dx, \tag{7}$$

where

$$x_e = \left[\frac{\rho_r}{|A_{III}|\,\mathrm{tg}\,\alpha_0}\right]^{1/3} \left[1 - \left(\frac{\rho}{\rho_r}\right)^2\right]^{1/6}.$$

The quantity

$$\left[\frac{\rho_r}{|A_{III}|\,\mathrm{tg}\,\alpha_0}\right]^{1/3} = \Delta\alpha_{li}$$

is the limiting divergence half-angle of the beam. As is shown in ref. 2, the luminosity of a cylindrical analyzer increases nearly linearly with increasing beam divergence over the range $\Delta\alpha \le \Delta\alpha_{li}$; then, at $\Delta\alpha > \Delta\alpha_{li}$, it becomes constant, and the instrumental line shape becomes blurred at the base. Under these conditions, therefore, $\Delta\alpha_{li}$ is the optimum value of the divergence half-angle for the beam to be analyzed in the axial plane. We assume $\Delta\alpha = \Delta\alpha_{li}$; then by using the substitution $z = x/\Delta\alpha_{li}$ in (7) we find

$$L = 8 \sin\alpha_0 \cos\alpha_0 S\Delta\alpha_{li} \left\{ \frac{\pi}{2}\left[1 - \left(\frac{\rho}{\rho_r}\right)^2\right]^{1/6} + \int_{\left[1-\left(\frac{\rho}{\rho_r}\right)^2\right]^{1/6}}^{1} \arcsin\left[\frac{\rho_r}{\rho}\sqrt{1 - z^6}\right] dz. \right. \tag{8}$$

3. In the case $\rho = \rho_r$ we find from (8)

$$L = 8 \sin\alpha_0 \cos\alpha_0 S\Delta\alpha_{li} \int_0^1 \arccos(z^3)\, dz. \tag{9}$$

4. $\rho > \rho_r$. In this case we find from (4) and (5)

$$L = 8 \sin\alpha_0 \cos\alpha_0 S\Delta\alpha_{li} \int_0^1 \arcsin\left[\frac{\rho}{\rho_r}\sqrt{1 - z^6}\right] dz. \tag{10}$$

Using Eqs. (6) and (8)-(10) we calculate the relative luminosity $l = L/L_0$ as a function of ρ/ρ_r over the range 0-4 (Fig. 3). We see that with $\rho \ge \rho_r$ the luminosity of the analyzer falls off considerably. If the region in which the microprobe is scanned over the specimen surface is bounded by a circle $\rho \le 0.8\rho_r$, then the changes in the luminosity and thus in the intensity of the detected signal due to the displacement of the microprobe from the symmetry axis do not exceed 5% of the maximum luminosity, corresponding to the placement of the microprobe on the symmetry axis.

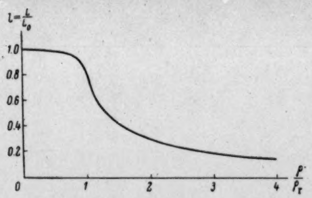

Fig. 3. Relative luminosity of the cylindrical mirror, $l = L/L_0$, as a function of the relative radial displacement of the source from the symmetry axis, ρ/ρ_r.

Heat transport problems with time-varying boundary conditions or moving boundaries (Stefan problem)

G. A. Grinberg

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted April 24, 1974)
Zh. Tekh. Fiz., 44, 2033-2042 (October 1974)

We propose a certain general method for investigating problems described by equations like $\Delta u + Q(x, y, z, \tau) = \partial u/\partial\tau$, where $Q(x, y, z, \tau)$ is a given function. The method is based on a set of special functions φ_m ($m = 0, 1, 2, \ldots, \infty$) which depend only on the coordinates and not on the time; these make it possible to reduce the problem to an infinite system of simple differential-difference equations. Using this system we can obtain a relation between the time-varying boundary condition and the outer surface of the medium being considered [Eq. (17)]; in addition, using the Laplace transform and generating function $\varphi(\lambda) = \sum_{m=1}^{\infty} \lambda^m \varphi_m$ we can form integral equations, one of which serves for determining the unknown functions on the moving boundary if the motion of the boundary is given [Eq. (29)], or, in the case of problems of the Stefan type,[1] for determining the unknown boundary motion [Eq. (30)]. When the solution of the appropriate equation (29) or (30) is known (or is assumed to be known – the inverse problem), to find the function u, we must use Eq. (28). The general theory is illustrated with a number of examples. In particular, when the shape of the boundary is known a priori in the Stefan problem and only the law of its displacement in time is unknown (when the solution depends on only one Cartesian coordinate or has cylindrical or spherical symmetry), a connection is developed between the second stage of the solution of the problem indicated above and the expansion of the unknown solution in "instantaneous" eigenfunctions of the problem. The proposed method allows a direct extension to equations of the form $\Delta u = a\partial^2 u/\partial\tau^2 = b\,\partial u/\partial\tau + cu + Q(x, y, z, \tau)$, where a, b, and c are constants.

1. We proceed to the problem. Let a medium fill some simply connected or multiply connected time-varying volume $V = V(\tau)$ which is bounded by the surface $f = f_1 + f_2 + f_3 + f_\tau$; the segments f_1, f_2, and f_3 are fixed, and on these we are given boundary conditions of the first, second, or third kind, respectively, i.e.,

$$\left.\begin{aligned} u|_{f_1} &= F_1(M, \tau),\\ \left.\frac{\partial u}{\partial n}\right|_{f_2} &= F_2(M, \tau),\\ \left.\left(\frac{\partial u}{\partial n} + \gamma u\right)\right|_{f_3} &= F_3(M, \tau), \end{aligned}\right\} \tag{1}$$

where M is a point on the corresponding part of the surface, $\partial u/\partial n$ is the derivative of u normal to the surface, and $F_k(M, \tau)$ ($k = 1, 2, 3$) are specified functions of M and τ. The segment f_τ is displaced in a specified way, and on it we are given boundary conditions of first, second, or third kind. In another formulation the Stefan conditions are satisfied on this segment, i.e.,

$$u|_{f_\tau} = 0; \quad \left.\frac{\partial u}{\partial n}\right|_{f_\tau} = -\alpha v_n, \tag{2}$$

where α is a known constant, v_n is the component of the velocity normal to the surface of f_τ; this component is unknown and is to be determined.

Inside the volume the function u everywhere satisfies the equation

$$\Delta u + Q = \frac{\partial u}{\partial \tau}, \quad Q = Q(x, y, z, \tau) \tag{3}$$

and the initial condition

$$u|_{\tau=0} = u^0(x, y, z), \tag{4}$$

which is satisfied inside the initial volume $V|_{\tau=0} = V_0$.

We construct a sequence of functions $\varphi_m = \varphi_m(x, y, z)$, independent of τ, such that $\Delta\varphi_0 = 0$ and

$$\Delta\varphi_{m+1} = \varphi_m, \quad m \geqslant 0, \tag{5}$$

where we take[2]

$$\varphi_m|_{f_1} = 0; \quad \left.\frac{\partial \varphi_m}{\partial n}\right|_{f_2} = 0; \quad \left.\left(\frac{\partial \varphi_m}{\partial n} + \gamma\varphi_m\right)\right|_{f_3} = 0, \quad m \geqslant 0. \tag{6}$$

We introduce the notation (here $m \geq 0$ everywhere)

$$u_m = u_m(\tau) = \int_V u\varphi_m dV, \tag{7}$$

$$Q_m = Q_m(\tau) = \int_V Q\varphi_m dV, \tag{8}$$

$$a_m = a_m(\tau) = \int_{f_\tau} \left[\left(\frac{\partial u}{\partial n} + v_n u\right)\varphi_m - u\frac{\partial \varphi_m}{\partial n}\right] df_\tau, \tag{9}$$

$$b_m = b_m(\tau) = -\int_{f_1} F_1 \frac{\partial \varphi_m}{\partial n} df_1 + \int_{f_2} F_2\varphi_m df_2 + \int_{f_3} F_3\varphi_m df_3. \tag{10}$$

For the Stefan problem we have

$$a_m = -\alpha \int_{f_\tau} v_n\varphi_m df_\tau, \tag{9'}$$

when f_τ moves in a specified way and on f_τ we are given values of u; in this case Eq. (9) contains a single unknown term $\int_{f_\tau} (\partial u/\partial n)\varphi_m df_\tau$, for boundary conditions of the second kind

$$-\int_{f_\tau} u\left(v_n\varphi_m - \frac{\partial \varphi_m}{\partial n}\right) df_\tau,$$

For boundary conditions of the third kind we can replace one of the quantities u or ∂u/∂n by the other so that both are expressed in terms of one unknown quantity.

Denoting the total time derivative by d/dτ, we obtain

$$\int_V (\varphi_{m+1}\Delta u - u\Delta\varphi_{m+1})\,dV + u_m + Q_{m+1} = \int_V \varphi_{m+1}\frac{\partial u}{\partial \tau}\,dV$$

$$= u_m + Q_{m+1} + \int_f \left(\varphi_{m+1}\frac{\partial u}{\partial n} - u\frac{\partial \varphi_{m+1}}{\partial n}\right)df = \frac{du_{m+1}}{d\tau} - \int_{f_\tau} \varphi_{m+1}v_n u\,df_\tau,$$

i.e.,

$$\frac{du_{m+1}}{d\tau} = u_m + a_{m+1} + b_{m+1} + Q_{m+1},\ m \geqslant 0, \tag{11}$$

$$\frac{du_0}{d\tau} = a_0 + b_0 + Q_0. \tag{12}$$

For brevity we write

$$a_m + b_m + Q_m = -c_m, \tag{13}$$

and rewrite Eqs. (11) and (12) in the form

$$u_m = u'_{m+1} + c_{m+1},\quad m \geqslant 0, \tag{11'}$$

$$0 = c_0 + u'_0, \tag{12'}$$

whence, by differentiating n times with respect to τ we obtain the relation

$$u_m^{(n)} = u_{m+1}^{(n+1)} + c_{m+1}^{(n)},\ m \geqslant 0. \tag{14}$$

Equations (12)-(14) give

$$0 = c_0 + u'_0 = c_0 + c'_1 + u''_1 = \ldots = \sum_{k=0}^{k=m} c_k^{(k)} + u_m^{(m+1)}. \tag{15}$$

If the selected system of functions φ_m is such that $\lim\limits_{m=\infty} u_m{}^{(m+1)} = 0$, then (15) can be written as

$$\sum_{k=0}^{\infty} c_k^{(k)} = 0 = \sum_{k=0}^{\infty} a_k^{(k)} + \sum_{k=0}^{\infty} (b_k^{(k)} + Q_k^{(k)}),$$

i.e.,

$$\sum_{k=0}^{\infty} \frac{d^k}{d\tau^k}\int_{f_\tau}\left[\left(\frac{\partial u}{\partial n} + v_n u\right)\varphi_k - u\frac{\partial \varphi_k}{\partial n}\right]df_\tau = -\sum_{k=0}^{\infty}(b_k^{(k)} + Q_k^{(k)}), \tag{16}$$

whence, in particular, for the Stefan problem we obtain

$$\alpha\sum_{k=0}^{\infty}\frac{d^k}{d\tau^k}\int_{f_\tau} v_n\varphi_k\,df_\tau = \sum_{k=0}^{\infty}(b_k^{(k)} + Q_k^{(k)}), \tag{17}$$

relations in which the distribution of the function u over the volume V does not enter, the right side is the known function τ, and the left side contains the value of u or ∂u/∂n, unknown on the surface f_τ, and for the case of the Stefan problem – the quantity (9').

On the other hand, using the Laplace transform in (11) and (12) and introducing the notation

$$\bar{\psi} \equiv \bar{\psi}(p) = \int_0^\infty e^{-p\tau}\psi(\tau)\,d\tau$$

[ψ(τ) is some function of τ], we obtain

$$\bar{u}_m = p\bar{u}_{m+1} - u_{m+1}(0) + \bar{c}_{m+1} = r_{m+1} + p\bar{u}_{m+1},\quad m \geqslant 0, \tag{18}$$

$$0 = p\bar{u}_0 - u_0(0) + \bar{c}_0 = r_0 + p\bar{u}_0, \tag{19}$$

where

$$r_m = -[\bar{a}_m + \bar{b}_m + \bar{Q}_m + u_m(0)],\quad m \geqslant 0, \tag{20}$$

where $\bar{b}_m$, $\bar{Q}_m$, and $u_m(0)$ are known quantities.[3]

From (18) and (20) we have

$$0 = r_0 + p\bar{u}_0 = r_0 + pr_1 + p^3\bar{u}_1 = \ldots = \sum_{s=0}^{s=n} p^s r_s + p^{n+1}\bar{u}_n, \tag{21}$$

from which it also follows that if $\lim\limits_{n\to\infty} p^{n+1}\bar{u}_n \mid 0$, then

$$\sum_{s=0}^{\infty} p^s r_s = 0. \tag{21'}$$

Below, we assume that this limit actually is equal to zero for the selected φ_m. This assumption must be verified later when the solution obtained in this approximation has been found.

Equation (21) can be rewritten as

$$\bar{u}_n = -\sum_{s=0}^{s=n}\frac{r_s}{p^{n+1-s}}.\quad n \geqslant 0. \tag{21''}$$

Introducing the generation function[4]

$$\varphi(x,\ y,\ z,\ \lambda) \equiv \varphi(\lambda) = \sum_{n=0}^{\infty}\lambda^n\varphi_n, \tag{22}$$

and the functions

$$\bar{M}(\lambda,\ p) = \sum_{n=0}^{\infty}\lambda^n\bar{u}_n, \tag{23}$$

$$N(\lambda,\ p) = \sum_{s=0}^{\infty}\lambda^s r_s = -\sum_{s=0}^{\infty}\lambda^s(\bar{a}_s + \bar{b}_s + \bar{Q}_s) - \sum_{s=0}^{\infty}\lambda^s u_s(0)$$

$$\equiv -\bar{w}(\lambda,\ p) - M(\lambda,\ 0), \tag{24}$$

which can be considered as Laplacians, transformed from the functions

$$M(\lambda,\ \tau) = \int_V u\varphi(\lambda)\,dV \tag{25}$$

and

$$w(\lambda,\ \tau) = \int_{f_\tau}\left[\left(\frac{\partial u}{\partial n} + v_n u\right)\varphi(\lambda) - u\frac{\partial\varphi(\lambda)}{\partial n}\right]df_\tau$$

$$-\int_{f_1} F_1\frac{\partial\varphi(\lambda)}{\partial n}df_1 + \int_{f_2} F_2\varphi(\lambda)\,df_2 + \int_{f_3} F_3\varphi(\lambda)\,df_3 + \int_V Q\varphi(\lambda)\,dV \tag{26}$$

respectively, it is easy to verify that[5]

$$\bar{M}(\lambda,\ p) = -\frac{N(\lambda,\ p)}{p-\lambda} = \frac{\bar{w}(\lambda,\ p)}{p-\lambda} + M(\lambda,\ 0)\frac{1}{p-\lambda}. \tag{27}$$

Converting from the transformed functions to the inverse transforms, taking account of (20) and using Duhamel's theorem, we obtain the equation

$$M(\lambda, \tau)=\int_V u\varphi(\lambda)\,dV=e^{\lambda\tau}\left[\int_0^\tau e^{-\lambda\eta}w(\lambda, \eta)\,d\eta+\int_{V_0} u^0\varphi(\lambda)\,dV_0\right]. \quad (28)$$

It can be obtained more simply, as will be shown below, by the method in Sec. 2. When (24) and (26) are used Eq. (21') becomes

$$\int_0^\infty e^{-p\tau}d\tau\int_{f_\tau}\left[\left(\frac{\partial u}{\partial n}+v_n u\right)\varphi(p)-u\frac{\partial\varphi(p)}{\partial n}\right]df_\tau=\int_0^\infty e^{-p\tau}d\tau\left\{\int_{f_1}F_1\frac{\partial\varphi(p)}{\partial n}df_1\right.$$

$$\left.-\int_{f_2}F_2\varphi(p)\,df_2-\int_{f_3}F_3\varphi(p)\,df_3-\int_V Q\varphi(p)\,dV\right\}-\int_{V_0}u^0\varphi(p)\,dV_0. \quad (29)$$

Here, the right side is known, so that when the motion of the boundary of f_T is given, this relation is an integral equation for finding whichever of the quantities u or ∂u/∂n is unknown. In the Stefan problem, Eq. (29) takes the form

$$\alpha\int_0^\infty e^{-p\tau}d\tau\int_{f_\tau}v_n\varphi(p)\,df_\tau=\int_0^\infty e^{-p\tau}d\tau\left\{-\int_{f_1}F_1\frac{\partial\varphi(p)}{\partial n}df_1\right.$$

$$\left.+\int_{f_2}F_2\varphi(p)\,df_2+\int_{f_3}F_3\varphi(p)\,df_3+\int_V Q\varphi(p)\,dV\right\}+\int_{V_0}u^0\varphi(p)dV_0, \quad (30)$$

and equations of this kind can be used to find the motion of the phase boundary f_T. This generally requires construction and use of an infinite set of functions φ(p) which form a complete (in a specific sense) set. The solution of the inverse problem is simpler when the motion of the phase boundary is known and it is required to determine the distribution of the external surface and volume sources that are responsible for such motion. Below, we give examples.

2. Returning now to the function $\varphi(\lambda)$, using Eq. (22) and the condition $\Delta\varphi_0 = 0$, we verify directly that it satisfies the equation

$$\Delta\varphi(\lambda)=\lambda\varphi(\lambda), \quad (31)$$

and since all the functions φ_m satisfy the boundary conditions (6) on f_1, f_2, and f_3 of the boundary surface, the same boundary conditions must also be satisfied by the function φ, i.e.,

$$\varphi|_{f_1}=0, \quad (32)$$

$$\frac{\partial\varphi}{\partial n}\Big|_{f_2}=0, \quad (33)$$

$$\left(\frac{\partial\varphi}{\partial n}+\gamma\varphi\right)\Big|_{f_3}=0. \quad (34)$$

This gives a direct method for constructing the functions $\varphi(\lambda)$, which can be any holomorphic solutions of (31) at the point $\lambda = 0$ which satisfy[6] the boundary conditions (32)-(34). At the same time, since the function $\varphi(\lambda)$ is a generating function for the functions φ_m, the latter can be obtained from the former by a simple expansion[7] in powers of λ.

Note that Eqs. (28) and (29) can be obtained directly from Eqs. (3) and (31). Actually,

$$\int_V[\varphi(\lambda)\,\Delta u-u\Delta\varphi(\lambda)]\,dV+\int_V Q\varphi(\lambda)\,dV+\int_{f_\tau}\varphi u v_n df_\tau=-\int_{f_1}F_1\frac{\partial\varphi(\lambda)}{\partial n}df_1$$

$$+\int_{f_2}F_2\varphi(\lambda)\,df_2+\int_{f_3}F_3\varphi(\lambda)df_3+\int_{f_\tau}\left[\left(\frac{\partial u}{\partial n}+v_n u\right)\varphi(\lambda)-u\frac{\partial\varphi(\lambda)}{\partial n}\right]df_\tau$$

$$+\int_V Q\varphi(\lambda)\,dV=\frac{dM(\lambda, \tau)}{d\tau}-\lambda M(\lambda, \tau);$$

integrating this equation for the initial condition $M(\lambda, 0) = \int_{V_0} u^0\varphi(\lambda)dV_0$, we obtain (28). Assuming that $\mathrm{Re}(\lambda) > 0$, multiplying (28) by $e^{-\lambda\tau}$ and taking the limit $\tau = \infty$, we obtain Eq. (29).

3. In the integrals over τ on the right side of Eq. (28) we take λ to be a constant. However, after the calculation is performed it is possible to determine $\lambda(\tau)$ the time dependence of λ. This follows since both the left and right sides of this equation contain analytic functions of λ and these must be identical.

4. In order to illustrate the general theory we first consider the simplest case of a Stefan problem, in which the solution depends only on a single Cartesian coordinate x or only on the radius r in cylindrical or spherical coordinate systems.

a) Process depends only on x. We denote the coordinate of the moving boundary by $\xi(\tau)$, so that $v_n = \dot{\xi}$; we note that in the present case the volume V means a cylinder of height ξ with cross section f_T equal to unity, i.e., $\int_V \psi dV = \int_0^\xi \psi dx$ and $\int_{f_\tau} \psi df_T = \psi$, where ψ is any function of x and τ. Moreover, on the moving boundary $\partial/\partial n = \partial/\partial x$, and on f_1, i.e., for $x = 0$, $\partial/\partial n = -\partial/\partial x$. Since the function $\varphi(\lambda)$ must satisfy the equation $d^2\varphi/dx^2 = \lambda\varphi$ and any one of the three boundary conditions (32)-(34) and be a holomorphic function of λ at the value $\lambda = 0$, then the corresponding three functions are

$$\varphi^{(1)}(\lambda)=\frac{\operatorname{sh}\sqrt{\lambda}x}{\sqrt{\lambda}}=\sum_{m=0}^\infty\lambda^m\frac{x^{2m+1}}{(2m+1)!},\quad\varphi_m^{(1)}=\frac{x^{2m+1}}{(2m+1)!}, \quad (35)$$

$$\varphi^{(2)}(\lambda)=\operatorname{ch}\sqrt{\lambda}x=\sum_{m=0}^\infty\lambda^m\frac{(x^{2m})!}{(2m)!};\quad\varphi_m^{(2)}=\frac{x^{2m}}{(2m)!}, \quad (36)$$

$$\varphi^{(3)}(\lambda)=\gamma\varphi^{(1)}-\varphi^{(2)}. \quad (37)$$

Note that for m ≥ 1 and k = 1, 2, 3 the following expression is obtained:

$$\varphi_m^{(k)}\big|_{x=0}=\frac{d\varphi_m^{(k)}}{dx}\Big|_{x=0}=0,$$

by virtue of which $b_m = 0$ for m ≥ 1 [cf. (10)].

For the case of boundary conditions of the first kind, Eq. (17) gives

$$\alpha\sum_{k=0}^\infty\frac{d^k}{d\tau^k}\left[\frac{\xi^{2k+1}}{(2k+1)!}\dot{\xi}\right]=\sum_{n=1}^\infty\frac{1}{(2n)!}\frac{d^n}{d\tau^n}(\xi^{2n})$$

$$=F_1(\tau)+\sum_{k=0}^{\infty}\frac{1}{(2k+1)!}\frac{d^k}{d\tau^k}\int_0^{\xi}Q(x,\tau)x^{2k+1}dx, \qquad (38)$$

where $F_1(\tau) = u|_{x=0}$, and similar equations for the cases of boundary conditions of the second and third kind. These equations coincide for $Q(x, \tau) = 0$ with the corresponding equations in refs. 1-3, where they were obtained by different methods, and extend the equations to the case[8] of a medium containing volume sources with density $Q(x, \tau)$.

Substituting the function $\varphi^{(1)}(\lambda)$ into (30), we obtain the equation

$$\alpha\int_0^{\infty}e^{-p\tau}\frac{\operatorname{sh}\sqrt{p}\,\xi(\tau)}{\sqrt{p}}\xi(\tau)\,d\tau=-\frac{\alpha\operatorname{ch}[\sqrt{p}\,\xi(0)]}{p}+\alpha\int_0^{\infty}e^{-p\tau}\operatorname{ch}[\sqrt{p}\,\xi(\tau)]\,d\tau$$
$$=F_1(p)+\frac{1}{\sqrt{p}}\left[\int_0^{\xi(\tau)}Q(x,\tau)\operatorname{sh}\sqrt{p}x\,dx+\int_0^{\xi(0)}u^0\operatorname{sh}\sqrt{p}x\,dx\right], \qquad (39)$$

whereas substitution into (28) gives

$$\int_0^{\xi(\tau)}u\frac{\operatorname{sh}\sqrt{\lambda}x}{\sqrt{\lambda}}dx=\int_0^{\tau}e^{\lambda(\tau-\eta)}\left[F_1(\eta)+\int_0^{\xi(\eta)}Q(x,\eta)\frac{\operatorname{sh}\sqrt{\lambda}x}{\sqrt{\lambda}}dx\right.$$
$$\left.-\alpha\frac{\operatorname{sh}\sqrt{\lambda}\,\xi(\eta)}{\sqrt{\lambda}}\xi'(\eta)\right]d\eta+e^{\lambda\tau}\int_0^{\xi(0)}u^0\frac{\operatorname{sh}\sqrt{\lambda}x}{\sqrt{\lambda}}dx. \qquad (40)$$

Similarly we obtain corresponding equations for the case of boundary conditions of the second and third kind.

When $Q(x, \tau) = 0$ Eq. (39) coincides with Eq. (2.5) in ref. 4 for $\xi(0) = 0$, and with Eq. (4.8) in ref. 6 for $\xi(0) \neq 0$, and (40) – with (4.7) in ref. 6, in which both these equations and also similar equations for problems with cylindrical and spherical symmetry are obtained with the help of special integral transformations, which are only useful in "one-dimensional" problems. In ref. 6 it is noted that integral relations of form (39) and similar relations for problems with cylindrical and spherical symmetry can be used to find the motion of the phase boundary.

An important result in Eq. (40) has not been indicated in these papers: When the boundary motion is known it is then possible to get the complete solution of the problem, i.e., the function u at any τ for any point in the medium. We now show this using Eq. (40).

Assuming that $\sqrt{\lambda} = ik\pi/\xi(\tau)$, where k is any integer, $k \geq 0$ (this is admissible, as was indicated in Sec. 3), we obtain

$$\int_0^{\xi(\tau)}u\sin\frac{\pi kx}{\xi(\tau)}dx\equiv u_k^{(1)}(\tau)=e^{-\frac{\pi^2k^2}{\xi^2(\tau)}\tau}\int_0^{\xi(0)}u_0(x)\sin\frac{\pi kx}{\xi(\tau)}dx$$
$$+\int_0^{\tau}e^{-\frac{\pi^2k^2(\tau-\eta)}{\xi^2(\tau)}}\left[\frac{\pi k}{\xi(\tau)}F_1(\eta)-\alpha\xi'(\eta)\sin\frac{\pi k\xi(\eta)}{\xi(\tau)}\right.$$
$$\left.+\int_0^{\xi(\eta)}Q(x,\eta)\sin\frac{\pi kx}{\xi(\tau)}dx\right]d\eta. \qquad (41)$$

The integrals on the left, however, are nothing more than the coefficients of the expansion of the function $u(x, \tau)$, determined at time τ in the interval $[0, \xi(\tau)]$ according to the system of "instantaneous" eigenfunctions (see ref. 7) $v_k^{(1)}(x, \tau) = \sin\pi kx/\xi(\tau)$, $k \geq 1$, corresponding to the boundary conditions of the first kind for $x = 0$ and for $x = \xi(\tau)$, where

$$u(x,\tau)=\frac{2}{\xi(\tau)}\sum_{k=1}^{\infty}u_k^{(1)}(\tau)\sin\frac{\pi kx}{\xi(\tau)},\quad 0<x<\xi(\tau). \qquad (42)$$

Therefore, if $\xi(\tau)$ is known, Eqs. (41) and (42) give the final solution of the initial problem.[9] Thus, e.g., if $\xi = 2\beta\sqrt{\tau}$, where $\beta = \text{const}$, such that $\xi(0) = 0$, and if $Q(x, \tau) = 0$, then (38) gives

$$F_1(\tau)=\alpha\sum_{n=1}^{\infty}\frac{n!}{(2n)!}(2\beta)^{2n}=\alpha\left[\int_0^{\infty}e^{-t}\operatorname{ch}2\beta\sqrt{t}\,dt-1\right]$$
$$=\alpha\sqrt{\pi}\beta e^{\beta^2}\Phi(\beta)\equiv U^0, \qquad (43)$$

where $\Phi(\beta) = (2/\sqrt{\pi})\int_0^{\beta}e^{-y^2}dy$, and (41), after simple transformations, takes the form

$$u_k^{(1)}(\tau)=\frac{2\beta\sqrt{\tau}}{\pi k}\left\{U^0\left(1-e^{-\frac{\pi^2k^2}{4\beta^2}}\right)-2\alpha\beta e^{-\frac{\pi^2k^2}{4\beta^2}}\int_0^{k\pi/2\beta}e^{y^2}\sin 2\beta y\,dy\right\}. \qquad (44)$$

Using the equation

$$\int_0^{b}e^{y^2}\sin 2\beta y\,dy=e^{\beta^2}\left[e^{b^2}\int_0^{\beta}e^{-x^2}\cos 2bx\,dx-\int_0^{\beta}e^{-x^2}dx\right], \qquad (45)$$

where b is an arbitrary constant, and using Eq. (43) it is easy to verify, by a direct calculation, that the quantities (44) coincide with the expansion coefficient in the series of the considered type of function

$$u(x,\tau)=U^0\left[1-\frac{\Phi\left(\frac{x}{2\sqrt{\tau}}\right)}{\Phi(\beta)}\right], \qquad (46)$$

which, as is known, is in fact a solution of the formulated problem.

We consider the solution of the problem for boundary conditions of the first kind. For boundary conditions of the second and third kind the calculations are similar, and we shall not discuss them. For example, note that for conditions of the second kind we find from Eq. (28) the quantities

$$u_k^{(2)}(\tau)=\int_0^{\xi(\tau)}u(x,\tau)\cos\frac{\pi kx}{\xi(\tau)}dx,$$

the expansion coefficients of the solution in a series of the form

$$u(x,\tau)=\frac{u_0^{(2)}(\tau)}{\xi(\tau)}+\frac{2}{\xi(\tau)}\sum_{k=1}^{\infty}u_k^{(2)}(\tau)v_k^{(2)}(x,\tau) \qquad (47)$$

according to the instantaneous functions $v_k^{(2)}(x, \tau) = \cos\pi kx/\xi(\tau)$, which satisfy boundary conditions of the second kind for x = 0 and x = $\xi(\tau)$ for conditions of the third kind.

b) Process depends only on cylindrical coordinate r. Then

$$\Delta\varphi=\frac{1}{r}\frac{d}{dr}\left(r\frac{d\varphi}{dr}\right)=\lambda\varphi,$$

and the solution, holomorphic at $\lambda = 0$, becoming zero at $r = a$, will be

$$\varphi^{(1)}(r,\ \lambda)=K_0(\sqrt{\lambda}\,a)\,I_0(\sqrt{\lambda}\,r)-I_0(\sqrt{\lambda}\,a)\,K_0(\sqrt{\lambda}\,r), \tag{48}$$

whereas for conditions of the second kind[10)]

$$\varphi^{(2)}(\lambda,\ r)=\frac{K_1(\sqrt{\lambda}\,a)\,I_0(\sqrt{\lambda}\,r)+I_1(\sqrt{\lambda}\,a)\,K_0(\sqrt{\lambda}\,r)}{\sqrt{\lambda}}. \tag{49}$$

Assuming the radius of the moving boundary to be equal to $\rho(\tau)$ as in the plane problems, we obtain a system of relations for determining $\rho(\tau)$ and for finding the function $u(r, \tau)$ based on known $\rho(\tau)$, initial state, and distribution of sources $Q(r, \tau)$. At the same time, Eq. (28) again gives, with substitution in it of the appropriate values of λ, the coefficients of the expansion $u(r, \tau)$ based on the corresponding system of instantaneous eigenfunctions. For boundary conditions of the first kind these eigenvalues $\lambda = \lambda(\tau)$ should be determined from the condition: $\varphi^{(1)}[\rho(\tau), \lambda(\tau)] = 0$, and for conditions of the second kind from the equation

$$\left.\frac{\partial\varphi^{(2)}(r,\ \lambda)}{\partial r}\right|_{r=\rho(\tau)}=0.$$

c) We now consider the Stefan problem for the half-space $z > 0$, on the boundary of which, i.e., for $z = 0$, we are given the values of $u|_{z=0} = F_1(x, y)$ or $\partial u/\partial z|_{z=0} = F_2(x, y)$ (three-dimensional problems).

In the first case we take $\varphi^{(1)}$ to be the function

$$\varphi^{(1)}=\frac{\operatorname{sh}\sqrt{\lambda+k^2+l^2}\,z}{\sqrt{\lambda+k^2+l^2}}\,e^{i(kx+ly)}, \tag{50}$$

where k and l are arbitrary real numbers. It satisfies Eq. (31) and is an entire function of λ. Since

$$\varphi^{(1)}|_{z=0}=0,\text{ and }\left.\frac{\partial\varphi^{(1)}}{\partial z}\right|_{z=0}=e^{i(kx+ly)}=\left.\frac{\partial\varphi_0^{(1)}}{\partial z}\right|_{z=0},$$

for all values of λ, we have the relations

$$\varphi_m^{(1)}|_{z=0}=0,\ m\geqslant 0\text{ and }\left.\frac{\partial\varphi_m^{(1)}}{\partial z}\right|_{z=0}=0,\ m\geqslant 1,$$

such that for $m \geq 1$, $b_m = 0$ [cf. (10)].

In the second case we set

$$\varphi^{(2)}=\operatorname{ch}(\sqrt{\lambda+k^2+l^2}\,z)\,e^{i(kx+ly)}, \tag{51}$$

where

$$\varphi_m^{(2)}|_{z=0}=0,\ m\geqslant 1;\ \left.\frac{\partial\varphi_m^{(2)}}{\partial z}\right|_{z=0}=0,\ m\geqslant 0.$$

Equation (10) shows that in both cases only the quantity b_0 is nonzero, whereas for $m \geq 1$, $b_m = 0$.

We assume that we know some possible law of displacement of the boundary f_τ and we pose the question of the nature of those external conditions on the plane $z = 0$ that cause such a motion, assuming that $Q(x, y, z, \tau) = 0$. Since we know the law of motion of the surface f_τ, we also know at each moment the normal component v_n of the velocity of displacement of all its elements; then we know the function of time and all the integrals of the form $\int_{f_\tau} v_n\varphi_k^{(s)}df_\tau$, s = 1, 2, appearing on the left side of Eq. (17). From this we therefore also find the sum appearing on its right side, which, according to what has been said above, reduces to the single term b_0, which in the case of the first boundary-value problem is

$$b_0\equiv b_0^{(1)}(k,\ l)=\int\limits_{x=-\infty}^{\infty}\int\limits_{y=-\infty}^{\infty}F_1(x,\ y)\,e^{i(kx+ly)}\,dxdy, \tag{52}$$

and for a condition of the second kind

$$b_0\equiv b_0^{(2)}(k,\ l)=\int\limits_{-\infty}^{\infty}\int\limits_{-\infty}^{\infty}F_2(x,\ y)\,e^{i(kx+ly)}\,dxdy. \tag{53}$$

Transformation of these equations using the Fourier integral gives

$$F_1(x,\ y)=\frac{1}{4\pi^2}\int\limits_{-\infty}^{\infty}\int\limits_{-\infty}^{\infty}b_0^{(1)}(k,\ l)\,e^{-i(xk+yl)}\,dkdl, \tag{54}$$

$$F_2(x,\ y)=\frac{1}{4\pi^2}\int\limits_{-\infty}^{\infty}\int\limits_{-\infty}^{\infty}b_0^{(2)}(k,\ l)\,e^{-i(xk+yl)}\,dkdl, \tag{55}$$

and this is also the complete solution of the formulated problem.

d) As a last example we consider one more problem with the boundary moving in a given way, where we assume that everything depends only on x, and on the moving boundary $\xi(\tau)$ we are given one of the values: $u|_{x=\xi} = \psi_1(\tau)$ or $\partial u/\partial x|_{x=\xi} = \psi_2(\tau)$, for x = 0 – the value $u|_{x=0} = F_1(\tau)$, and $u|_{\tau=0} = u^0(x)$. Equations (29) and (35) then give, for example, in the first of the indicated cases, if we set $\partial u/\partial n|_{x=\xi} = q(\tau)$

$$\begin{aligned}\int\limits_0^{\infty}e^{-p\tau}q(\tau)\operatorname{sh}[\sqrt{p}\,\xi(\tau)]\,d\tau&=-\sqrt{p}\,F_1(p)-\int\limits_0^{\xi(0)}u^0(x)\operatorname{sh}\sqrt{p}\,x\,dx\\&+\int\limits_0^{\infty}e^{-p\tau}\Big\{\psi_1(\tau)[\sqrt{p}\operatorname{ch}\sqrt{p}\,\xi(\tau)-\dot{\xi}(\tau)\operatorname{sh}\sqrt{p}\,\xi(\tau)]\\&-\int\limits_0^{\xi(\tau)}Q(x,\ \tau)\operatorname{sh}\sqrt{p}\,x\,dx\Big\}\,d\tau,\end{aligned} \tag{56}$$

and this equation, the right side of which is known, should also serve for finding the function $q(\tau)$. After $q(\tau)$ has been found, the right side of Eq. (28) becomes known [cf. (26)], and since its left side in the given case equals $\int_0^{\xi(\tau)} u(\operatorname{sh}\sqrt{\lambda}x/\sqrt{\lambda})dx$, the equation obtained agrees in type with Eq. (40) and can be solved immediately by the method given in Sec. 3.

The case when on the moving boundary we are given the value $\partial u/\partial x|_{x=\xi} = \psi_2(\tau)$ or when $x = 0$ we are given the values $\partial u/\partial x|_{x=0} = -F_2(\tau)$ or $(\partial u/\partial x - \gamma u)|_{x=0} = -F_3(\tau)$ can be considered in a completely similar way.

---

[1] By a Stefan problem we shall here mean the particular case in which one of two adjoining phases is at the temperature of the phase transition and the phase boundary is displaced laterally. The boundary conditions on the boundary surface will have the form (2) (the transition temperature is assumed to be zero).

[2] We note that in the selection of such a system of functions we have some arbitrariness because on the part f_τ of the surface bounded by V no conditions are placed on the functions. We assume that these functions have all the properties that are necessary for the validity of the further calculations.

[3] The quantity $u_m(0)$ is the value of the integral (7) for $\tau = 0$, i.e., at the initial time.

[4] Here and below, we everywhere assume that all the series introduced in the course of the calculations converge uniformly in the ranges of the variables being considered so that we can interchange the order of summation and integration.

[5] Comparing the coefficients for identical powers of λ from the right and from the left.

[6] As indicated above, the conditions for the function $\varphi(\lambda)$ are not unique.

[7] It is sometimes advantageous to obtain these directly from the system (5), (6).

[8] In ref. 5, similar relations are also obtained for a continuous cylinder and sphere, on the external surface of which the Stefan conditions are satisfied.

[9] We recall that the function $F_1(\tau)$ that appears in (41) is also known, because it is obtained with known $\xi(\tau)$ from Eq. (38).

[10] It is easy to verify that, although the functions $K_0(\sqrt{\lambda}r)$ and $K_1(\sqrt{\lambda}r)$ contain ln λ, it drops out of the combinations (48) and (49).

(Submitted November 30, 1973)
Zh. Tekh. Fiz., 44, 2043-2050 (October 1974)

The generalized Cauchy series for the heat-conduction equation is used to find new exact solutions for the one-dimensional Stefan problem in a plane region and in a region with spherical symmetry; the phase boundary moves according to $y(\tau) = \sqrt{A\tau^2 + B\tau + h^2}$, where A, B, and h are known constants. The solution for the corresponding problem is given when the boundary moves according to $y(\tau) = \sqrt{A\tau^2 + B\tau}$ for a region bounded by a cylindrical phase-transition surface with an interior heat source located along the axis.

1. In this work, using the generalized Cauchy series we obtain exact solutions of certain single-phase Stefan problems.

We consider the following problem. Let the region $0 < x < h$ be initially filled with a substance in which there is some initial temperature distribution $\varphi(x)$ such that $\varphi(h) = 0$; in the region $x > h$ this substance is at its melting point, which we take equal to zero. As a result of heating or cooling of the medium from the surface $x = 0$ to the plane $x = h$, at time $\tau = 0$ a phase transition arises; this propagates continuously to the right.

We obtain the following system of equations for the problem:

$$\frac{\partial^2 u}{\partial x^2} = \frac{\partial u}{\partial \tau}, \quad 0 < x < y(\tau), \ \tau > 0, \tag{1.1}$$

$$u(x, 0) = \varphi(x), \quad 0 < x < h = y(0), \quad \varphi(h) = 0, \tag{1.2}$$

$$u[y(\tau), \tau] = 0, \tag{1.3}$$

$$\alpha \left.\frac{\partial u}{\partial x}\right|_{x=y(\tau)} = \frac{dy}{d\tau}. \tag{1.4}$$

Beginning at the time $\tau = 0$ on the surface $x = 0$ we are given one of the three boundary conditions

$$u(0, \tau) = f_1(\tau), \tag{1.5a}$$

$$\left.\frac{\partial u}{\partial x}\right|_{x=0} = f_2(\tau), \tag{1.5b}$$

$$\left.\frac{\partial u}{\partial x}\right|_{x=0} = \chi[u(0, \tau) - f_3(\tau)], \tag{1.5c}$$

where $y(\tau)$ is the coordinate of the moving surface, α is a constant, which can be greater than or less than zero, χ is a known coefficient, and τ is the dimensionless time.

Replacing x by ξ in Eq. (1.1) we multiply it by $\xi - x$ and integrate over ξ from x to $y(\tau)$. Then, as a result of successive integration by parts (as in ref. 1), we obtain

$$u(x, \tau) = -\sum_{n=0}^{\infty} \frac{\partial^n}{\partial \tau^n} \left\{ \frac{[y(\tau) - x]^{2n+1}}{(2n+1)!} \left[\dot{y}(\tau) u(y(\tau), \tau) + \left.\frac{\partial u}{\partial x}\right|_{x=y(\tau)} \right] \right\} + \sum_{n=0}^{\infty} \frac{\partial^n}{\partial \tau^n} \left\{ \frac{[y(\tau) - x]^{2n}}{(2n)!} u(y(\tau), \tau) \right\}, \quad x < 0 < y(\tau). \tag{1.6}$$

Equation (1.6) is a generalized Cauchy series for the heat-conduction equations, when the Cauchy conditions are given along some analytic arc $x = y(\tau)$.

Using conditions (1.3) and (1.4) we obtain

$$u(x, \tau) = -\frac{1}{\alpha} \sum_{n=1}^{\infty} \frac{1}{(2n)!} \frac{\partial^n}{\partial \tau^n} [y(\tau) - x]^{2n}, \quad 0 < x < y(\tau). \tag{1.7}$$

Using the boundary conditions (1.5) we obtain the relations

$$f_1(\tau) = -\frac{1}{\alpha} \sum_{n=1}^{\infty} \frac{1}{(2n)!} \frac{d^n}{d\tau^n} y^{2n}(\tau), \tag{1.8a}$$

$$f_2(\tau) = \frac{1}{2} \sum_{n=1}^{\infty} \frac{1}{(2n-1)!} \frac{d^n}{d\tau^n} [y(\tau)]^{2n-1}, \tag{1.8b}$$

$$-\alpha f_3(\tau) = \sum_{n=1}^{\infty} \frac{d^n}{d\tau^n} \left[\frac{y^{2n}(\tau)}{(2n)!} + \frac{1}{\chi} \frac{y^{2n-1}(\tau)}{(2n-1)!} \right]. \tag{1.8c}$$

To these equations we must add an initial condition, which follows from (1.2) and (1.7):

$$\varphi(x) = -\frac{1}{\alpha} \sum_{n=1}^{\infty} \frac{1}{(2n)!} \left\{ \frac{\partial^n}{\partial x^n} [y(\tau) - x]^{2n} \right\}_{\tau=0}, \quad 0 < x < h. \tag{1.9}$$

Equations (1.7) and (1.9) can be written in a more convenient form. Since the solution of Eq. (1), $u(x, \tau)$, and its derivative $\partial u/\partial x$ on the surface $x = 0$ become, respectively, the functions $f_1(\tau)$ and $f_2(\tau)$, we can use the well-known (see ref. 2) expansion of the integral of the heat-conduction equation (1.1) in a series in powers of x:

$$u(x, \tau) = \sum_{n=0}^{\infty} \frac{x^{2n}}{(2n)!} \frac{d^n}{d\tau^n} f_1(\tau) + \sum_{n=0}^{\infty} \frac{x^{2n+1}}{(2n+1)!} \frac{d^n}{d\tau^n} f_2(\tau); \tag{1.10}$$

hence

$$\varphi(x) = \sum_{n=0}^{\infty} \frac{x^{2n}}{(2n)!} \left[\frac{d^n}{d\tau^n} f_1(\tau) \right]_{\tau=0} + \sum_{n=0}^{\infty} \frac{x^{2n+1}}{(2n+1)!} \left[\frac{d^n}{d\tau^n} f_2(\tau) \right]_{\tau=0}. \tag{1.11}$$

Equations (1.7)-(1.9) can be considered as the solution of an inverse Stefan problem in the following sense: If a law of motion of the boundary $y(\tau)$ is given, then the function $u(x, \tau)$, defined by (1.7), is a solution of the heat-conduction equation (1.1) which satisfies conditions (1.3) and (1.4) on the boundary $x = y(\tau)$. Then Eqs. (1.5) and (1.9) give the boundary values $f_i(\tau)$ and the initial distribution

$\varphi(x)$, corresponding to a given law of motion of the phase-boundary surface.

2. We assume that the phase-transition surface moves according to

$$y(\tau)=\sqrt{A\tau^2+B\tau+h^2}, \qquad (2.1)$$

where A and B are known coefficients.

We investigate thermal regimes for which such motions are possible. We determine the conditions on the boundary x = 0 corresponding to the given motion of the front of the phase boundary. We first find the temperature on the surface x = 0. We substitute (2.1) into Eq. (1.8a):

$$f_1(\tau)=-\frac{1}{a}\sum_{n=1}^{\infty}\frac{1}{(2n)!}\frac{d^n}{d\tau^n}(A\tau^2+B\tau+h^2)^n. \qquad (2.2)$$

We rewrite y(τ) in the form

$$y^2(\tau)=A\tau^2+B\tau+h^2=\left(\sqrt{A}\,\tau+\frac{B}{2\sqrt{A}}\right)^2-\frac{B^2}{4A}+h^2=\beta^2(z^2-1). \qquad (2.3)$$

where

$$\beta^2=\frac{B^2}{4A}-h^2,\quad z^2=\frac{1}{\beta^2}\left(\sqrt{A}\,\tau+\frac{B}{2\sqrt{A}}\right)^2; \qquad (2.4)$$

then

$$f_1(\tau)=-\frac{1}{a}\sum_{n=1}^{\infty}\frac{\beta^{2n}}{(2n)!}\frac{d^n}{d\tau^n}\left[\frac{\left(\sqrt{A}\,\tau+\frac{B}{2\sqrt{A}}\right)^2}{\beta^2}-1\right]^n$$
$$=-\frac{1}{a}\sum_{n=1}^{\infty}\frac{A^{n/2}\beta^n}{(2n)!}\frac{d^n}{dz^n}(z^2-1)^n. \qquad (2.5)$$

The right side of (2.5) is a series in Legendre polynomials, which, for all real or complex z, are defined by the Rodrigues equation[3]

$$P_n(z)=\frac{1}{2^n n!}\frac{d^n}{dz^n}(z^2-1)^n.$$

Hence

$$f_1(\tau)=-\frac{1}{a}\sum_{n=1}^{\infty}\frac{A^{n/2}\beta^n}{(2n-1)!!}P_n\left(\frac{\tau\sqrt{A}+\frac{B}{2\sqrt{A}}}{\beta}\right). \qquad (2.6)$$

Using Eq. (A.1) of the Appendix, we obtain

$$f_1(\tau)=-\frac{1}{a}\int_0^1\frac{1}{\sqrt{1-\zeta}}\frac{d}{d\zeta}e^{\frac{\sqrt{A}\beta}{2}z\zeta}I_0\left(\frac{\beta\sqrt{A}}{2}\zeta\sqrt{z^2-1}\right)d\zeta$$
$$=-\frac{1}{a}\int_0^1 e^{\frac{\sqrt{A}\beta z}{1}\zeta}\left[\frac{\sqrt{A}\beta}{2}zI_0\left(\frac{\sqrt{A}\beta}{2}\zeta\sqrt{z^2-1}\right)\right.$$
$$\left.+\frac{\beta\sqrt{A}}{2}\sqrt{z^2-1}\,I_1\left(\frac{\sqrt{A}\beta}{2}\zeta\sqrt{z^2-1}\right)\right]\frac{d\zeta}{\sqrt{1-\zeta}}\ ; \qquad (2.7)$$

taking account of (2.3) and (2.4), we obtain the final expression for $f_1(\tau)$:

$$f_1(\tau)=-\frac{1}{2a}\int_0^1 e^{\frac{y(\tau)\dot{y}(\tau)}{2}\zeta}\left\{y(\tau)\dot{y}(\tau)I_0\left[\frac{\sqrt{A}}{2}y(\tau)\zeta\right]\right.$$
$$\left.+\sqrt{A}y(\tau)I_1\left[\frac{\sqrt{A}}{2}y(\tau)\zeta\right]\right\}\frac{d\zeta}{\sqrt{1-\zeta}}. \qquad (2.8)$$

We now calculate the value of the heat flux on the surface x = 0. After substituting (2.1) into Eq. (1.8b) we obtain

$$f_2(\tau)=\frac{1}{a}\sum_{n=1}^{\infty}\frac{A^{n/2}\beta^{n-1}}{(2n-1)!}\frac{d^n}{dz^n}(z^2-1)^{n-1/2}. \qquad (2.9)$$

By definition, for every real and complex z we have

$$\frac{\sqrt{z^2-1}}{(2n-1)!!}\frac{d^n}{dz^n}(z^2-1)^{n-1/2}=T_n(z),\ |z|\geqslant 1,$$

where the $T_n(z)$ are Tschebyshev polynomials of the first kind; then

$$f_2(\tau)=\frac{1}{a\sqrt{z^2-1}}\sum_{n=1}^{\infty}\frac{A^{n/2}\beta^{n-1}}{2^{n-1}(n-1)!}T_n(z)=\frac{\sqrt{A}}{a\sqrt{z^2-1}}\sum_{n=0}^{\infty}\frac{A^{n/2}\beta^n}{2^n n!}T_{n+1}(z). \qquad (2.10)$$

Since

$$T_n(z)=\operatorname{ch}(n\operatorname{arch}z)=\frac{1}{2}[(z+\sqrt{z^2-1})^n$$
$$+(z-\sqrt{z^2-1})^n],\ |z|\geqslant 1, \qquad (2.11)$$

then Eq. (2.10) can be summed:

$$f_2(\tau)=\frac{\sqrt{A}}{2a\sqrt{z^2-1}}\sum_{n=0}^{\infty}\frac{A^{n/2}\beta^n}{2^n n!}[(z+\sqrt{z^2-1})^{n+1}+(z-\sqrt{z^2-1})^{n+1}]$$
$$=\frac{\sqrt{A}}{a\sqrt{z^2-1}}e^{\frac{\sqrt{A}\beta}{2}z}\left[z\operatorname{ch}\frac{\beta\sqrt{A}}{2}\sqrt{z^2-1}+\sqrt{z^2-1}\operatorname{sh}\frac{\sqrt{A}}{2}\beta\sqrt{z^2-1}\right].$$

Thus,

$$f_2(\tau)=\frac{1}{a}e^{\frac{y(\tau)\dot{y}(\tau)}{2}}\left\{\dot{y}(\tau)\operatorname{ch}\left[\frac{\sqrt{A}}{2}y(\tau)\right]+\sqrt{A}\operatorname{sh}\left[\frac{\sqrt{A}}{2}y(\tau)\right]\right\}. \qquad (2.12)$$

If the phase-transition surface moves according to $y(\tau)=\sqrt{B\tau+h^2}$ from Eqs. (2.8) and (2.12) we have

$$f_1(\tau)=-\frac{\sqrt{\pi B}}{2a}e^{B/4}\Phi\left(\frac{\sqrt{B}}{2}\right), \qquad (2.13)$$

$$f_2(\tau)=\frac{Be^{B/4}}{2a\sqrt{B\tau+h^2}}, \qquad (2.14)$$

and from (1.10) and (1.11)

$$u(x,\tau)=-\frac{\sqrt{\pi B}}{2a}e^{B/4}\left[\Phi\left(\frac{\sqrt{B}}{2}\right)-\Phi\left(\frac{x}{2}\sqrt{\frac{B}{B\tau+h^2}}\right)\right],\ 0<x<y(\tau), \qquad (2.15)$$

$$\varphi(x)=-\frac{\sqrt{\pi B}}{2a}e^{B/4}\left[\Phi\left(\frac{\sqrt{B}}{2}\right)-\Phi\left(\frac{\sqrt{B}}{2}\frac{x}{h}\right)\right],\ 0<x<h, \qquad (2.16)$$

where

$$\Phi(z)=\frac{2}{\sqrt{\pi}}\int_0^z e^{-\zeta^2}d\zeta.$$

If the velocity of the boundary is such that the quantity B/12 can be neglected in comparison with unity, then the initial temperature distribution, corresponding to motion of the boundary according to $y(\tau) = \sqrt{B\tau + h^2}$, is essentially linear:

$$\varphi(x)\simeq\frac{B}{2\alpha}\left(1-\frac{x}{h}\right). \qquad (2.17)$$

3. Using the same method we can investigate a similar problem for a spherically symmetric layer. The equations of the problem have the form

$$\frac{1}{r^2}\frac{\partial}{\partial r}r^2\frac{\partial u(r,\tau)}{\partial r}=\frac{\partial u}{\partial\tau},\quad a<r<R(\tau), \qquad (3.1)$$

$$u[R(\tau),\tau]=0,\quad R(0)=b\geqslant a, \qquad (3.2)$$

$$\alpha\frac{\partial u}{\partial r}\Big|_{r=R(\tau)},\quad \dot{R}(\tau), \qquad (3.3)$$

$$u(r,0)=\varphi(r),\quad 0<r<R(0)=b. \qquad (3.4)$$

On the interior fixed boundary we are given one of the two conditions

$$u(a,\tau)=f_1(\tau), \qquad (3.5a)$$

$$\frac{\partial u}{\partial r}\Big|_{r=a}=f_2(\tau). \qquad (3.5b)$$

Assuming, as usual, that

$$v(r,\tau)=ru(r,\tau),\quad x=r-a, \qquad (3.6)$$

we obtain the following system of equations for the function $v(x, \tau)$:

$$\frac{\partial^2 v}{\partial x^2}=\frac{\partial v}{\partial\tau},\quad 0<x<y(\tau)=R(\tau)-a, \qquad (3.7)$$

$$v[y(\tau),\tau]=0, \qquad (3.8)$$

$$\alpha\frac{\partial v}{\partial x}\Big|_{x=y(\tau)}=[y(\tau)+a]\dot{y}(\tau), \qquad (3.9)$$

$$v(x,0)=\varphi(x)(x+a),\quad 0<x<h=b-a, \qquad (3.10)$$

$$v(0,\tau)=af_1(\tau), \qquad (3.11a)$$

$$\left(\frac{\partial v}{\partial x}-\frac{v}{a}\right)_{x=0}=af_2(\tau). \qquad (3.11b)$$

If we now use Eqs. (1.6), (1.8a), (1.8b), and (1.11), we obtain

$$v(x,\tau)=-\frac{1}{\alpha}\sum_{n=0}^{\infty}\frac{1}{(2n+1)!}\frac{\partial^n}{\partial\tau^n}\{[y(\tau)-x]^{2n+1}[y(\tau)+a]\dot{y}(\tau)\}, \quad 3.12)$$

$$af_1(\tau)=-\frac{1}{\alpha}\sum_{n=0}^{\infty}\frac{1}{(2n+1)!}\frac{d^n}{d\tau^n}\{y^{2n+1}(\tau)[y(\tau)+a]\dot{y}(\tau)\}, \qquad (3.13)$$

$$af_2(\tau)=-f_1(\tau)+\frac{1}{\alpha}\sum_{n=0}^{\infty}\frac{1}{(2n)!}\frac{d^n}{d\tau^n}\{[y(\tau)]^{2n}[y(\tau)+a]\dot{y}(\tau)\}, \qquad (3.14)$$

$$\varphi(x)(x+a)=a\sum_{n=0}^{\infty}\frac{x^{2n}}{(2n)!}\left[\frac{d^n}{d\tau^n}f_1(\tau)\right]_{\tau=0}$$
$$+\sum_{n=0}^{\infty}\frac{x^{2n+1}}{(2n+1)!}\left\{\frac{d^n}{d\tau^n}[af_2(\tau)+f_1(\tau)]\right\}_{\tau=0}. \qquad (3.15)$$

We present here (omitting the calculations) values of the temperature and heat flux on the surface r = a, if the phase-boundary surface moves according to

$$y(\tau)=R(\tau)-a=\sqrt{A\tau^2+B\tau+(b-a)^2}=\sqrt{A\tau^2+B\tau+h^2}, \qquad (3.16)$$

$$af_1(\tau)=-\frac{2}{\alpha}e^{\frac{1}{2}\left(A\tau+\frac{B}{2}\right)}\left\{\frac{1}{\sqrt{A}}\left(A\tau+\frac{B}{2}-2\right)\operatorname{sh}\left[\frac{\sqrt{A}}{2}y(\tau)\right]\right.$$
$$\left.+y(\tau)\operatorname{ch}\left[\frac{\sqrt{A}}{2}y(\tau)\right]\right\}-\frac{a}{\alpha}\int_0^1\frac{1}{\sqrt{1-\zeta}}\frac{d}{d\zeta}e^{\frac{1}{2}y(\tau)\dot{y}(\tau)\zeta}I_0\left[\frac{\sqrt{A}}{2}\zeta y(\tau)\right]d\zeta, \qquad (3.17)$$

$$af_2(\tau)=-f_1(\tau)+\frac{S}{\alpha}, \qquad (3.18)$$

$$S=\frac{a\sqrt{A}}{\sqrt{z^2-1}}e^{\frac{\beta\sqrt{A}}{2}z}\left[z\operatorname{ch}\left(\frac{\beta\sqrt{A}}{2}\sqrt{z^2-1}\right)+\sqrt{z^2-1}\operatorname{sh}\left(\frac{\beta\sqrt{A}}{2}\sqrt{z^2-1}\right)\right]$$
$$+\beta\sqrt{A}z+\frac{\beta^2Az^2}{2}\int_0^1 e^{\frac{\beta\sqrt{A}}{2}\zeta z}I_0\left(\frac{\beta\sqrt{A}}{2}\zeta\sqrt{z^2-1}\right)\frac{d\zeta}{\sqrt{1-\zeta}}$$
$$+\beta^2A\sqrt{z^2-1}\int_0^1 e^{\frac{\beta\sqrt{A}}{2}z\zeta}\left(z-\frac{1}{\beta\sqrt{A}\zeta}\right)I_1\left(\frac{\beta\sqrt{A}}{2}\zeta\sqrt{z^2-1}\right)\frac{d\zeta}{\sqrt{1-\zeta}}$$
$$+\beta^2A\frac{z^2-1}{2}\int_0^1 e^{\frac{\beta\sqrt{A}}{2}z\zeta}I_0\left(\frac{\beta\sqrt{A}}{2}\zeta\sqrt{z^2-1}\right)\frac{d\zeta}{\sqrt{1-\zeta}}, \qquad (3.19)$$

where

$$\beta\sqrt{z^2-1}=y(\tau),\quad \frac{\beta\sqrt{A}}{2}z=\frac{1}{2}\left(A\tau+\frac{B}{2}\right)$$
$$=\frac{1}{2}y(\tau)\dot{y}(\tau),\quad \beta^2=\frac{B^2}{4A}-h^2.$$

If A = 0, i.e., $y(\tau) = R(\tau) - a = \sqrt{B\tau + h^2}$, then

$$af_1(\tau)=-\frac{B}{2\alpha}e^{B/4}\sqrt{B\tau+h^2}-\frac{a\sqrt{\pi B}}{2\alpha}e^{B/4}\Phi\left(\frac{\sqrt{B}}{2}\right), \qquad (3.20)$$

$$af_2(\tau)=\frac{B}{2\alpha}e^{B/4}\left[\frac{1}{a}\sqrt{B\tau+h^2}+\frac{a}{\sqrt{B\tau+h^2}}+\frac{\sqrt{\pi}}{\sqrt{B}}\Phi\left(\frac{\sqrt{B}}{2}\right)\right.$$
$$\left.+\frac{\sqrt{\pi B}}{2}\Phi\left(\frac{\sqrt{B}}{2}\right)\right]+\frac{B}{2\alpha}, \qquad (3.21)$$

$$\varphi(x)(x+a)=-a\frac{\sqrt{\pi B}}{2\alpha}e^{B/4}\left[\Phi\left(\frac{\sqrt{B}}{2}\right)+\Phi\left(\frac{x}{h}\frac{\sqrt{B}}{2}\right)\right]$$
$$+\frac{Bx}{2\alpha}\left[1+\frac{\sqrt{\pi B}}{2}e^{\frac{B}{4}}\Phi\left(\frac{\sqrt{B}}{2}\right)\right]-\frac{Bh}{2\alpha}e^{\frac{B}{4}\left(1-\frac{x^2}{h^2}\right)}\left[1+\frac{x}{h}\frac{\sqrt{\pi B}}{2}e^{\frac{B}{4}\frac{x^2}{h^2}}\Phi\left(\frac{x}{h}\frac{\sqrt{B}}{2}\right)\right]. \qquad (3.22)$$

If B/12 ≪ 1, then

$$\varphi(r) \simeq -\frac{B}{2a}\frac{b}{b-a}\frac{b-r}{r}, \quad a<r<b. \tag{3.23}$$

4. In conclusion we present a solution of an axisymmetric problem with an interior heat source located on the axis.

The general equations for such a problem are as follows:

$$\frac{1}{r}\frac{\partial u}{\partial r} r \frac{\partial u}{\partial r} = \frac{\partial u}{\partial \tau}, \quad 0<r<R(\tau), \tag{4.1}$$

$$u[R(\tau), \tau] = 0, \tag{4.2}$$

$$a \frac{\partial u}{\partial r}\Big|_{r=R(\tau)} = \frac{dR(\tau)}{d\tau}, \quad R(0)=0, \tag{4.3}$$

$$\lim_{r\to 0} 2\pi r \frac{\partial u}{\partial r} = f_2(\tau). \tag{4.4}$$

Proceeding in the same way as in ref. 4, we multiply (4.1) by $2\pi r$ and integrate over r from 0 to $R(\tau)$. We obtain

$$f_2(\tau) = \frac{2\pi}{a}\sum_{n=0}^{\infty}\frac{1}{[(2n)!!]^2\, 2(n+1)}\frac{d^{n+1}}{d\tau^{n+1}} R^{2n+2}(\tau). \tag{4.5}$$

If the boundary moves according to

$$R(\tau) = \sqrt{Ar^2 + B\tau}, \tag{4.6}$$

after substituting (4.6) into (4.5) and making transformations similar to those in the preceding sections, we find that the power of the source corresponding to such motion should be as follows:

$$\left.\begin{aligned} f_2(\tau) = \frac{4\pi}{a} e^{\frac{R(\tau)\dot{R}(\tau)}{2}} \Big\{ & \frac{R(\tau)\dot{R}(\tau)}{2} I_0\Big[\frac{\sqrt{A}}{2}R(\tau)\Big] \\ & + \frac{\sqrt{A}}{2}R(\tau) I_1\Big[\frac{\sqrt{A}}{2}R(\tau)\Big]\Big\}, \\ R(\tau) = \sqrt{A\tau^2 + B\tau}. & \end{aligned}\right\} \tag{4.7}$$

When A = 0, i.e., $R(\tau) = \sqrt{B\tau}$, we obtain the solution for the case of a source of constant power:

$$\lim_{r\to 0} 2\pi r \frac{\partial u}{\partial r} = Q = \frac{4\pi}{a}\frac{B}{4} e^{B/4}, \tag{4.8}$$

which agrees with the known case.[5]

APPENDIX

We consider the series

$$\sum_{n=1}^{\infty}\frac{\gamma^{n-\frac{1}{2}}}{(2n-1)!!}P_n(z) = F(\gamma, z).$$

We apply a Laplace transformation with respect to γ. We then obtain

$$\int_0^{\infty} e^{-p\gamma}F(\gamma, z)\,d\gamma = \int_0^{\infty} e^{-p\gamma}\Bigg[\sum_{n=1}^{\infty}\frac{\gamma^{n-\frac{1}{2}}}{(2n-1)!!}P_n(z)\Bigg]d\gamma$$

$$= \sum_{n=1}^{\infty}\frac{P_n(z)}{(2n-1)!!}\frac{(2n-1)!!}{2^n p^n}\int_0^{\infty}\frac{e^{-p\gamma}d\gamma}{\sqrt{\gamma}} = \sqrt{\pi}\sum_{n=1}^{\infty}\frac{P_n(z)}{2^n p^{n+\frac{1}{2}}},$$

i.e., the function $\overline{F}(p, z)$ is correct at an infinitely distant point, and has in its neighborhood a Laurent expansion

$$F(p, z) = \sqrt{\frac{\pi}{p}}\sum_{n=1}^{\infty}\frac{P_n(z)}{2^n p^n}.$$

Using the first expansion theorem and the multiplication theorem we obtain

$$F(\gamma, z) = \int_0^{\gamma}\sum_{n=1}^{\infty}\frac{P_n(z)\,\eta^{n-1}}{2^n(n-1)!}\frac{d\eta}{\sqrt{\gamma-\eta}} = \int_0^{\gamma}\frac{1}{\sqrt{\gamma-\eta}}\frac{\partial}{\partial\eta}\sum_{n=1}^{\infty}\frac{P_n(z)}{2^n n!}\eta^n d\eta$$

$$= \int_0^{\gamma}\frac{1}{\sqrt{\gamma-\eta}}\frac{\partial}{\partial\eta}\sum_{n=0}^{\infty}\frac{P_n(z)\,\eta^n}{2^n n!}\,d\eta.$$

In view of the generating function for Legendre polynomials[3]

$$\sum_{n=0}^{\infty}\frac{P_n(z)\,\eta^n}{n!} = e^{\eta z} I_0(\eta\sqrt{z^2-1}), \quad |z| \geqslant 1,$$

we obtain

$$F(\gamma, z) = \sum_{n=1}^{\infty}\frac{\gamma^{n-\frac{1}{2}}}{(2n-1)!!}P_n(z) = \int_0^{\gamma}\frac{1}{\sqrt{\gamma-\eta}}\frac{d}{d\eta}\Big\{e^{\frac{z\eta}{2}} I_0\Big[\frac{\eta}{2}\sqrt{z^2-1}\Big]\Big\}d\eta$$

$$= \frac{1}{\sqrt{\gamma}}\int_0^{1}\frac{1}{\sqrt{1-\zeta}}\frac{d}{d\zeta}e^{\frac{\gamma z}{2}\zeta} I_0\Big[\frac{\gamma}{2}\zeta\sqrt{z^2-1}\Big]d\zeta. \tag{A.1}$$

Magnetic topography of toroidal systems

M. N. Skoblik, V. E. Ziser, A. V. Georgievskii, and V. G. Peletminskaya

(Submitted September 21, 1973)
Zh. Tekh. Fiz., 44, 2051-2057 (October 1974)

Magnetic fields of toroidal systems are calculated, taking account of the finite size of the elements producing the field. The rule for locating the helical windings on the surface of the torus is discussed in general form, yielding the choice of the optimum pitch for a given device. An algorithm is developed and a computer program is given for calculating the field at any point in space from a single helix or a set of n-helical windings. Results for specific thermonuclear devices are presented.

INTRODUCTION

The mathematical simulation of all kinds of systems and processes has long ago justified itself and is more and more widely used in various fields of science and technology, including the construction of various magnetic systems.

In order to investigate the magnetic field of a device, to calculate the ponderomotive forces, which control the capacity rating of the structure, to analyze the effectiveness of the use of superconducting materials, etc., it is first necessary to determine the magnetic field inside and outside the current elements.

The field can be determined experimentally only after the system has been constructed, and an accurate measurement of the field is difficult close to a conductor wound on a torus, and almost impossible inside the conductor. By mathematical simulation one can choose the optimum values of the geometrical and other parameters and perform a detailed calculation of the system before construction.

The creation of a mathematical model which reflects physical reality makes it possible to investigate magnetic systems and to determine the dependence of the physical parameters of the systems on geometry, etc. The development of a calculational procedure greatly increases the possibilities of optimizing the system parameters with minimum effort.

Magnetic fields of helical coils wound on a torus are analyzed in refs. 1-3, but under the assumption that the wire is infinitesimally thin. Alexander and Downing[4] take account of the finite size of the conductor, but for circular cylindrical coils.

We discuss the simulation of magnetic systems whose elements are helical coils wound on a torus, taking account of the finite size of the elements producing the field.

1. DESCRIPTION OF THE MODEL

In actual physical devices an element producing the field is finite in width and thickness. If the field point, i.e., the point at which the field is calculated, is sufficiently far from the current element its dimensions can be neglected and the field can be assumed to be produced by an infinitesimally thin conductor. As the field point approaches the conductor its width begins to matter first. To take account of the width the conductor is replaced by an infinitesimally thin sheet with width equal to the actual width of the conductor. If the field point is very close to the element or inside it the thickness of the element must be taken into account by replacing the conductor by a stack of k very thin uniformly spaced sheets (Fig. 1).

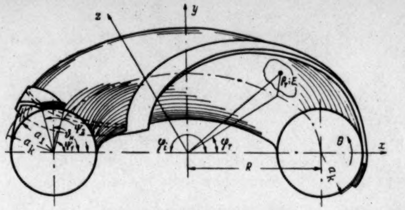

Fig. 1. System of coordinates.

Expansion of the field in spatial harmonics is inappropriate in calculating the magnetic field at a point inside a conductor or very near it, so the exact Biot–Savart law must be used. The field of an infinitesimally thin conductor is

$$\mathbf{H}=\frac{I}{c}\int\limits_{l}\frac{[d\mathbf{l}\mathbf{r}]}{r^3}, \tag{1.1}$$

where **dl** is an element of the conductor producing the field, **r** is the radius vector from the element to the field point, and I is the current in the conductor.

As already noted, however, the intensity can be calculated by assuming that the current element is infinitesimally thin only when the field point is sufficiently far from the element. If the point is close to the current element or inside it the finite dimensions of the element must be taken into account to obtain the intensity with sufficient accuracy. Its width is $\psi_2 - \psi_1$ and its thickness is $a_2 - a_1$ (Fig. 1), where ψ_i is the polar angle in a cross section at a fixed φ.

By integrating Eq. (1.1) over ψ from ψ_1 to ψ_2 we obtain the field of an infinitesimally thin sheet. By considering a stack of k very thin uniformly spaced sheets, each of width $\psi_{2k} - \psi_{1k}$, and summing over k, we find the magnetic field due to a conductor of finite cross section:

$$\mathbf{H}=\sum_{k}\frac{I_k}{c\,(\psi_{2k}-\psi_{1k})}\int\limits_{\psi_{1k}}^{\psi_{2k}}\int\frac{[d\mathbf{l}_k\mathbf{r}_k]}{r_k^3}\,d\psi, \tag{1.2}$$

where a_k is the radial distance to the k-th sheet. The current in the k-th sheet is

$$I_k=\frac{Ia_k}{\sum\limits_k a_k}. \tag{1.3}$$

Let us consider the magnetic field of a helical coil wound on a torus of minor radius a and major radius R (Fig. 1). The final expressions for the quantities entering the integrand depend on the choice of coordinate system, on the rule for winding the coil, and on the method of specifying the coordinates of the field point (x_T, y_T, z_T).

The field components in the XYZ Cartesian coordinate system are

$$\left.\begin{aligned} H_x &= \sum_k \frac{I_k}{c(\psi_{2k}-\psi_{1k})} \int\limits_{\psi_{1k}}^{\psi_{2k}} \int\limits_{l_k} \frac{1}{r^3}[dl_{yk}(z_T-z_k)-dl_{zk}(y_T-y_k)]\,d\psi_k, \\ H_y &= \sum_k \frac{I_k}{c(\psi_{2k}-\psi_{1k})} \int\limits_{\psi_{1k}}^{\psi_{2k}} \int\limits_{l_k} \frac{1}{r^3}[dl_{zk}(x_T-x_k)-dl_{xk}(z_T-z_k)]\,d\psi_k, \\ H_z &= \sum_k \frac{I_k}{c(\psi_{2k}-\psi_{1k})} \int\limits_{\psi_{1k}}^{\psi_{2k}} \int\limits_{l_k} \frac{1}{r^3}[dl_{xk}(y_T-y_k)-dl_{yk}(x_T-x_k)]\,d\psi_k, \end{aligned}\right\} \tag{1.4}$$

where $r^3 = [(x_T - x_k)^2 + (y_T - y_k)^2 + (z_T - z_k)^3]^{3/2}$; x_k, y_k, z_k are the running coordinates of the current element; x_T, y_T, z_T are the coordinates of the field point.

Let us consider the general expression for the location of the helical windings in parametric form,[5]

$$m\varphi = \pm(\theta - \alpha\sin\theta - \beta\sin 2\theta), \tag{1.5}$$

where φ is the azimuthal angle in the plane containing the major radii of the torus, θ is the polar angle in a cross section of the torus at constant φ, m is the number of the periods of the field, and α and β are variable parameters:

$$\alpha = \varkappa\alpha_0;\quad \beta = \varkappa\beta_0,$$

$$\alpha_0 = \frac{a}{R}\left(\ln\frac{8R}{a} - \frac{1}{2}\right);\quad \beta = \frac{a^2}{8R^2}\left(\frac{17}{4} - 4\ln\frac{8R}{a}\right).$$

By varying α and β the optimum relation for locating the helical windings for a specific arrangement can be found. The ± signs distinguish right- and left-hand windings. Below we assume right-hand windings, which does not affect the generality of the discussion.

Then in the XYZ system the running coordinates of the conductor producing the field, and the quantities dl, dl_y, dl_z entering the integrand, divided by the radius, are

$$\left.\begin{aligned} x &= (R_1 + \cos\theta)\sin\varphi, \\ y &= \sin\theta, \\ z &= (R_1 + \cos\theta)\cos\varphi, \\ dl_x &= [(R_1 + \cos\theta)\cos\varphi f - \sin\theta\sin\varphi]\,d\theta, \\ dl_y &= \cos\theta\, d\theta, \\ dl_z &= -[(R_1 + \cos\theta)\sin\varphi f + \sin\theta\cos\varphi]\,d\theta, \end{aligned}\right\} \tag{1.6}$$

where $R_1 = R/a$; $f = (1/m)(-\theta + \alpha\cos\theta + 2\beta\cos 2\theta)$.

The field point is specified in polar coordinates ρ_T, ξ in a cross section at a given value of φ. In the XYZ system the coordinates of the field point are

$$\left.\begin{aligned} x_T &= \frac{1}{a}[A\cos(\varphi_i + \theta_i) + B\sin(\varphi_i + \theta_i)], \\ y_T &= \frac{1}{a}\rho_T \sin\xi, \\ z_T &= \frac{1}{a}[A\sin(\varphi_i + \theta_i) - B\cos(\varphi_i + \theta_i)], \end{aligned}\right\} \tag{1.7}$$

where

$$\left.\begin{aligned} A &= (R + \rho_T\cos\xi)\cos\varphi_T - a_i - R\cos\varphi_i, \\ B &= (R + \rho_T\cos\xi)\sin\varphi_T - R\sin\varphi_i, \end{aligned}\right\} \tag{1.8}$$

φ_T is the value of φ in the cross section which contains the field point; a_i, φ_i, and θ_i locate the coordinate system fixed at the origin of the current element relative to the XYZ system.

Using the fact that in calculating the field of finite-sized conductors the running coordinate is $\theta_n = \theta - \psi$, the final expressions for the field components in electromagnetic units from n-helical conductors are

$$H_x = \sum_k \frac{0.1}{(\psi_{2k}-\psi_{1k})} \int\limits_{\psi_{1k}}^{\psi_{2k}} \Bigg\{ \sum \frac{I_k}{a_k} \int\limits_{\theta_{1n}}^{\theta_{2n}} \frac{1}{r^3} \Big\{ \cos\theta_n \Big[\frac{1}{a}\{A\sin(\varphi_i + \theta_i)$$
$$- B\cos(\varphi_i + \theta_i)\} - (R_1 + \cos\theta_n)\cos\varphi\Big] + [(R_1 + \cos\theta_n)\cos\varphi m^{-1}$$
$$\times(-1 + \alpha\cos\theta_n + 2\beta\cos 2\theta_n)$$
$$+ \sin\theta_n\sin\varphi]\left(\frac{\rho_T}{a}\sin\xi - \cos\theta_n\right)\Big\}\, d\theta_n \Bigg\}\, d\psi_k,$$

$$H_y = \sum_k \frac{0.1}{\psi_{2k}-\psi_{1k}} \int\limits_{\psi_{1k}}^{\psi_{2k}} \Bigg\{ \sum_n \frac{I_k}{a_k} \int\limits_{\theta_{1n}}^{\theta_{2n}} \frac{1}{r^3} \Big\{ [(R_1 + \cos\theta_n)\sin\varphi(1 - \alpha\cos\theta_n$$
$$- 2\beta\cos\theta_n) - \sin\theta_n\cos\varphi]\Big[\frac{1}{a}[A\cos(\varphi_i + \theta_i) - B\sin(\varphi_i + \theta_i)]$$
$$- (R_1 + \cos\theta_n)\sin\varphi\Big] - [(R_1 + \cos\theta_n)$$
$$\cos\varphi(-1 + \alpha\cos\theta_n + \beta\cos 2\theta_n)m^{-1}$$
$$- \sin\theta_n\sin\varphi]\Big[\frac{1}{a}[A\sin(\varphi_i + \theta_i) - B\cos(\varphi_i + \theta_i)]$$
$$- (R_1 + \cos\theta_n)\cos\varphi\Big]\Big\}\, d\theta_n \Bigg\}\, d\psi_k,$$

$$H_z = \sum_k \frac{0.1}{\psi_{2k}-\psi_{1k}} \int\limits_{\psi_{1k}}^{\psi_{2k}} \Bigg\{ \sum_k \frac{I_k}{a_k} \int\limits_{\theta_{1n}}^{\theta_{2n}} \frac{1}{r^3} [(R_1 + \cos\theta_n)\cos\varphi(-1 + \alpha\cos\theta_n$$
$$+ \beta\cos 2\theta_n)m^{-1} - \sin\theta_n\sin\varphi]\left(\frac{\rho_T}{a}\sin\xi - \sin\theta_n\right)$$
$$- \cos\theta_n\Big[\frac{1}{a}[A\cos(\varphi_i + \theta_i)$$
$$+ B\sin(\varphi_i + \theta_i)] - (R_1 + \cos\theta_n)\sin\varphi\Big]\Big\}\, d\theta_n \Bigg\}\, d\psi_k,$$

where

$$r^3 = \Big\{\Big[\frac{1}{a}[A\cos(\varphi_i + \theta_i) + B\sin(\varphi_i + \theta_i)] - (R_1 + \cos\theta_n)\sin\varphi\Big]^2$$
$$+ \left(\frac{\rho_T}{a}\sin\xi - \sin\theta_n\right)^2 + \Big[\frac{1}{a}[A\sin(\varphi_i + \theta_i) - B\cos(\varphi_i + \theta_i)]$$
$$- (R_1 + \cos\theta_n)\cos\varphi\Big]^2\Big\}^{3/2}; \tag{1.9}$$

the summation over n is a summation over the number of conductors.

In stellarators the windings for producing a magnetic field with a rotational transform consist of several helical conductors uniformly spaced in φ. The resulting field of such windings can be obtained by summing the fields of the separate conductors, each of which has its own value of the angle φ where the helical winding begins. The transition from conductor to conductor is accomplished by the substitution

$$\varphi_i=\vartheta_0+\frac{2\pi}{mn}(i-1);\quad i=1,\ 2,\ \ldots,\ n, \tag{1.10}$$

where ϑ_0 is the initial angle of the first conductor, and n is the number of identical helical conductors spaced in φ. In this case expressions are obtained for the field components for helical windings of torsatrons,[4] i.e., when equal currents flow in the same direction in adjacent conductors.

For stellarators, i.e., when there are 2n-helical conductors with the current flowing in opposite directions in adjacent conductors, the summation is performed with the factor $(-1)^k (k = 1, 2, \ldots, 2n)$ and in addition n is replaced by 2n in Eq. (1.10). θ_{1n} and θ_{2n} are found in terms of φ by an iterative method.[6] As a first approximation $\theta_{1n} = 2\pi m(i-1)$. In special cases integrations over θ are replaced by integration1) over φ:

$$\theta=\vartheta_0+\frac{2\pi}{n}(i-1)-\psi,\quad i=1,\ 2,\ \ldots,\ n \text{ for a torsatron,}$$

$$\theta=\vartheta_0+\frac{2\pi}{2n}(i-1)-\psi,\quad i=1,\ 2,\ \ldots,\ 2n \text{ for a stellarator.}$$

2. DESCRIPTION OF THE PROGRAM AND THE CALCULATIONAL PROCEDURE

For arbitrary values of the parameters of the torus and the current element and an arbitrary field point Eq. (1.9) is suitable for computer calculations. Only one restriction is imposed on the location of the field point: It must not coincide with a point current element or lie on a thin plate element. No restrictions are imposed on the parameters of the torus and the current element.

The calculation is programmed for an M-220 computer. In one manipulation the field intensity can be computed at $N \le 100$ points from several ($k \le 25$) n-helical windings. The integration is performed by Simpson's rule.[6] All three integrals are computed simultaneously, and in order to save machine time the trigonometric functions in the integrand are computed by the formulas for the sums of angles. The limits of integration θ_{1n} and θ_{2n} are found by an iteration method[6] using Eq. (1.5) for $\varphi = \varphi$ initial and $\varphi = \varphi_{\text{final}}$.

The number of steps in the internal integral per field period for satisfactory accuracy is determined in the process of checking out the program by comparing the results for h and h/2, where h is the integration step. If the field point is outside the element it is sufficient for the internal integral to take $(\theta_{2n} - \theta_{1n})/\text{nmh} = 100$; if the point is inside the element $(\theta_{2n} - \theta_{1n})/\text{nmh} \ge 200$.

As previously noted, a current element can be considered a point (having no transverse dimensions) when the field point is far enough away from the conductors. It has been established in the calculational process that if an element of thickness $a_2 - a_1$ is replaced by a point conductor at the radius $a = (a_2 - a_1)/2$ the field components are determined with 1% accuracy for $\rho_T \ge 1.2a_2$ or $\rho_T \le 0.55a_1$.

To achieve 1% accuracy for $0.55a_1 < \rho_T < 0.8a_1$ and $1.05a_2 < \rho < 1.2a_2$ the element must be replaced by an infinitesimally thin sheet having the actual width of the conductor $\psi_2 - \psi_1$ and located at the same place as the point conductor, i.e., $a = (a_2 - a_1)/2$.

In all other cases 1% accuracy is achieved by replacing the element by a set of k sheets uniformly spaced from a_1 to a_2. The current in the sheets is given by Eq. (1.3). It is sufficient to take the number of sheets k = 12 since there is no significant change in the field components for

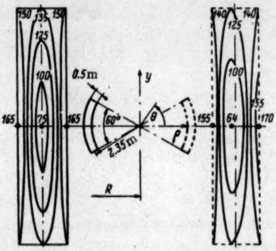

Fig. 2. Distribution of magnetic field intensity inside a current element. $\alpha = \beta = 0$, $a = 2.35$, R = 12, m = 5.33, n = 3, $a_2 - a_1 = 0.5$ m, $\psi_2 - \psi_1 = 60°$, $H_0 = 90$ kOe.

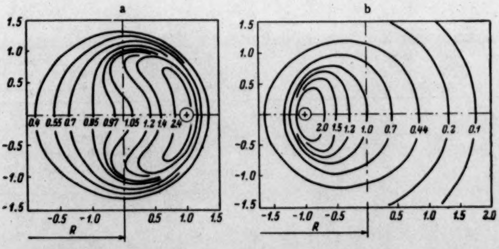

Fig. 3. Distribution of magnetic field intensity in the active volume of a torsatron. a) φ = period of the field; b) φ = 1/2 period of the field. $a = 7.25$ cm, R = 13.5 cm, n = 1, $\alpha = 0.875\alpha_0$, $\beta = 0.875\beta_0$, m = 13.

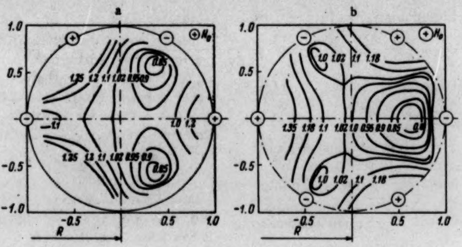

Fig. 4. Distribution of magnetic field intensity in the active volume of a stellarator. a) φ = period of the field; b) φ = 1/2 period of the field. a = 10 cm, R = 35.6 cm, n = 3, m = 2.666, $\alpha = \beta = 0$.

a further increase in k.

Using the program developed here calculations have been reformed to select the magnetic systems of such thermonuclear devices as Saturn-1 (ref. 3), Vint-20 (ref. 7), and others. A study of the structure of the magnetic fields of these devices shows that in principle a stellarator can be used to construct a thermonuclear reactor.[8] As an illustration of the use of the algorithm and the program the results of some of the calculations are presented below.

Figure 2 shows the lines $H = \sqrt{H_x^2 + H_y^2 + H_z^2}$ = const inside a current element for the magnetic system of a torsatron. The calculation is performed according to the procedure described above. The element is replaced by very thin sheets of radius $a_k = a_1 \pm (a_2 - a_1)/12$ with the current given by Eq. (1.3).

In the investigation of the magnetic system of a stellarator reactor[8] the calculation of the magnetic field inside an element and the construction of the lines H = const permit a determination of the ponderomotive forces acting on the windings and give a basis for the choice of material for the winding.

Figures 3 and 4 show the lines H = const in the active volume of the single-helix torsatron Vint-20 and the l = 3 stellarator Saturn-1. The principal characteristics of the magnetic field (absolute value of the field intensity in the active volume, ratio of maximum to minimum intensity, etc.) are calculated from these data.

The algorithm and program described can be used as a component in calculating the topography of the magnetic lines of force of closed toroidal systems. The algorithm and calculational program for the topography of the magnetic lines of force will be described later.

The machine time for the calculation depends on the parameters of the device being calculated, but is acceptable in all the cases examined here.

---

1) If $\alpha = \beta = 0$ Eq. (1.5) is easily solved for θ, and the integration over θ can be replaced by an integration over φ.

Rectangular conducting wedge in a moving electromagnetic field

I. D. Maergoiz and L. P. Nizhnik

(Submitted October 8, 1973; resubmitted February 26, 1974)
Zh. Tekh. Fiz., 44, 2058-2068 (October 1974)

The problem of determining the eddy current distribution over the surface of a rectangular conducting wedge in the field of a moving current sheet is discussed. Analytic solutions are found when the surface of the wedge is perfectly conducting and for the Leontovich impedance boundary condition. Eddy current distribution patterns are constructed. A solution is also presented for another method of exciting the external field.

INTRODUCTION

In a number of technical problems, for example the design of electrical machines with solid rotors, the magnetic field and eddy current distributions in the end zones of solid conducting cylinders are of interest. The solution of this problem with a detailed account of the geometry of the conducting body and the extent of the penetration of the electromagnetic field into its interior presents considerable mathematical difficulties. The purpose of the present paper is to show that these difficulties can be overcome under the following simplifying assumptions: 1) The solid conducting cylinder is replaced by an infinite rectangular wedge; 2) the skin effect is well defined. By assuming the sharp manifestation of the skin effect approximate boundary conditions can be assumed on the surface of the conducting body, and the calculation of the field can be reduced to the solution of the exterior boundary-value problem. If the conducting body is nonmagnetic ($\mu = \mu_0$) it is expedient to take the perfect conductivity boundary condition; for a ferromagnetic ($\mu \gg \mu_0$) conducting body the Leontovich impedance boundary conditions are used. We note that the use of approximate boundary conditions is not rigorously justified in the immediate vicinity of the edge of the dihedral corner. One expects, however, that the calculated results will be in error only in the vicinity of the edge and that the general character of the field and eddy current distributions will not be changed. The use of approximate boundary conditions to calculate the field in corner regions is transitional;[1-3] it significantly simplifies the calculation and leads to analytic solutions.

STATEMENT OF THE PROBLEM

Let us consider the problem of calculating the electromagnetic field produced by a current sheet which is infinite in the x direction and moves in the z direction above a dihedral conducting corner (Fig. 1). We write the magnetic field in vacuum as the sum of two terms:

$$\dot{\mathbf{H}} = \dot{\mathbf{H}}^J + \dot{\mathbf{H}}^0,$$

where $\dot{\mathbf{H}}^J$ is the magnetic field produced by the current sheet of density $\dot{\mathbf{J}} = \mathbf{k}_x j e^{j\alpha z}$ moving in a region of uniform permeability μ_0; $\dot{\mathbf{H}}^0$ is the field produced by the eddy currents and the magnetization of the medium of the dihedral corner. The following equations hold for $\dot{\mathbf{H}}^J$:

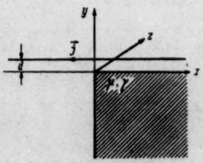

Fig. 1

$$\left.\begin{aligned} \dot{H}^J_y &= -j\frac{J e^{-\alpha d}}{2} e^{\alpha y} e^{j\alpha z}, \\ \dot{H}^J_x &= \frac{J e^{-\alpha d}}{2} e^{\alpha y} e^{j\alpha z}, \end{aligned}\right\} \tag{1}$$

if y < d, and

$$\left.\begin{aligned} \dot{H}^J_y &= -j\frac{J e^{\alpha d}}{2} e^{-\alpha y} e^{j\alpha z}, \\ \dot{H}^J_x &= -\frac{J e^{\alpha d}}{2} e^{-\alpha y} e^{j\alpha z}, \end{aligned}\right\} \tag{2}$$

if y > d.

The principal difficulty is the calculation of the secondary field $\dot{\mathbf{H}}^0$. In the quasistationary approximation the field $\dot{\mathbf{H}}^0$ has a zero curl; hence, a scalar potential can be introduced in the region outside the corner

$$\begin{gathered} \dot{\mathbf{H}}^0 = -\operatorname{grad} \dot{\varphi}, \\ \dot{\varphi}(x, y, z) = \dot{\Phi}(x, y) e^{j\alpha z}, \end{gathered} \tag{3}$$

where $\dot{\Phi}(x, y)$ satisfies the equation

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} - \alpha^2 \Phi = 0. \tag{4}$$

If the medium inside the dihedral corner is assumed to be perfectly conducting

$$(\mathbf{n}, \dot{\mathbf{H}}) = 0. \tag{5}$$

Using (1)-(3) and (5) we obtain the boundary conditions for $\dot{\Phi}(x, y)$

$$\frac{\partial \Phi}{\partial y}(x, 0) = \dot{A}; \; x > 0; \; \dot{A} = -j\frac{J e^{-\alpha d}}{2}, \tag{6}$$

$$\frac{\partial \Phi}{\partial x}(0, y) = 0; \; y < 0. \tag{7}$$

Thus the calculation of the field is reduced to solving the Neumann boundary-value problem (4), (6), (7).

For a ferromagnetic conducting medium ($\mu \gg \mu_0$) the magnetic field lines are drawn in; therefore even for a sharply defined skin effect there will be a strong deviation from boundary condition (5). In this situation we use the Leontovich boundary condition

$$[\mathbf{n}, \dot{\mathbf{E}}] = (1 + j)\sqrt{\frac{\omega\mu}{2\gamma}}[\mathbf{n}, [\mathbf{n}, \dot{\mathbf{H}}]]. \tag{8}$$

Let us reformulate this boundary condition as a boundary condition for $\dot{\Phi}(x, y)$.

We consider, for example, the side $y = 0, x > 0$. Here (8) takes the form

$$\dot{E}_z = (1+j)\sqrt{\frac{\omega\mu}{2\gamma}}\,\dot{H}_x;\ \dot{E}_x = -(1+j)\sqrt{\frac{\omega\mu}{2\gamma}}\,\dot{H}_z. \tag{9}$$

Using Maxwell's equations we obtain from (9)

$$\mathrm{curl}_y\,\dot{\mathrm{E}} = \frac{\partial \dot{E}_x}{\partial z} - \frac{\partial \dot{E}_z}{\partial x} = -j\omega\mu_0 \dot{H}_y$$

$$= (1+j)\sqrt{\frac{\omega\mu}{2\gamma}}\left(\frac{\partial \dot{H}_z}{\partial z} + \frac{\partial \dot{H}_x}{\partial x}\right) = -(1+j)\sqrt{\frac{\omega\mu}{2\gamma}}\frac{\partial \dot{H}_y}{\partial y},$$

from which

$$\frac{\partial \dot{H}_y}{\partial y} - (1+j)\sqrt{\frac{\omega\gamma\mu_0^2}{2\mu}}\,\dot{H}_y = 0. \tag{10}$$

Using (1)-(3) we find from (10)

$$\frac{\partial^2 \Phi}{\partial y^2} - \dot{\beta}\frac{\partial \Phi}{\partial y} = \dot{A} \text{ for } y = 0,\ x > 0. \tag{11}$$

Here,

$$\dot{\beta} = (1+j)\sqrt{\frac{\omega\gamma\mu_0^2}{2\mu}};\ \ \dot{A} = -j\frac{f e^{-\alpha d}(\alpha - \dot{\beta})}{2}. \tag{12}$$

In complete analogy with the above

$$\frac{\partial^2 \Phi}{\partial x^2} + \dot{\beta}\frac{\partial \Phi}{\partial x} = 0 \text{ for } x = 0,\ y < 0. \tag{13}$$

Thus when impedance boundary conditions are used the calculation of the field is reduced to solving the boundary-value problem (4), (11), (13).

SOLUTION OF THE PROBLEM FOR A PERFECTLY CONDUCTING MEDIUM

Since the right-hand sides of boundary conditions (6) and (7) are constants we can use the following simple method of solution. We introduce the new function

$$\Psi(x, y) = \frac{\partial^2 \Phi}{\partial x \partial y}, \tag{14}$$

and from (4), (6) and (7) we obtain the following homogeneous boundary-value problem:

$$\frac{\partial^2 \Psi}{\partial x^2} + \frac{\partial^2 \Psi}{\partial y^2} - \alpha^2 \Psi = 0, \tag{15}$$

$$\Psi(x, 0) = 0,\ x > 0, \tag{16}$$

$$\Psi(0, y) = 0,\ y < 0. \tag{17}$$

We note that a similar scheme for solving boundary-value problems for a rectangular wedge, based on the introduction of auxiliary functions,$^{1)}$ was developed earlier.[4]

The solution of the boundary-value problem (15)-(17) is easily obtained by separating variables in polar coordinates

$$\Psi(x, y) = \sum_{i=1}^{\infty} \dot{B}_{2i/3} K_{2i/3}(\alpha r) \sin\frac{2i}{3}\theta. \tag{18}$$

Here, the $K_{2i/3}$ are Macdonald functions and the $\dot{B}_{2i/3}$ are arbitrary constants. It is physically obvious that the field $\dot{H}^0$ can have only integrable singularities in the neighborhood of the edge of the dihedral corner. Therefore only two terms need be retained in (18), i.e.

$$\Psi(x, y) = \dot{B}_{2/3} K_{2/3}(\alpha r) \sin\frac{2}{3}\theta + \dot{B}_{4/3} K_{4/3}(\alpha r) \sin\frac{4}{3}\theta. \tag{19}$$

From (19) and (14) we find

$$\frac{\partial \Phi}{\partial x}(x, y) = -\dot{B}_{2/3}\int_y^{\infty} K_{2/3}(\alpha r) \sin\frac{2}{3}\theta dy_1 - \dot{B}_{4/3}\int_y^{\infty} K_{4/3}(\alpha r)\sin\frac{4}{3}\theta dy_1, \tag{20}$$

$$\frac{\partial \Phi}{\partial y}(x, y) = \dot{B}_{2/3}\int_{-\infty}^{x} K_{2/3}(\alpha r) \sin\frac{2}{3}\theta dx_1 + \dot{B}_{4/3}\int_{-\infty}^{x} K_{4/3}(\alpha r)\sin\frac{4}{3}\theta dx_1. \tag{21}$$

The constants $\dot{B}_{2/3}$ and $\dot{B}_{4/3}$ are determined from boundary conditions (6) and (7). In order to satisfy these boundary conditions it is necessary to let $x \to 0 (y < 0)$ and $y \to 0 (x > 0)$ in (20) and (21). However, going to the limit directly in (20) and (21) leads to divergent integrals. To overcome this difficulty we use the easily proved relation

$$K_{4/3}(\alpha r)\sin\frac{4}{3}\theta = -\frac{2}{\alpha}\frac{\partial}{\partial y}\left(K_{1/3}(\alpha r)\cos\frac{1}{3}\theta\right) - K_{2/3}(\alpha r)\sin\frac{2}{3}\theta \tag{22}$$

and transform (20) to the form

$$\frac{\partial \Phi}{\partial x}(x, y) = (\dot{B}_{4/3} - \dot{B}_{2/3})\int_y^{\infty} K_{2/3}(\alpha r)\sin\frac{2}{3}\theta dy_1 - \frac{2}{\alpha}\dot{B}_{4/3}K_{1/3}(\alpha r)\cos\frac{1}{3}\theta. \tag{23}$$

Taking account of (7) we find from (23)

$$\lim_{\substack{x \to 0 \\ y < 0}} \frac{\partial \Phi}{\partial x}(x, y) = (\dot{B}_{4/3} - \dot{B}_{2/3})\frac{\sqrt{3}}{2}\int_0^{\infty} K_{2/3}(\alpha y)\, dy = 0,$$

hence

$$\dot{B}_{4/3} = \dot{B}_{2/3}. \tag{24}$$

Similarly we transform (21) to the form

$$\frac{\partial \Phi}{\partial y}(x, y) = (\dot{B}_{2/3} + \dot{B}_{4/3})\int_{-\infty}^{x} K_{2/3}(\alpha r)\sin\frac{2}{3}\theta dx_1 - \frac{2}{\alpha}\dot{B}_{4/3}K_{1/3}(\alpha r)\sin\frac{1}{3}\theta, \tag{25}$$

from which, according to (6),

$$\lim_{\substack{y \to 0 \\ x > 0}} \frac{\partial \Phi}{\partial y}(x, y) = (\dot{B}_{2/3} + \dot{B}_{4/3})\frac{\sqrt{3}}{2}\int_{-\infty}^{0} K_{2/3}(\alpha x)\, dx = \dot{A}.$$

Using (24) and the fact that[5]

$$\int_{-\infty}^{0} K_{2/3}(\alpha x)\, dx = \int_0^{\infty} K_{2/3}(\alpha x)\, dx = \frac{\pi}{\alpha}, \tag{26}$$

we obtain

$$\dot{B}_{1/3}=\dot{B}_{2/3}=\frac{\alpha\dot{A}}{\pi\sqrt{3}}=-j\frac{\alpha\dot{J}e^{-\alpha d}}{2\pi\sqrt{3}}. \qquad (27)$$

From (27), (23), (25), and (3) we find

$$\dot{H}_x^0=-\frac{\partial\Phi}{\partial x}e^{j\omega t}=-j\frac{\dot{J}e^{-\alpha d}}{\pi\sqrt{3}}K_{1/3}(\alpha r)\cos\frac{1}{3}\theta e^{j\omega t}, \qquad (28)$$

$$\dot{H}_y^0=-\frac{\partial\Phi}{\partial y}e^{j\omega t}$$

$$=\left(\frac{j\alpha\dot{J}e^{-\alpha d}}{\pi\sqrt{3}}\int\limits_{-\infty}^{x}K_{2/3}(\alpha r)\sin\frac{2}{3}\theta dx_1-j\frac{\dot{J}e^{-\alpha d}}{\pi\sqrt{3}}K_{1/3}(\alpha r)\sin\frac{1}{3}\theta\right)e^{j\omega t}, \qquad (29)$$

$$\dot{H}_z^0=-j\alpha\Phi e^{j\omega t}=\frac{\alpha\dot{J}e^{-\alpha d}}{\pi\sqrt{3}}\int\limits_{-\infty}^{x}K_{1/3}(\alpha r)\cos\frac{1}{3}\theta dx_1 e^{j\omega t}. \qquad (30)$$

SOLUTION OF THE PROBLEM FOR IMPEDANCE BOUNDARY CONDITIONS

Since the right-hand sides of boundary conditions (11) and (13) are constants a method similar to that of the previous section can be used to solve the boundary-value problem (4), (11), (13). We introduce the auxiliary function

$$\Psi(x,\ y)=\left(\frac{\partial}{\partial x}+\dot{\beta}\right)\left(\frac{\partial}{\partial y}-\dot{\beta}\right)\Phi(x,\ y)$$

$$=\frac{\partial}{\partial x}\left(\frac{\partial\Phi}{dy}-\beta\Phi\right)+\dot{\beta}\left(\frac{\partial\Phi}{\partial y}-\beta\Phi\right)=\frac{\partial}{\partial y}\left(\frac{\partial\Phi}{\partial x}+\beta\Phi\right)-\dot{\beta}\left(\frac{\partial\Phi}{\partial x}+\beta\Phi\right). \qquad (31)$$

From (31), (4), (11), and (13) we find that $\dot{\Psi}(x, y)$ is a solution of the following boundary-value problem:

$$\frac{\partial^2\Psi}{\partial x^2}+\frac{\partial^2\Psi}{\partial y}-\alpha^2\Psi=0, \qquad (32)$$

$$\frac{\partial\Psi}{\partial y}(x,\ 0)=\dot{\beta}\dot{A},\ x>0, \qquad (33)$$

$$\frac{\partial\Psi}{\partial x}(0,\ y)=0,\ y<0; \qquad (34)$$

here $\dot{\beta}$ and A are given by (12).

The boundary-value problem (32), (33), (34) is similar to the boundary-value problem (4), (6), (7) whose solution is discussed in the preceding section. Therefore if we do not require that the solution of problem (32)-(34) be bounded, its general form is

$$\Psi(x,\ y)=\Psi_0(x,\ y)+\sum_{i=0}^{\infty}\dot{B}_{2i/3}K_{2i/3}(\alpha r)\cos\frac{2i}{3}\theta, \qquad (35)$$

$$\Psi_0(x,\ y)=\dot{B}_{1/3}\int\limits_{-\infty}^{x}K_{1/3}(\alpha r)\cos\frac{1}{3}\theta dx_1, \qquad (36)$$

$$\dot{B}_{1/3}=-\frac{2}{\pi\sqrt{3}}\dot{\beta}\dot{A}=\frac{j\dot{J}e^{-\alpha d}\dot{\beta}(\alpha-\dot{\beta})}{\pi\sqrt{3}}. \qquad (37)$$

We find from (31)

$$\frac{\partial^2\Phi}{\partial y^2}-\dot{\beta}\frac{\partial\Phi}{\partial y}=\int\limits_{-\infty}^{x}e^{-\dot{\beta}(x-x_1)}\frac{\partial\Psi}{\partial y}(x_1,\ y)dx_1, \qquad (38)$$

$$\frac{\partial^2\Phi}{\partial x^2}+\dot{\beta}\frac{\partial\Phi}{\partial x}=-\int\limits_{y}^{\infty}e^{\dot{\beta}(y-y_1)}\frac{\partial\Psi}{\partial x}(x,\ y_1)dy_1. \qquad (39)$$

. . It can be shown from (38) and (39) that $\partial^2\dot{\Phi}/\partial y^2-\beta\partial\Phi/\partial y=0$ and $\partial^2\dot{\Phi}/\partial x^2+\dot{\beta}\partial\dot{\Phi}/\partial x$ will be bounded in the neighborhood of the edge of the dihedral corner; consequently boundary conditions (11) and (13) can be satisfied only if $\dot{\Psi}(x, y)$ increases no faster than $1/r$ in the neighborhood of the edge. Hence it follows that in the infinite sum in (35) only the first two terms need be retained, i.e.,

$$\Psi(x,\ y)=\Psi_0(x,\ y)+\dot{B}_0K_0(\alpha r)+\dot{B}_{2/3}K_{2/3}(\alpha r)\cos\frac{2}{3}\theta. \qquad (40)$$

Since $\dot{\Psi}_0(x, y)$ satisfies boundary conditions (33) and (34),

$$\lim_{\substack{y\to0\\x>0}}\int\limits_{-\infty}^{x}e^{-\dot{\beta}(x-x_1)}\frac{\partial\Psi_0}{\partial y}(x_1,\ y)dx_1=\dot{\beta}\dot{A}\int\limits_{0}^{x}e^{-\dot{\beta}(x-x_1)}dx_1$$

$$+\lim_{\substack{y\to0\\x>0}}\int\limits_{-\infty}^{0}e^{-\dot{\beta}(x-x_1)}\frac{\partial\Psi_0}{\partial y}(x_1,\ y)dx_1$$

$$=\dot{A}(1-e^{-\dot{\beta}x})+\lim_{\substack{y\to0\\x>0}}\int\limits_{-\infty}^{0}e^{-\dot{\beta}(x-x_1)}\frac{\partial\Psi_0}{\partial y}(x_1,\ y)dx_1. \qquad (41)$$

Since $\dot{\Psi}_0(x, y)$ is a bounded solution of the boundary-value problem (32)-(34), according to the results of the preceding section (cf. 29)

$$\frac{\partial\Psi_0}{\partial y}(x_1,\ y)=-\alpha\dot{B}_{1/3}\int\limits_{-\infty}^{x_1}K_{2/3}(\alpha r)\sin\frac{2}{3}\theta dx_2+\dot{B}_{1/3}K_{1/3}(\alpha r)\sin\frac{1}{3}\theta.$$

Substituting the last expression into (41), integrating by parts, and making some simple transformations we find

$$\lim_{\substack{y\to0\\x>0}}\int\limits_{-\infty}^{x}e^{-\dot{\beta}(x-x_1)}\frac{\partial\Psi_0}{\partial y}(x_1,\ y)dx_1=\dot{A}(1-e^{-\dot{\beta}x})$$

$$+\dot{B}_{1/3}\frac{\sqrt{3}}{2}\left[\frac{\alpha}{\dot{\beta}}\left(-\int\limits_{0}^{\infty}K_{2/3}(\alpha x)dx+\int\limits_{0}^{\infty}e^{-\dot{\beta}x}K_{2/3}(\alpha x)dx\right)\right.$$

$$\left.+\int\limits_{0}^{\infty}e^{-\dot{\beta}x}K_{1/3}(\alpha x)dx\right]e^{-\dot{\beta}x}. \qquad (42)$$

It is easy to see that

$$\lim_{y\to+0}\frac{\partial K_0(\alpha r)}{\partial y}=-\pi\delta(x),\quad \lim_{x\to-\infty}\frac{\partial K_0(\alpha r)}{\partial x}=\pi\delta(y), \qquad (43)$$

where δ is the Dirac delta function. Therefore

$$\lim_{\substack{y\to+\infty\\x>0}}\dot{B}_0\int\limits_{-\infty}^{x}e^{-\dot{\beta}(x-x_1)}\frac{\partial K_0(\alpha r)}{\partial y}dx_1=-\pi\dot{B}_0e^{-\dot{\beta}x}. \qquad (44)$$

Using the easily proved relation

$$\frac{\partial}{\partial y}\left(K_{2/3}(\alpha r)\cos\frac{2}{3}\theta\right)=\frac{\partial}{\partial x}\left(K_{2/3}(\alpha r)\sin\frac{2}{3}\theta\right)-\alpha K_{1/3}(\alpha r)\sin\frac{1}{3}\theta \quad (45)$$

and integrating by parts we find, after some simple transformations,

$$\lim_{\substack{y\to 0\\ x>0}}\dot{B}_{2/3}\int_{-\infty}^{x}e^{-\dot{\beta}(x-x_1)}\frac{\partial}{\partial y}\left(K_{2/3}(\alpha r)\cos\frac{2}{3}\theta\right)dx_1$$

$$=-\dot{B}_{2/3}\frac{\sqrt{3}}{2}\left(\dot{\beta}\int_0^\infty e^{-\dot{\beta}x}K_{2/3}(\alpha x)\,dx+\alpha\int_0^\infty e^{-\dot{\beta}x}K_{1/3}(\alpha x)\,dx\right)e^{-\dot{\beta}x}. \quad (46)$$

It follows from (38), (40), (42), (44), and (46) that boundary condition (11) will be satisfied if the constants $\dot{B}_0$ and $\dot{B}_{2/3}$ satisfy the equation

$$-\dot{A}+\dot{B}_{1/3}\frac{\sqrt{3}}{2}\left[\frac{\alpha}{\dot{\beta}}\left(-\int_0^\infty K_{2/3}(\alpha x)\,dx\right.\right.$$

$$\left.\left.+\int_0^\infty e^{\dot{\beta}-x}K_{2/3}(\alpha x)\,dx\right)+\int_0^\infty e^{-\dot{\beta}x}K_{1/3}(\alpha x)\,dx\right]$$

$$-\pi\dot{B}_0-\dot{B}_{2/3}\frac{\sqrt{3}}{2}\left(\dot{\beta}\int_0^\infty e^{-\dot{\beta}x}K_{2/3}(\alpha x)\,dx+\alpha\int_0^\infty e^{-\dot{\beta}x}K_{1/3}(\alpha x)\,dx\right)=0. \quad (47)$$

Using (43) and the relation

$$\frac{\partial}{\partial x}\left(K_{2/3}(\alpha r)\cos\frac{2}{3}\theta\right)=-\frac{\partial}{\partial y}\left(K_{2/3}(\alpha r)\sin\frac{2}{3}\theta\right)-\alpha K_{1/3}(\alpha r)\cos\frac{1}{3}\theta,$$

we find similarly from (39) and (40) that boundary condition (13) is satisfied if the constants $\dot{B}_0$ and $\dot{B}_{2/3}$ satisfy the equation

$$\dot{B}_{1/3}\frac{\sqrt{3}}{2}\int_0^\infty e^{-\dot{\beta}y}K_{1/3}(\alpha y)\,dy+\pi\dot{B}_0$$

$$-\dot{B}_{2/3}\frac{\sqrt{3}}{2}\left(\dot{\beta}\int_0^\infty e^{-\dot{\beta}y}K_{2/3}(\alpha y)\,dy+\alpha\int_0^\infty e^{-\dot{\beta}y}K_{1/3}(\alpha y)\,dy\right)=0. \quad (48)$$

Using (26) and (27) we obtain from (47) and (48)

$$\dot{B}_{2/3}=\frac{\dot{B}_{1/3}}{\dot{\beta}}\frac{\frac{1}{2\dot{\beta}}\int_0^\infty e^{-\frac{\dot{\beta}}{\alpha}x}K_{2/3}(x)\,dx+\int_0^\infty e^{-\frac{\dot{\beta}}{\alpha}x}K_{1/3}(x)\,dx}{\int_0^\infty e^{-\frac{\dot{\beta}}{\alpha}x}K_{2/3}(x)\,dx+\frac{\alpha}{\dot{\beta}}\int_0^\infty e^{-\frac{\dot{\beta}}{\alpha}x}K_{1/3}(x)\,xd}, \quad (49)$$

$$\dot{B}_0=\frac{\sqrt{3}\dot{B}_{1/3}}{4\pi\dot{\beta}}\int_0^\infty e^{-\frac{\dot{\beta}}{\alpha}x}K_{2/3}(x)\,dx. \quad (50)$$

The integrals in (49) and (50) are tabulated,[5] and therefore (49) and (50) can be simplified to

$$\dot{B}_{2/3}=\frac{\dot{B}_{1/3}\left(\frac{\dot{\varkappa}}{2}\operatorname{sh}\frac{2}{3}u+\operatorname{sh}\frac{1}{3}u\right)}{\dot{\beta}\left(\operatorname{sh}\frac{2}{3}u+\dot{\varkappa}\operatorname{sh}\frac{1}{3}u\right)};\quad \dot{B}_0=\frac{\dot{B}_{1/3}\operatorname{sh}\frac{2}{3}u}{\dot{\beta}\operatorname{sh}u}, \quad (51)$$

where

$$\dot{\varkappa}=\frac{\dot{\beta}}{\alpha}\operatorname{ch}u. \quad (52)$$

It follows from (40), (31), and (36) that

$$\Phi(x,\ y)=\frac{\dot{B}_{1/3}}{\dot{\beta}}\int_{-\infty}^{x}\int_{y}^{\infty}e^{\dot{\beta}(y-y_1)}K_{1/3}(\alpha r)\cos\frac{1}{3}\theta\,dx_1dy_1$$

$$+\int_{-\infty}^{x}\int_{y}^{\infty}e^{-\dot{\beta}[(x-x_1)-(y-y_1)]}\left\{\frac{\dot{B}_{1/3}}{\dot{\beta}}K_{1/3}(\alpha r)\cos\frac{1}{3}\theta-\dot{B}_0K_0(\alpha r)\right.$$

$$\left.-\dot{B}_{2/3}K_{2/3}(\alpha r)\cos\frac{2}{3}\theta\right\}dx_1dy_1. \quad (53)$$

Equations (53), (52), (51) and (37) give a complete solution of the boundary-value problem (4), (11), (12), (13).

RESULTS AND DISCUSSION

In the problem under discussion the greatest interest is in the distribution of the tangential components of the magnetic intensity and the eddy currents over the surface of the conducting wedge. The magnetic field is simply expressed in terms of $\dot{\Phi}(x, y)$ by using Eqs. (1)-(3). We show that the eddy current pattern can be constructed from the values of $\dot{\Phi}(x, y)$ on the surface of the dihedral corner.

Let Q be an arbitrary point, and $L_{Q,\infty}$ some open contour on the surface of the wedge, one end of which coincides with Q; the other extends to infinity in the y direction along the boundary x = 0. We introduce the stream function

$$\Psi(Q,\ t)=\int_{L_{Q,\infty}}\delta_\nu(Q,\ t)\,dl_Q=\gamma\operatorname{Re}\int_{L_{Q,\infty}}([\mathbf{n},\ \dot{\mathbf{E}}(Q)],\ d\mathbf{l}_Q), \quad (54)$$

where $\delta(Q, t)$ is the component of the current density on the surface of the dihedral corner normal to $L_{Q,\infty}$, and the integration is extended from infinity to the point Q. It follows from (54) that at any time t the level lines of the stream function coincide with the eddy current lines.

Using the impedance boundary condition (8), Eq. (54) can be put in the form

$$\Psi(Q,\ t)=\operatorname{Re}(1+j)\sqrt{\frac{\omega\mu\gamma}{2}}\int_{L_{Q,\infty}}\mathbf{H}(Q)\,d\mathbf{l}_Q$$

$$=\operatorname{Re}(1+j)\sqrt{\frac{\omega\mu\gamma}{2}}\,(\dot{\varphi}(Q)+\dot{\varphi}^J(Q))$$

$$=\sqrt{\omega\mu\gamma}\,(\dot{\varphi}(Q)+\dot{\varphi}^J(Q))\cos\left[\omega t+\frac{\pi}{4}+\arg(\dot{\varphi}(Q)+\dot{\varphi}^J(Q))\right]. \quad (55)$$

In the last expression $\dot{\varphi}^J(Q)$ is the potential of the field $\dot{H}^J$, which is equal to $[(jJe^{-\alpha d}e^{\alpha y})/2A]e^{j\alpha z}$ for $y < d$. In a similar way it can be shown that for a perfectly conducting medium

$$\Psi(Q,\ t)=\varphi(Q,\ t)+\varphi^J(Q,\ t), \quad (56)$$

where

$$\Psi(Q,\ t)=\int_{L_{Q,\infty}}i_\nu(Q,\ t)\,dl_Q, \quad (57)$$

where $\mathbf{i}(Q, t)$ is the surface current density vector. It follows from (55) and (56) that it is easy to construct the streamlines if $\dot{\Phi}(x, y)$ has been computed on the surface of the dihedral corner. To calculate $\dot{\Phi}(x, y)$ it is expedient to go over to dimensionless coordinates and to write the expression for $\dot{\Phi}(x, y)$ in dimensionless form.

Introducing the coordinates $X = \alpha x$, $Y = \alpha y$, and the notation $R = \alpha r$, we transform (37), (51), and (53)

$$\Phi(X, Y) = -\dot{C}_{1/3} \int_{-\infty}^{X} \int_{Y}^{\infty} e^{\dot{\varkappa}(Y-Y_1)} K_{1/3}(R) \cos\frac{1}{3}\theta \, dX_1 dY_1$$

$$+ \int_{-\infty}^{X} \int_{Y}^{\infty} e^{-\dot{\varkappa}[(X-X_1)-(Y-Y_1)]} \left\{ \dot{C}_{1/3} K_{1/3}(R) \cos\frac{1}{3}\theta \right.$$

$$\left. - \dot{C}_0 K_0(R) - \dot{C}_{2/3} K_{2/3}(R) \cos\frac{2}{3}\theta \right\} dX_1 dY_1, \quad (58)$$

$$\dot{C}_{1/3} = -\frac{2(1-\dot{\varkappa})}{\sqrt{3}\pi} \dot{M}; \quad \dot{C}_0 = \dot{C}_{1/3} \frac{\operatorname{sh}\frac{2}{3}u}{2\operatorname{sh}u}, \quad (59)$$

$$\dot{C}_{2/3} = \dot{C}_{1/3} \frac{\frac{\dot{\varkappa}}{2}\operatorname{sh}\frac{2}{3}u + \operatorname{sh}\frac{1}{3}u}{\operatorname{sh}\frac{2}{3}u + \dot{\varkappa}\operatorname{sh}\frac{1}{3}u}; \quad \dot{M} = -\frac{j\dot{J}e^{-\alpha d}}{2\alpha}, \quad (60)$$

$$\dot{\varkappa} = \frac{\dot{\beta}}{\alpha} = (1+j)\sqrt{\frac{\omega\mu_0^2\gamma}{2\mu\alpha^2}} = \operatorname{ch}u. \quad (61)$$

In accord with Eqs. (58)-(61) a program was written in FORTRAN for a BÉSM-6 computer to calculate the distribution of $\dot{\Phi}(x, y)$ on the surface of the dihedral angle.

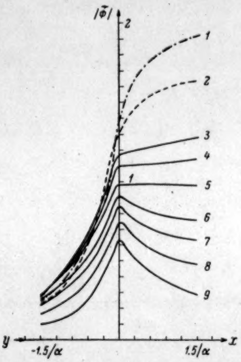

Fig. 2

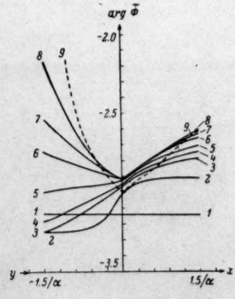

Fig. 3

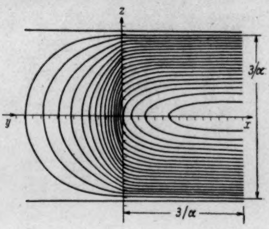

Fig. 4

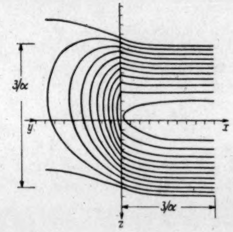

Fig. 5

This program was used to calculate the normalized total distribution $\dot{\tilde{\Phi}} = \dot{\Phi}/M - 1$, that is, taking account of the field of the current sheet. The results were checked by comparing the calculated values of $\dot{\tilde{\Phi}}$ for Y = 0 and large X with $\dot{\tilde{\Phi}}(\infty, 0) = -2\dot{\varkappa}(1 + \dot{\varkappa})$. The distribution of $\dot{\tilde{\Phi}}(X, Y)$ for a perfect conductor is given by

$$\dot{\Phi}(X, Y) = \frac{\Phi(X, Y)}{\dot{M}} - 1 = -\frac{2}{\pi\sqrt{3}} \int_{-\infty}^{x} K_{1/3}(R) \cos\frac{1}{3}\theta \, dX_1 - 1. \quad (62)$$

The results of the calculations are shown in Figs. 2 and 3. Here, curve 1 is for a perfectly conducting wedge; curves 2-9 are calculated by Eqs. (58)-(61) and correspond to the following values of $\dot{\varkappa}$: $\dot{\varkappa}_2 = 2 + 2j$, $\dot{\varkappa}_3 = 1 + j$, $\dot{\varkappa}_4 = 0.8 - 0.8j$, $\dot{\varkappa}_5 = 0.6 + 0.6j$, $\dot{\varkappa}_6 = 0.4 + 0.4j$, $\dot{\varkappa}_7 = 0.3 + 0.3j$, $\dot{\varkappa}_8 = 0.2 + 0.2j$, $\dot{\varkappa}_9 = 0.1 + 0.1j$. On the basis of these results and the procedure described above, diagrams of the streamlines have been constructed for perfect conductivity $\dot{\varkappa} = \infty$ (Fig. 4), $\dot{\varkappa} = 1 + j$ (Fig. 5) and $\dot{\varkappa} = 0.3 + 0.3j$ (Fig. 6). In Fig. 4 the increment of the stream function in going from one line of force to another is $\Delta\psi = 0.1|\dot{M}|$, in Fig. 5 $\Delta\psi = 0.12\sqrt{\omega\mu\gamma}|\dot{M}|$, and in Fig. 6 $\Delta\psi = 0.085\sqrt{\omega\mu\gamma}|\dot{M}|$. In contrast with perfect conductivity, in which the phase of the stream function is the same at all points, with the impedance boundary conditions the phase of the stream function varies from point to point, which leads to asymmetry of the streamlines. In this case in the neighborhood of the edge of the dihedral corner there is always a phase lag of the stream function relative to its values at distant points along the X axis (Fig. 3). For small absolute values of $\dot{\varkappa}$ local closed streamlines are observed in the neighborhood of the edge of the dihedral corner (Fig. 6). This can be explained by the fact that small absolute values of $\dot{\varkappa}$ correspond to large values

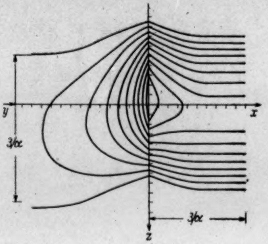

Fig. 6

of μ. For large μ magnetic lines of force are strongly drawn in near the edge of the dihedral corner, and this leads to the production of closed streamlines in this location. Generally the skin effect in a ferromagnetic conducting body involves two opposite tendencies: The drawing of magnetic lines of force into the body because of the large magnetic permeability, and the expulsion of lines of force by the eddy currents produced in the body. For various values of the parameters of a conducting ferromagnet one or the other phenomenon can predominate, and the streamline pattern changes sharply as shown in Figs. 4, 5, and 6. We note that the streamline patterns for other values of $\dot{\varkappa}$ can be constructed by using Figs. 2 and 3.

SOLUTION OF THE PROBLEM FOR ANOTHER METHOD OF EXCITING THE EXTERNAL FIELD

More complicated problems can be solved by using the results of the preceding sections. Let us consider a conducting wedge in the magnetic field of a line current $\dot{I}$ parallel to the x axis. Expanding the current axis into a continuous superposition of current sheets moving in the z direction with values of the parameter α varying from $-\infty$ to $+\infty$, using for each value of α the solution found in the preceding sections, and integrating over α gives the solution of the original problem. For a perfectly conducting medium the integrals which arise can be evaluated exactly[5] and the final result is

$$\dot{\varphi}(x,\ y,\ z)=-\frac{\dot{I}}{3\pi}\int\limits_{-\infty}^{x}\frac{1}{r}\left(\frac{\operatorname{sh}\frac{1}{3}u}{\operatorname{sh}u}+\frac{\operatorname{sh}\frac{1}{3}v}{\operatorname{sh}v}\right)\cos\frac{1}{3}\theta\,dx_1. \quad (63)$$

Here, $\dot{\varphi}$ is the potential of the secondary magnetic field, $\operatorname{ch}u = (d - jz)/r$, $\operatorname{ch}v = (d + jz)/r$, $r = \sqrt{x^2 + y^2}$, $\theta = \arctan y/x$, d is the ordinate of the current axis, and its z coordinate is taken as zero.

More complicated expressions arise for impedance boundary conditions. Here numerical results can be obtained by using the program described in the last section or the data shown in Figs. 2 and 3.

By using the superposition principle solutions can be obtained for several parallel current axes.

CONCLUSION

In treating boundary effects in solid rotors the "angular" character of a region is generally not taken into account. As a rule the end zone is rectified and considered as an extension of the active zone.[6-7] In this connection the authors hope their work can be used for a more accurate study of boundary effects.

Our method of solution is special and uses specific boundary conditions. Nevertheless there are many problems which are amenable to this method of solution.

---

Diffusion regime for electrostatic probes as singular-perturbation problem

I. B. Chekmarev
A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted November 30, 1973)
Zh. Tekh. Fiz., 44, 2069-2074 (October 1974)

Singular perturbation theory is used to analyze a flat electrostatic probe in a weakly ionized collisional plasma in a uniform external magnetic field parallel to the surface of the probe. The voltage—current characteristic is obtained in analytic form in the zeroth approximation. Higher approximations are discussed.

The study of the structure of the transition region between an unperturbed plasma and the walls confining it, which started with the well-known work of Langmuir, remains one of the most important topics in gas discharge.

In extensive studies of the properties of a weakly ionized gas during the last decade considerable attention has been focused on the development of the diffusion theory for the boundary layer close to the walls, particularly when the mean free path of the charged particles is small in comparison with the thickness of the sheath, which in turn is small in comparison with the macroscopic linear dimensions in the problem.[1-8]

In the present work it is shown that the collisional Debye sheath can be treated as a problem in singular perturbation theory. The use of singular-perturbation theory is illustrated by the example of a flat probe in a transverse magnetic field.

For weak ionization and constant temperatures of the components the behavior of the electrons and ions is described by the following system of equations (α = e, i):

$$\left.\begin{aligned} &\nabla\Gamma_\alpha = \nu_I n_e - \beta_R n_e^2 n_i,\\ &\nabla p_\alpha + e_\alpha n_\alpha \nabla\varphi - e_\alpha \Gamma_\alpha \times \mathbf{B} = -\frac{m_\alpha}{\tau_\alpha}\Gamma_\alpha,\\ &\Delta\varphi = \frac{e}{\varepsilon_0}(n_e - n_i).\end{aligned}\right\} \tag{1}$$

We introduce the dimensionless quantities

$$\mathbf{R} = \frac{\mathbf{r}}{L},\ g_\alpha = \frac{n_\alpha}{n_0},\ \mathbf{G}_\alpha = \frac{\Gamma_\alpha}{\Gamma_0},\ \Phi = \frac{\varphi}{\varphi_0},\ \mathbf{b} = \frac{\mathbf{B}}{B},$$

where

$$L = \sqrt{\frac{D}{\nu_I}},\ \Gamma_0 = \frac{Dn_0}{L},\ D = \frac{k(T_e + T_i)\tau_i}{m_i},$$
$$\varphi_0 = \frac{kT_e}{e},\ \mu_\alpha = \frac{e\tau_\alpha}{m_\alpha},\ \nu_I n_0 - \beta_R n_0^3 = 0.$$

Then system (1) becomes

$$\left.\begin{aligned} &\nabla\mathbf{G}_\alpha = g_e - g_e^2 g_i,\\ &\nabla g_e - g_e\nabla\Phi + \frac{T_e + T_i}{T_e}\omega_i\tau_i\mathbf{G}_e \times \mathbf{b} = -\frac{T_e + T_i}{T_e}\frac{\mu_i}{\mu_e}\mathbf{G}_e,\\ &\frac{T_i}{T_e}\nabla g_i + g_i\nabla\Phi - \frac{T_e + T_i}{T_e}\omega_i\tau_i\mathbf{G}_i \times \mathbf{b} = -\frac{T_e + T_i}{T_e}\mathbf{G}_i,\\ &\varepsilon\Delta\Phi = g_e - g_i.\end{aligned}\right\} \tag{2}$$

Since $\lambda_\alpha \ll \lambda_D \ll L$ ($\lambda_D^2 = \varepsilon_0 kT_e/e^2 n_0$) and $\varepsilon = (\lambda_D/L)^2 \ll 1$, the coefficient of the highest derivative in the last equation is a small parameter, making this a problem in singular perturbation theory.[9-11]

We take the x and z axes of a right-handed coordinate system in the surface of the flat probe with the y axis directed into the region occupied by the plasma and the x axis in the direction of the uniform external magnetic field **B**.

Then system (2) is reduced to the equations

$$\left.\begin{aligned} &\frac{dG_e}{dy} = g_e - g_e^2 g_i,\ \frac{dG_i}{dy} = g_e - g_e^2 g_i,\\ &\frac{dg_e}{dy} - g_e\frac{d\Phi}{dy} + \frac{T_e + T_i}{T_e}\frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right)G_e = 0,\\ &\frac{T_i}{T_e}\frac{dg_i}{dy} + g_i\frac{d\Phi}{dy} + \frac{T_e + T_i}{T_e}\left(1 + \frac{\mu_i}{\mu_e}\beta\right)G_i = 0,\\ &\varepsilon\frac{d^2\Phi}{dy^2} = g_e - g_i,\end{aligned}\right\} \tag{3}$$

where $\beta = \omega_e\tau_e\omega_i\tau_i$.

We assume that the conducting surface of the probe is also a perfect absorber. Then the total fluxes of reflected particles vanish. We then have the following dimensionless boundary conditions at the wall:

$$y = 0,\ g_e = -\frac{c_i}{c_e}hG_e,\ g_i = -hG_i,\ \Phi = 0, \tag{4}$$

where

$$c_\alpha = \sqrt{\frac{8kT_\alpha}{\pi m_\alpha}},\ h = \frac{\pi}{4}\frac{T_e + T_i}{T_i}\left(\frac{\lambda_i}{L}\right).$$

We also have

$$y \to \infty,\ g_e \to 1,\ g_i \to 1. \tag{5}$$

As a last condition we specify the current

$$j = G_i - G_e. \tag{6}$$

Following the method of singular-perturbation theory we seek the "outer" solution of system (3) in the form (u = g_e, g_i, G_e, G_i, Φ)

$$u = u_0(y) + \sqrt{\varepsilon}\,u_1(y) + \varepsilon u_2(y) + \dots. \tag{7}$$

In the original system (3) we transform to a new independent variable $\eta = y/\sqrt{\varepsilon}$ and seek the "inner" solution of the system in the form ($\tilde{u}$ = $\tilde{g}_e$, $\tilde{g}_i$, $\tilde{G}_e$, $\tilde{G}_i$, Φ)

$$\tilde{u} = \tilde{u}_0(\eta) + \sqrt{\varepsilon}\,\tilde{u}_1(\eta) + \varepsilon\tilde{u}_2(y) + \dots. \tag{8}$$

Omitting the obvious intermediate steps we obtain the following equations in the zeroth approximation:

for the outer solution

$$\left.\begin{aligned} &g_{e0} = g_{i0} = g,\\ &\frac{dG_{e0}}{dy} = g - g^3,\ \frac{dG_{i0}}{dy} = g - g^3,\\ &\frac{dg}{dy} - g\frac{d\Phi_0}{dy} + \frac{T_e + T_i}{T_e}\frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right)G_{e0} = 0,\\ &\frac{T_i}{T_e}\frac{dg}{dy} + g\frac{d\Phi_0}{dy} + \frac{T_e + T_i}{T_e}\left(1 + \frac{\mu_i}{\mu_e}\beta\right)G_{i0} = 0\end{aligned}\right\} \tag{9}$$

with the boundary conditions

$$y \to \infty,\ g \to 1,\ j = G_{i0} - G_{e0}, \tag{10}$$

for the inner solution (the case $\sqrt{\varepsilon}\,\beta \sim 1$ is not considered)

$$\left.\begin{gathered}\frac{d\bar G_{e0}}{d\eta} = 0,\ \frac{d\bar G_{i0}}{d\eta} = 0,\\ \frac{d\bar g_{e0}}{dy} - \bar g_{e0}\frac{d\Phi_0}{dy} = 0,\ \frac{T_i}{T_e}\frac{d\bar g_{i0}}{d\eta} + \bar g_{i0}\frac{d\Phi_0}{d\eta} = 0,\\ \frac{d^2\Phi_0}{d\eta^2} = \bar g_{e0} - \bar g_{i0}\end{gathered}\right\} \tag{11}$$

with the boundary conditions

$$\eta = 0,\ \bar g_{e0} = -\frac{c_i}{c_e} h\bar G_{e0},\ \bar g_{i0} = -h\bar G_{i0},\ \Phi_0 = 0. \tag{12}$$

The asymptotic matching of the outer and inner solutions provides the missing five conditions for the solution of systems (9) and (11). By transforming from the variables y and η to the intermediate variable $\tau = y/\delta(\varepsilon) = [\sqrt{\varepsilon}/\delta(\varepsilon)]\eta$, where $\sqrt{\varepsilon}/\delta(\varepsilon)|_{\varepsilon\to 0} \to 0$, in the region of overlap of the outer and inner solutions we obtain the matching condition in the zeroth approximation for the electron density:

$$\begin{aligned}\lim_{\substack{\varepsilon\to 0\\ \tau\ \text{fixed}}} [g_e - \bar g_e] = \lim_{\substack{\varepsilon\to 0\\ \text{fixed}}} \Big\{ & g[\delta(\varepsilon)\tau] + \sqrt{\varepsilon}\, g_{e1}[\delta(\varepsilon)\tau] + \ldots\\ & - \bar g_{e0}\left[\frac{\delta(\varepsilon)}{\sqrt{\varepsilon}}\tau\right] - \sqrt{\varepsilon}\,\bar g_{e1}\left[\frac{\delta(\varepsilon)}{\sqrt{\varepsilon}}\tau\right] + \ldots\Big\} = 0\end{aligned}$$

and similar relations for g_i, G_e, G_i, and Φ. Hence we find that as $y \to 0$, $\eta \to \infty$

$$\left.\begin{gathered}\bar g_{e0} \to g(0),\ \bar g_{i0} \to g(0),\ \bar G_{e0} \to G_{e0}(0),\\ \bar G_{i0} \to G_{i0}(0),\ \Phi_0 \to \Phi_0(0).\end{gathered}\right\} \tag{13}$$

We consider system (9). It follows from the first two equations that

$$G_{i0} - G_{e0} = \text{const} = j. \tag{14}$$

Combining the last two equations and eliminating G_{e0} and G_{i0} by differentiating we obtain

$$\frac{d^2 g}{dy^2} + (1+\beta)(g - g^3) = 0. \tag{15}$$

Using (14) we eliminate G_{e0} and G_{i0} in turn and express the fluxes in terms of j and g

$$\left.\begin{aligned}G_{e0} &= -\frac{1}{1+\beta}\left[\frac{dg}{dy} + \left(1 + \frac{\mu_i}{\mu_e}\beta\right) j\right],\\ G_{i0} &= -\frac{1}{1+\beta}\left[\frac{dg}{dy} - \frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right) j\right].\end{aligned}\right\} \tag{16}$$

The solution of Eq. (15) can be written in the form

$$g = \operatorname{th}\left[\operatorname{arth} g(0) + \sqrt{\frac{1+\beta}{2}}\, y\right],\ \frac{dg}{dy} = \sqrt{\frac{1+\beta}{2}}\,(1 - g^2), \tag{17}$$

where g(0) is the as yet unknown value of g at y = 0.

We turn now to the inner system (11). Using the matching conditions we find

$$\left.\begin{aligned}\bar G_{e0} &= -\frac{1}{1+\beta}\left[\sqrt{\frac{1+\beta}{2}}\,(1 - g^2(0)) + \left(1 + \frac{\mu_i}{\mu_e}\beta\right) j\right] = \text{const},\\ \bar G_{i0} &= -\frac{1}{1+\beta}\left[\sqrt{\frac{1+\beta}{2}}\,(1 - g^2(0)) - \frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right) j\right] = \text{const}.\end{aligned}\right\} \tag{18}$$

Integration of the middle two of Eqs. (11) with boundary conditions (12) gives

$$\bar g_{e0} = -\frac{c_i}{c_e} h\bar G_{e0}\exp(\Phi_0),\ \bar g_{i0} = -h\bar G_{i0}\exp\left(-\frac{T_e}{T_i}\Phi_0\right). \tag{19}$$

By applying the matching conditions to (19) we obtain relations for determining g(0) and $\Phi_0(0)$

$$\begin{aligned}g(0) = {} & \frac{h}{1+\beta}\left\{\frac{c_i}{c_e}\left[\sqrt{\frac{1+\beta}{2}}\,(1 - g^2(0)) + \left(1 + \frac{\mu_i}{\mu_e}\beta\right) j\right]\right\}^{\frac{T_e}{T_e+T_i}}\\ & \times\left[\sqrt{\frac{1+\beta}{2}}\,(1 - g^2(0)) - \frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right) j\right]^{\frac{T_i}{T_e+T_i}},\end{aligned} \tag{20}$$

$$\Phi_0(0) = \frac{T_i}{T_e + T_i}\ln\left[\frac{c_e}{c_i}\,\frac{\sqrt{\frac{1+\beta}{2}}\,(1 - g^2(0)) - \frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right) j}{\sqrt{\frac{1+\beta}{2}}\,(1 - g^2(0)) + \left(1 + \frac{\mu_i}{\mu_e}\beta\right) j}\right], \tag{21}$$

where the second equation is the voltage–current characteristic of the sheath.

We write the equations and boundary conditions of the first approximation. For the outer solution we obtain

$$\left.\begin{gathered}g_{e1} = g_{i1} = g_1,\ G_{e1} = G_{i1} = G_1,\\ \frac{dG_1}{dy} = (1 - 3g^2)\, g_1,\\ \frac{dg_1}{dy} - g_1\frac{d\Phi_0}{dy} - g\frac{d\Phi_1}{dy} + \frac{T_e + T_i}{T_e}\frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right) G_1 = 0,\\ \frac{T_i}{T_e}\frac{dg_1}{dy} + g_1\frac{d\Phi_0}{dy} + g\frac{d\Phi_1}{dy} + \frac{T_e + T_i}{T_e}\left(1 + \frac{\mu_i}{\mu_e}\beta\right) G_1 = 0,\end{gathered}\right\} \tag{22}$$

with the boundary conditions

$$y \to \infty,\ g_1 \to 0.$$

We find for the inner solution

$$\left.\begin{gathered}\bar G_{e1} = \bar G_{i1} = \bar G_1,\\ \frac{d\bar G_1}{d\eta} = \bar g_{e0} - \bar g_{e0}^2\bar g_{i0},\\ \frac{d\bar g_{e1}}{d\eta} - \bar g_{e1}\frac{d\Phi_0}{d\eta} - \bar g_{e0}\frac{d\Phi_1}{d\eta} + \frac{T_e + T_i}{T_e}\frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right)\bar G_{e0} = 0,\\ \frac{T_i}{T_e}\frac{d\bar g_{i1}}{d\eta} + \bar g_{i1}\frac{d\Phi_0}{d\eta} + \bar g_{i0}\frac{d\Phi_1}{d\eta} + \frac{T_e + T_i}{T_e}\left(1 + \frac{\mu_i}{\mu_e}\beta\right)\bar G_{i0} = 0,\\ \frac{d^2\Phi_1}{d\eta^2} = \bar g_{e1} - \bar g_{i1}\end{gathered}\right\} \tag{23}$$

with the boundary conditions

$$\eta = 0,\ \bar g_{e1} = -\frac{c_i}{c_e} h\bar G_1,\ \bar g_{i1} = -h\bar G_1,\ \Phi_1 = 0.$$

By definition of an asymptotic expansion the matching condition for the first approximation has the form

$$\begin{aligned}&\lim_{\substack{\varepsilon\to 0\\ \tau\ \text{fixed}}}\frac{1}{\delta(\varepsilon)}\left[g(\delta\tau) + \sqrt{\varepsilon}\, g_1(\delta\tau) + \ldots - \bar g_{e0}(\eta) - \sqrt{\varepsilon}\,\bar g_{e1}(\eta) + \ldots\right]\\ &= \lim_{\substack{\varepsilon\to 0\\ \tau\ \text{fixed}}}\frac{1}{\delta(\varepsilon)}\Big[g(0) + \delta\tau g'(0) + \ldots + \frac{\delta\tau}{\eta} g_1(\delta\tau) + \ldots\\ &\qquad - \bar g_{e0}(\eta) - \frac{\delta\tau}{\eta}\bar g_{e1}(\eta) + \ldots\Big] = 0,\end{aligned}$$

from which it follows that as $\eta \to \infty$

$$g'(0)\,\eta + g_1(0) - \bar g_{e1}(\eta) \to 0,$$

We obtain similar relations for the remaining unknowns as $\eta \to \infty$

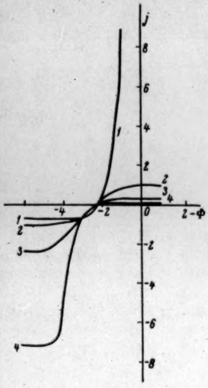

Fig. 1. $T_e = T_i$, $c_e/c_i = 10^2$, $\mu_e/\mu_i = 10^3$; 1) $\beta = 0$; 2) 1; 3) 10; 4) 100.

$$g'(0)\eta + g_1(0) - \tilde{g}_{e1}(\eta) \to 0,$$
$$G'_{e0}(0)\eta + G_1(0) - \tilde{G}_1(\eta) \to 0,$$
$$\Phi'_0(0)\eta + \Phi_1(0) - \tilde{\Phi}_1(\eta) \to 0.$$

The sequence of solving the equations of the outer and inner expansions is the same as in the zeroth approximation.

We note that in the case under consideration $\sqrt{\varepsilon\beta} \ll 1$ the effect of the fluxes on the distribution of charged particles in the Debye sheath appears only in the first approximation. In the quasineutral layer the electron and the ion densities are equal in both the zeroth and first approximations. A difference appears only in the second approximation.

In conclusion we return to Eqs. (20) and (21). Since $g(0) \ll 1$ we have as a good approximation

$$g(0) = \frac{h}{1+\beta}\left\{\frac{c_i}{c_e}\left[\sqrt{\frac{1+\beta}{2}} + \left(1 + \frac{\mu_i}{\mu_e}\beta\right)j\right]^{\frac{T_e}{T_e+T_i}}\right.$$
$$\times\left[\sqrt{\frac{1+\beta}{2}} - \frac{\mu_i}{\mu_e}\left(1 + \frac{\mu_e}{\mu_i}\beta\right)j\right]^{\frac{T_i}{T_e+T_i}}, \qquad (24)$$

$$\Phi_0(0) = \frac{T_i}{T_e+T_i}\ln\left[\frac{c_e}{c_i}\,\frac{\sqrt{\frac{1+\beta}{2}} - \frac{\mu_i}{\mu_e}\left(1+\frac{\mu_e}{\mu_i}\beta\right)j}{\sqrt{\frac{1+\beta}{2}} + \left(1+\frac{\mu_i}{\mu_e}\beta\right)j}\right]. \qquad (25)$$

The value of the floating potential

$$\Phi_f = \Phi_0(0)\big|_{j=0} = \frac{T_e}{T_e+T_i}\ln\left(\frac{c_e}{c_i}\right) \qquad (26)$$

in the zeroth approximation does not depend on the magnetic parameter β. All the voltage–current characteristics pass through the point $j = 0$, $\Phi = \Phi_f$ (Fig. 1).

In the limiting case of an ion saturation current

$$j_i = -\frac{\sqrt{\frac{1+\beta}{2}}}{1+\frac{\mu_i}{\mu_e}\beta} \qquad (27)$$

in the sheath $\tilde{G}_{e0} = 0$, $\tilde{g}_{e0} = 0$.

In the other limiting case of an electron saturation current

$$j_e = \frac{\mu_e}{\mu_i}\,\frac{\sqrt{\frac{1+\beta}{2}}}{1+\frac{\mu_e}{\mu_i}\beta} \qquad (28)$$

in the sheath $\tilde{G}_{i0} = 0$, $\tilde{g}_{i0} = 0$.

Since the absolute value of the ratio of the saturation currents

$$\left|\frac{j_i}{j_e}\right| = \frac{\mu_i}{\mu_e}\,\frac{1+\frac{\mu_e}{\mu_i}\beta}{1+\frac{\mu_i}{\mu_e}\beta} \qquad (29)$$

depends only on the mobility of the charged particles and the magnetic parameter β, a flat electrostatic probe can be used to measure the strength of the magnetic field.

Electromagnetic pulse radiated by a moving charged bunch in matter

N. A. Zvonnikov

V. I. Lenin Moscow Pedagogical Institute

(Submitted July 14, 1972; resubmitted April 18, 1974)
Zh. Tekh. Fiz., 44, 2075-2080 (October 1974)

The Cerenkov radiation from moving cylindrical and ellipsoidal charge bunches is discussed. As a result of the interference of the radiation fields produced by the various elements of the bunch the characteristic frequency of the radiation can lie outside the dispersion region. The electromagnetic field is found as a function of time and position for this case.

In the study of Cerenkov radiation from systems of electric charges the spectral characteristics of the radiation are generally investigated.[1-2] The duration of a pulse of Cerenkov radiation has been considered only for a point charge.[3] However, it is important to know the spatial and temporal structure of the radiation from a charged bunch in certain problems of microwave spectroscopy and radiation detection.

We consider Cerenkov radiation from uniformly charged cylindrical and ellipsoidal bunches moving with constant velocity in an infinite homogeneous medium. As a result of the interference of the radiation fields produced by various elements of the bunch the characteristic frequency of the radiation can lie outside the dispersion region. We obtain the temporal and spatial dependence of the electromagnetic field, taking account of the parameters of the bunches for this case.

1. Assume that a cylindrical bunch of length l and radius R moves with constant velocity v in an infinite homogeneous medium of permittivity ε. The longitudinal component E_z and the transverse component E_r of the electric field of a uniformly charged bunch with total charge q moving along the z axis of a cylindrical coordinate system are

$$E_z(z,\ r,\ t)=-\frac{2q}{\pi v}\int\limits_{-\infty}^{\infty}\frac{(\varepsilon\beta^2-1)\,\omega}{\varepsilon}e^{i\frac{\omega}{v}(z-vt)}\frac{2v}{\omega l}\sin\frac{\omega l}{2v}$$
$$\times\frac{I_1\left(-i\frac{\omega}{v}\sqrt{\varepsilon\beta^2-1}\,R\right)}{\sqrt{\varepsilon\beta^2-1}\,\omega R}K_0\left(-i\frac{\omega}{v}\sqrt{\varepsilon\beta^2-1}\,r\right)d\omega, \tag{1}$$

$$E_r(z,\ r,\ t)=\frac{2q}{\pi v}\int\limits_{-\infty}^{\infty}\frac{\sqrt{\varepsilon\beta^2-1}\,\omega}{\varepsilon}e^{i\frac{\omega}{v}(z-vt)}\frac{2v}{\omega l}\sin\frac{\omega l}{2v}$$
$$\times\frac{I_1\left(-i\frac{\omega}{v}\sqrt{\varepsilon\beta^2-1}\,R\right)}{\sqrt{\varepsilon\beta^2-1}\,\omega R}K_1\left(-i\frac{\omega}{v}\sqrt{\varepsilon\beta^2-1}\,r\right)d\omega \tag{2}$$

in the region $r \geq R$. Here, I_1 is the Bessel function of imaginary argument, K_0 is the Macdonald function, and $\beta = v/c$, where c is the velocity of light.

Equations (1) and (2) contain characteristic interference terms depending on the length and radius of the bunch

$$\frac{2v}{\omega l}\sin\frac{\omega l}{2v}\ \text{and}\ \frac{I_1\left(-i\frac{\omega v}{v}\sqrt{\varepsilon\beta^2-1}\,\beta\right)}{\sqrt{\varepsilon\beta^2-1}\,\omega R}.$$

For fixed l and R high frequencies make a negligible contribution to the electromagnetic field; it should then be expected that the dispersion of the permittivity can be neglected in certain real dielectrics. It is easy to estimate the order of magnitude of the duration of the perturbation Δt at points with coordinates z and r by noting that the range of frequencies $1/\Delta t$ in which the main part of the radiation is concentrated, and for which Eqs. (1) and (2) are markedly different from zero, is determined by the inequality $\omega < \min\{2v/l,\ v\sqrt{\varepsilon\beta^2-1}R\}$, so that

$$\Delta t\sim\frac{1}{\min\left\{\frac{2v}{l},\ \frac{v}{\sqrt{\varepsilon\beta^2-1}\,R}\right\}}. \tag{3}$$

Calculations performed below for a nondispersive medium show that the duration of the oscillation of the electromagnetic field in each half-wave is determined by the smallest characteristic size of the variation of charge density. The value agrees with estimate (3) in order of magnitude.

We first calculate the longitudinal component of the electric field. Using the relation

$$\sin\frac{\omega l}{2v}=\frac{e^{i\frac{\omega l}{2v}}-e^{-i\frac{\omega l}{2v}}}{2i},$$

we write Eq. (1) in the form

$$E_z=E_z(t)-E_z\left(t-\frac{l}{R\sqrt{\varepsilon\beta^2-1}}\right), \tag{4}$$

where

$$t\equiv t-\frac{z}{R\sqrt{\varepsilon\beta^2-1}}+\frac{l}{2R\sqrt{\varepsilon\beta^2-1}}+1$$

is the time counted from the arrival of the wave at point $r = R$ in units of $R\sqrt{\varepsilon\beta^2-1}/v$,

$$E_z(t)=-\frac{4q\sqrt{\varepsilon\beta^2-1}}{Rl}\frac{1}{2\pi i}\int\limits_{-i\infty}^{i\infty}e^{pt}K_0(kp)\frac{e^{-p}I_1(p)}{p}dp,\ k=\frac{r}{R}.$$

Substituting into the convolution integral from the tables[4] the inverse transforms of the functions in the last integral we have

$$E_z(t)=-\frac{4q\sqrt{\varepsilon\beta^2-1}}{Rl\varepsilon\pi}\begin{cases}\displaystyle\int\limits_0^{t-k}\frac{\sqrt{\tau(2-\tau)}}{\sqrt{(t-\tau)^2-k^2}}d\tau, & 0<t-k<2,\\ \displaystyle\int\limits_0^{2}\frac{\sqrt{\tau(2-\tau)}}{\sqrt{(t-\tau)^2-k^2}}d\tau, & t-k\geqslant 2.\end{cases} \tag{5}$$

The second part of the longitudinal field differs from $E_z(t)$ only by a time displacement $l/R\sqrt{\varepsilon\beta^2-1}$.

The transverse component of the electric field is found in the same way as the longitudinal component E_z:

$$E_r = E_r(t) - E_r\left(t - \frac{l}{R\sqrt{\varepsilon\beta^2-1}}\right), \tag{6}$$

$$E_r(t) = \frac{4q}{rl\varepsilon\pi}\begin{cases} \displaystyle\int_0^{t-k} \frac{(t-\tau)\sqrt{\tau(2-\tau)}}{\sqrt{(t-\tau)^2-k^2}}\,dt, & 0 < t-k < 2, \\ \displaystyle\int_0^{2} \frac{(t-\tau)\sqrt{\tau(2-\tau)}}{\sqrt{(t-\tau)^2-k^2}}\,d\tau, & t-k \geqslant 2. \end{cases} \tag{7}$$

To investigate the expressions obtained we evaluate integrals (5) and (7) approximately. For $0 < t-k < 2$, to $\approx 1/2(k+1)$

$$E_z(t) \simeq -\frac{4q\sqrt{\varepsilon\beta^2-1}}{Rl\varepsilon\pi\sqrt{u+2k}}f(u), \tag{8}$$

$$E_r(t) \simeq \frac{4q}{Rl\varepsilon\pi}\left(\frac{\sqrt{u+2k}}{k} - \frac{1}{\sqrt{u+2k}}\right)f(u) \tag{9}$$

and for $t \gg k + 2$

$$E_z(t) \simeq -\frac{2q\sqrt{\varepsilon\beta^2-1}}{Rl\varepsilon\sqrt{u(u+2k)}}, \tag{10}$$

$$E_r(t) \simeq \frac{2q(u+k)}{Rl\varepsilon\sqrt{u(u+2k)}\,k}. \tag{11}$$

Here, $u = t - k$, $F(\pi/2, \sqrt{u/2})$ and $E(\pi/2, \sqrt{u/2})$ are elliptic functions of the first and second kind

$$f(u) = \frac{2\sqrt{2}}{3}\left[(2-u)F\left(\frac{\pi}{2}, \sqrt{\frac{u}{2}}\right) + 2(u-1)E\left(\frac{\pi}{2}, \sqrt{\frac{u}{2}}\right)\right] + \frac{4}{3}(2-u)\sqrt{\frac{u}{2}}.$$

It follows from Eqs. (4), (6), (8)-(11) that at each point in space the field components E_z and E_r are positive and negative respectively from the beginning to the time $t \sim l/R\sqrt{\varepsilon\beta^2-1}$; after that time they change sign. The field decreases as $1/\sqrt{r}$ where r is the distance from the axis. Using these expressions the quantities E_z and E_r are calculated for $k = r/R = 2$, and curves are plotted for $l/R\sqrt{\varepsilon\beta^2-1} = 3$ (Fig. 1).

We also present equations for the components of the radiation field of a uniformly moving line charge of length l. Letting $R \to 0$ in (5) and (7) ($k \to \infty$, $t \to \infty$) and using the value of the integral $\int_0^2 \sqrt{\tau(2-\tau)}\cdot d\tau = \pi/2$ we obtain

$$E_{z|R\to0} = -\frac{2q\sqrt{\varepsilon\beta^2-1}}{rl\varepsilon}\left[\frac{1}{\sqrt{t^2-1}}\eta(t-1) - \frac{1}{\sqrt{\left(t-\frac{l}{r\sqrt{\varepsilon\beta^2-1}}\right)^2-1}}\eta\left(t-\frac{l}{r\sqrt{\varepsilon\beta^2-1}}-1\right)\right], \tag{12}$$

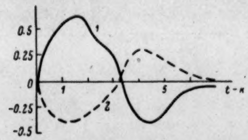

Fig. 1. Time dependence of components of the electromagnetic field of a cylindrical charge bunch. Time is in units of $R\sqrt{\varepsilon\beta^2-1}/v$. 1) E_r/E_r^0; 2) E_z/E_z^0. $E_r^0 = 4q/Rl\varepsilon$, $E_z^0 = \sqrt{\varepsilon\beta^2-1}E_r^0$, $H_\varphi = -\varepsilon\beta E_r$.

$$E_{r|R\to0} = \frac{2q}{rl\varepsilon}\left[\frac{t}{\sqrt{t^2-1}}\eta(t-1) - \frac{\left(t-\frac{l}{r\sqrt{\varepsilon\beta^2-1}}\right)}{\sqrt{\left(t-\frac{l}{r\sqrt{\varepsilon\beta^2-1}}\right)^2-1}}\eta\left(t-\frac{l}{r\sqrt{\varepsilon\beta^2-1}}-1\right)\right], \tag{13}$$

where

$$t \equiv t - \frac{z}{r\sqrt{\varepsilon\beta^2-1}} + \frac{l}{2r\sqrt{\varepsilon\beta^2-1}}$$

is the time in units of $r\sqrt{\varepsilon\beta^2-1}/v$, and $\eta(t)$ is the unit step function.

At the instants waves arrive from the front and rear ends of the line charge the field becomes infinite with opposite signs. The change in sign of the field occurs in a time l/v.

When both the radius and the length of the cluster are small the well-known equations of Tamm and Frank[3] for the Cerenkov radiation from a point charge are obtained from Eqs. (12) and (13) as $l \to 0$.

2. Following ref. 1 let us consider the electromagnetic field of a moving ellipsoidal bunch whose charge density in cylindrical coordinates is

$$\rho(r, z) = \begin{cases} \frac{3q}{4\pi ab^2}; & |z-vt| < a,\ r < b\sqrt{1-\frac{z^2}{a^2}}, \\ 0 - \text{in all other cases}. \end{cases} \tag{14}$$

In view of the axial symmetry of the problem the Fourier transform $\rho(k, \omega)$ of the distribution $\rho(r, z)$ is given by

$$\rho(k, \omega) = 2\pi\int_{-\infty}^{\infty}\int_0^{\infty}\rho(r, z)e^{-r\frac{\omega}{v}}rJ_0(rk)\,dz\,dr,$$

for the charge distribution (14) we have

$$\rho(k, \omega) = 3q\left[\frac{\sin\sqrt{b^2k^2+\frac{\omega^2}{v^2}a^2}}{\left(k^2b^2+\frac{\omega^2}{v^2}a^2\right)^{3/2}} - \frac{\cos\sqrt{k^2b^2+\frac{\omega^2}{v^2}a^2}}{\left(k^2b^2+\frac{\omega^2}{v^2}a^2\right)}\right]. \tag{15}$$

We note that if a parameter ξ is introduced into the sine term in (15) the expression for $\rho(k, \omega)$ can be written as the difference of two terms, the second of which is the derivative of the first with respect to ξ:

$$\left.\begin{aligned}\rho(k,\ \omega)&=\left[\rho^*(\xi)-\frac{\partial\rho^*(\xi)}{\partial\xi}\right]_{\xi=1},\\ \rho^*(k,\ \omega,\ \xi)&=\frac{3q\sin\xi\sqrt{k^2b^2+\frac{\omega^2}{v^2}a^2}}{\left(k^2b^2+\frac{\omega^2}{v^2}a^2\right)^{3/2}}.\end{aligned}\right\}\tag{16}$$

With the Fourier transform $\rho(k, \omega)$ in the form (16) the method of ref. 1 for calculating the field of a cylindrical bunch can be used to obtain the following expressions for the longitudinal component of the electromagnetic field E_z and the transverse component E_r in the region $r \geq b$:

$$E_z=\left[E_z^*(\xi)-\frac{\partial E_z^*(\xi)}{\partial\xi}\right]_{\xi=1},\tag{17}$$

$$E_z^*=\frac{3qvi}{\pi}\int\limits_{-\infty}^{\infty}\frac{(\varepsilon\beta^2-1)}{\varepsilon}\frac{\sin\left(\xi\frac{\omega}{v}\sqrt{(\varepsilon\beta^2-1)\,b^2+a^2}\right)}{\omega^2\left[(\varepsilon\beta^2-1)\,b^2+a^2\right]^{3/2}}$$

$$\times e^{i\frac{\omega}{v}(z-vt)}K_0\left(-i\frac{\omega}{v}\sqrt{\varepsilon\beta^2-1}\,r\right)d\omega,\tag{18}$$

$$E_r=\left[E_r^*(\xi)-\frac{\partial E_r^*(\xi)}{\partial\xi}\right]_{\xi=1},\tag{19}$$

$$E_r^*=-\frac{3qvi}{\pi}\int\limits_{-\infty}^{\infty}\frac{(\varepsilon\beta^2-1)^{1/2}}{\varepsilon}\frac{\sin\left(\xi\frac{\omega}{v}\sqrt{(\varepsilon\beta^2-1)\,b^2+a^2}\right)}{\omega^2\left[(\varepsilon\beta^2-1)\,b^2+a^2\right]^{3/2}}$$

$$\times e^{i\frac{\omega}{v}(z-vt)}K_1\left(-i\frac{\omega}{v}\sqrt{\varepsilon\beta^2-1}\,r\right)d\omega.\tag{20}$$

As in the preceding case, the components of the electric field contain interference terms which limit the high-frequency contribution. The order of magnitude of the duration of the perturbation Δt can be estimated by comparing it with $1/\Delta\omega$, where $\Delta\omega$ is the frequency spread:

$$\Delta t\sim\frac{v}{\sqrt{(\varepsilon\beta^2-1)\,b^2+a^2}}.\tag{21}$$

To evaluate (18) we write it in the form

$$E_z^*=E_z^*(t+\xi c)-E_z^*(t-\xi c),$$

where $t = t - z/b\sqrt{\varepsilon\beta^2-1}$ is the time from the instant the wave arrives at the point $r = b$ in units of $b\sqrt{\varepsilon\beta^2-1}/v$,

$$E_z^*(t)=\frac{3q(\varepsilon\beta^2-1)^{3/2}}{\varepsilon\left[(\varepsilon\beta^2-1)\,b^2+a^2\right]^{3/2}}\frac{1}{2\pi i}\int\limits_{-i\infty}^{i\infty}e^{pt}\frac{K_0(kp)}{p^3}dp,$$

$$c=\frac{\sqrt{(\varepsilon\beta^2-1)\,b^2+a^2}}{\sqrt{\varepsilon\beta^2-1}\,b},\ k=\frac{r}{b}.$$

Evaluating the last integral[4] and substituting the value of $E_z^*(t)$ into (17) we obtain

$$E_z=\frac{3q(\varepsilon\beta^2-1)^{3/2}b}{\varepsilon\left[(\varepsilon\beta^2-1)\,b^2+a^2\right]^{3/2}}\left\{\left[t\ln\left(\frac{t+c-\sqrt{(t+c)^2-k^2}}{k}\right)\right.\right.$$

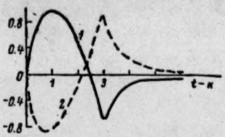

Fig. 2. Time dependence of the components of the electromagnetic field of an ellipsoidal bunch. $\sqrt{(\varepsilon b^2-1)b^2+a^2}/\sqrt{\varepsilon b^2-1}b = 3/2$, $k = r/b = 2$. Time units of $b\sqrt{\varepsilon b^2-1}/v$. 1) E_r/E_r^0; 2) E_z/E_z^0. $E_r^0 = 3q(\varepsilon b^2-1)b/\varepsilon[(\varepsilon\beta^2-1)b^2+a^2]^{3/2}$, $E_z^0 = \sqrt{\varepsilon b^2-1}E_r^0$, $H_\varphi = -\varepsilon\beta Er$.

$$\left.-\sqrt{(t+c)^2-k^2}\right]\eta(t+c-k)$$

$$\left.-\left[t\ln\left(\frac{t-c-\sqrt{(t-c)^2-k^2}}{k}\right)-\sqrt{(t+c)^2-k^2}\right]\eta(t-c-k)\right\}.\tag{22}$$

The component E_r is evaluated in a similar way:

$$E_r=\frac{3q(\varepsilon\beta^2-1)\,b}{\varepsilon\left[(\varepsilon\beta^2-1)\,b^2+a^2\right]^{3/2}}\left\{\left[\frac{k}{2}\ln\left(\frac{t+c-\sqrt{(t+c)^2-k^2}}{k}\right)\right.\right.$$

$$\left.-\frac{(t-c)\sqrt{(t+c)^2-k^2}}{2k}\right]\eta(t+c-k)$$

$$\left.-\left[\frac{k}{2}\ln\left(\frac{t-c-\sqrt{(t-c)^2-k^2}}{k}\right)-\frac{(t+c)\sqrt{(t-c)^2-k^2}}{2k}\right]\eta(t-c-k)\right\}.\tag{23}$$

Thus the electromagnetic field of an ellipsoidal bunch is expressed in terms of elementary functions and differs somewhat from the field of a cylindrical bunch (Fig. 2). The duration of the oscillation in each half-wave is of the same order of magnitude as estimate (21). It is easy to see from (22) and (23) that as $b \to 0$ the form of the radiation field function for an infinitesimally thin moving bunch (a line charge of length $2a$) is not changed, and as a consequence the field is everywhere finite in contrast with (12) and (13). This is a result of the fact that the density of the line charge obtained from an ellipsoidal bunch is not uniform.

In conclusion it should be noted that although the present analysis applies to nondispersive media it gives the correct result for media in which the dispersion region begins with wavelengths shorter than the scale of the characteristic variation of the charge density function in the bunch. The expressions for the fields of bunches depend on parameters (the linear dimensions of the bunches) which are not revealed by spectral analysis. We note that a similar method can be used to find the electromagnetic field inside a bunch. This permits a qualitative treatment of the important problem of the stability of a system of charged particles.

The author thanks K. A. Barsukov for posing the problem and for discussion.

State of a gas moving near a solid surface

S. P. Bakanov and B. M. Markeev

Institute of the Problems of Mechanics, Academy of Sciences of the USSR, Moscow

(Submitted November 21, 1973)
Zh. Tekh. Fiz., 44, 2081-2084 (October 1974)

The range of applicability of the method of half-range expansions to describe the state of a gas close to a phase interface is discussed. It is shown that by starting from physical premises the accuracy of the method can be estimated without having to resort to the very cumbersome evaluation of the succeeding terms. The velocity of slip is calculated for an arbitrary law of interaction of the gas molecules with the interface.

For a gas moving along a solid surface the distribution of velocities in the Knudsen layer differs significantly from that in the main volume of the gas. Maxwell[1] first called attention to this fact. The first attempt to find the distribution function of gas molecules in the Knudsen layer appeared in papers by Gross et al.,[2-3] treating the Couette flow of a monatomic gas between two plates. It was noted in ref. 4, however, that the results in ref. 3 contain errors of fundamental significance. In particular, the solution given in ref. 3 does not satisfy the most important physical requirement that at a point between two widely separated plates, sufficiently far from each of them, the distribution functions for the velocities of molecules moving in opposite directions must be the same. In those papers[2,3] the distribution functions for falling and rising fluxes are different even halfway between plates any distance apart.

It is shown below that this physically meaningless result[3] can be eliminated by taking account of the accuracy of the calculation of the moments of the collision integral.

It should be noted that the above difficulty has not gone unnoticed. Several papers[5,6] have treated the contradiction by matching the solution obtained for the Knudsen layer with the Chapman–Enskog solution. In an interesting paper by Cercignani it is pointed out correctly that if the distribution function is expanded in terms of a finite number of polynomials the expansion coefficients depend on velocity. Therefore, the author notes that the violation of the physical principle corresponding to the Chapman–Enskog solution is not the result of mistakes in evaluating the integrals, but arises from the nature of the approximation, which assumes that the expansion coefficients mentioned above are velocity independent. Yielding to the correct physical intuition, Cercignani had to note that his statement of the problem was not very helpful and that it is similar to attempts to obtain an exact solution of the linearized Boltzmann equation. At the same time the method of polynomial expansions, though approximate, enables one to solve the problem completely, of course not avoiding an estimate of the accuracy of the method.

In view of the above it is appropriate to return to the problem.

Let us consider the problem of Couette flow of a gas between two infinite parallel plates, using the method developed by Gross et al.[2-3]

Let the distance between the plates be 2L, and suppose they are both maintained at temperature T. The upper plate moves in the z direction with a velocity $u_0'/2$, and the lower plate with the velocity $-u_0'/2$. The x axis is perpendicular to the plates.

The distribution function for gas molecules $f(\mathrm{r}, \mathrm{v})$ depends on a single spatial coordinate. We assume that a stationary state exists so that $f(\mathrm{r}, \mathrm{v})$ does not depend on time. We also assume that the relative velocity of the plates u_0' is small in comparison with the mean thermal velocity of the gas molecules.

The distribution function for gas molecules satisfies the Boltzmann equation. We seek it in the form

$$f = f_0[1 + \varphi(x, c)], \tag{1}$$

where $c = (m/2kT)^{1/2}v$ and v is the velocity of a molecule. The remaining notation is standard.

We find the function $\varphi(c, x)$ from the equation

$$c_x \frac{\partial\varphi}{\partial x} = J(\varphi), \tag{2}$$

where $J(\varphi)$ is the collision integral.

We introduce two distribution functions, $f^+(v, x)$ for molecules with $v_X > 0$ and $f^-(v, x)$ for molecules with $v_X < 0$, and assume that $f^+(v_X, x) = 0$ for $v_X < 0$ and $f^-(v_X, x) = 0$ for $v_X > 0$. We take the usual boundary conditions: A fraction ε of the molecules are reflected diffusely, and a fraction 1 − ε specularly. Since $u_0'/v_Z \ll 1$, we have

$$\left.\begin{aligned}\varphi^+(c, -L) &= \varepsilon u_0 c_z + (1-\varepsilon)\varphi^-(-c_x, c_y, c_z, -L) \text{ for } c_x > 0,\\ \varphi^-(c, L) &= -\varepsilon u_0 c_z + (1-\varepsilon)\varphi^+(-c_x, c_y, c_z, L) \text{ for } c_x < 0,\end{aligned}\right\} \tag{3}$$

where

$$u_0 = u_0'\left(\frac{m}{2kT}\right)^{1/2}.$$

We seek a solution of Eq. (2) in the form

$$\varphi^\pm(c, x) = a_0^\pm(x)c_z + a_1^\pm(x)c_x c_z. \tag{4}$$

Boundary condition (3) will be satisfied by setting

$$\left.\begin{aligned}a_0^\pm(\mp L) &= \pm\varepsilon u_0 + (1-\varepsilon)\alpha_0^\mp(\mp L),\\ a_1^\pm(\mp L) &= -(1-\varepsilon)a_1^\mp(\mp L).\end{aligned}\right\} \tag{3'}$$

Introducing the auxiliary function

$$\operatorname{sign} c_x = \begin{cases} 1 \text{ for } c_x > 0,\\ -1 \text{ for } c_x < 0,\end{cases}$$

we have

$$\varphi(c, x) = \varphi^+\frac{1+\operatorname{sign} c_x}{2} + \varphi^-\frac{1-\operatorname{sign} c_x}{2}. \tag{5}$$

Substituting (5) into (2), multiplying successively by

$c_z(1 \pm \text{sign } c_x)e^{-c^2}dc$ and $c_x c_z(1 \pm \text{sign } c_x)e^{-c^2}dc$, and integrating with respect to c from $-\infty$ to ∞ we obtain a system of differential equations for $a_0^{\pm}(x)$ and $a_1^{\pm}(x)$:

$$\left.\begin{aligned} \frac{d}{dx} a_0^{\pm} &= (a_0^{+} - a_0^{-}) A_1 + (a_1^{+} + a_1^{-}) A_2 \mp (a_1^{+} - a_1^{-}) A_3, \\ \frac{d}{dx} a_1^{\pm} &= \pm (a_0^{+} - a_0^{-}) B_1 \pm (a_1^{+} + a_1^{-}) B_2 + (a_1^{+} - a_1^{-}) B_3, \end{aligned}\right\} \quad (6)$$

where A_i and B_i are functions of the pressure of the gas depending on the law of interaction between its molecules.[4]

The standard procedure for solving a system of ordinary differential equations with boundary conditions (3) gives

$$\left.\begin{aligned} a_0^{\pm} &= \frac{u}{F}\left\{\mp \frac{B_2}{B_1} - 2\left[\frac{B_2}{B_1} A_1 - A_2\right] x \pm \frac{2-\varepsilon}{N}\left[A e^{\pm \alpha x} - B e^{\mp \alpha x}\right]\right\}, \\ a_1^{\pm} &= \frac{u}{F}\left\{1 + \frac{2-\varepsilon}{N}\left[D e^{\pm \alpha x} - C e^{\mp \alpha x}\right]\right\}, \end{aligned}\right\} \quad (7)$$

where

$$\left.\begin{aligned} A &= \alpha\sqrt{\pi} - 4B_1\left(1 - \frac{\sqrt{\pi}}{2}\frac{B_2}{B_1}\right), \\ B &= -\alpha\sqrt{\pi} - 4B_1\left(1 - \frac{\sqrt{\pi}}{2}\frac{B_2}{B_1}\right), \\ C &= 2\left[\alpha + 2B_1\left(\frac{\sqrt{\pi}}{2} - \frac{B_2}{B_1}\right)\right], \\ D &= 2\left[-\alpha + 2B_1\left(\frac{\sqrt{\pi}}{2} - \frac{B_2}{B_1}\right)\right], \\ \alpha^2 &= -4B_1B_2\left(\frac{\sqrt{\pi}}{2} - \frac{B_2}{B_1}\right), \\ F &= -2A_2L + \frac{2-\varepsilon}{\varepsilon}\frac{M}{N}, \\ M &= [A - B(1-\varepsilon)]e^{-\alpha L} - [B - A(1-\varepsilon)]e^{\alpha L}, \\ N &= [C(1-\varepsilon) - D]e^{-\alpha L} - [D(1-\varepsilon) - C]e^{\alpha L}. \end{aligned}\right\} \quad (8)$$

It is clear from (7) and (8) that the distribution function for the molecules is discontinuous at the point $c_x = 0$. Physically the presence of a discontinuity is justified for large Knudsen numbers, but is completely inadmissible for $\lambda/L \ll 1$, i.e., distances from the plates appreciably larger than the mean free path of the molecules. Calculations show that the magnitude of the discontinuity depends on the law of interaction between the molecules. Actually we have

$$\frac{f^{+}(x, c_x = 0) - f^{-}(x, c_x = 0)}{f^{+}(x, c_x = 0) + f^{-}(x, c_x = 0)} \simeq \frac{B_2}{B_1}.$$

For the hard sphere model $B_2/B_1 = 0.013$; for Maxwell's law[8] $B_2/B_1 = 0$. In this way the physically reasonable result used in the approximation of the distribution function (4) is realized with a certain accuracy depending on the model of the molecular interaction assumed. The statement[4] that $B_2 = 0$ must be understood in this sense.

Thus the accuracy of expansion (4) can be estimated without having to perform the very cumbersome calculation of the succeeding terms. On the other hand without performing this estimate a more accurate evaluation of the integrals is not justified.[9]

It is easy to compute the flow rate of the gas in the space between the plates:

$$q_s(x) = \frac{u_0'}{2}\frac{\varepsilon}{M}\,\frac{2A_2\dfrac{N}{2-\varepsilon}x + \left(A + B + \dfrac{C+D}{\sqrt{\pi}}\right)\operatorname{sh}\alpha x}{1 - 2A_2L\dfrac{\varepsilon}{2-\varepsilon}\dfrac{N}{M}}. \quad (9)$$

The true q_s and the "apparent" q_s^* velocities of slip are given by the relations

$$q_s(L) = -\frac{u_0'}{2} - q_s(L),$$

$$q_s^*(L) = -\frac{u_0'}{2} - L\left(\frac{\partial q}{\partial x}\right)\Big|_{x=0}.$$

Hence

$$\left.\begin{aligned} q_s(L) &= -\frac{u_0'}{2}\,\frac{1 + \dfrac{\varepsilon}{M}\left(A + B + \dfrac{C+D}{\sqrt{\pi}}\right)\operatorname{sh}\alpha L}{1 - 2A_2L\dfrac{\varepsilon}{2-\varepsilon}\dfrac{N}{M}}, \\ q_s^*(L) &= -\frac{u_0'}{2}\,\frac{1 + \dfrac{\varepsilon}{M}\left(A + B + \dfrac{C+D}{\sqrt{\pi}}\right)\alpha L}{1 - 2A_2L\dfrac{\varepsilon}{2-\varepsilon}\dfrac{N}{M}}. \end{aligned}\right. \quad (10)$$

For specular reflection ($\varepsilon = 0$) the gas is stationary and slips along the surface of a plate with the velocity of the plate itself. The velocity gradient of the gas $\partial q/\partial x$ is of course zero. It should be noted that it is difficult to interpret the results of refs. 10 and 11 in this respect.

In conclusion the authors thank V. V. Struminskii and A. A. Rukhadze for helpful discussion.

Plasma

Drift instability in a weakly ionized plasma

S. V. Putvinskii and A. V. Timofeev

(Submitted November 19, 1973)
Zh. Tekh. Fiz., 44, 2085-2094 (October 1974)

It is shown that low-frequency ($\omega \ll \nu_i$) drift waves can be excited spontaneously in a current-free discharge when the ions are not fully magnetized ($\omega_i/\nu_i \sim 1$, $\rho_i/a \sim 1/2$-$1/3$). Here, ω_i is the ion cyclotron frequency, ν_i is the ion–neutral collision frequency, ρ_i is the ion Larmor radius and a is the characteristic scale length for changes in the plasma density. A comparison of theoretical and experimental results indicates that this instability has been observed.[1,2] In strong magnetic fields ($\omega_i/\nu_i \gg 1$, $\rho_i/a \ll 1$) the residual effect of incomplete ion magnetization has a stabilizing influence on the drift instability.

INTRODUCTION

A high-frequency gas discharge in a magnetic field exhibits an instability at a frequency which changes in a nonmonotonic fashion with the magnetic field and forms a characteristic sawtooth shape.[1,2] The absolute value of the frequency can be small compared to the ion–neutral collision frequency so that the instability is not a drift-dissipative instability.[3] However, the mechanism considered in ref. 4 can cause low-frequency instabilities. This is the case if the plasma is charged negatively with respect to the walls and the resultant radial electric field is strong. The authors of refs. 1 and 2 have used the results of the theory developed in ref. 4 to explain the increase of frequency with magnetic field. However, the decreasing branch can be excited even with a positive plasma charge.

The experimental conditions in refs. 1 and 2 are such that the mechanism related to violation of neutrality[5] is not effective because of the high charged-particle density.

The theoretical model of the phenomenon proposed here is based on certain properties of the unstable plasma state. The most important of these in refs. 1 and 2 is the fact that the ion component of the weakly ionized plasma is not fully magnetized; in the unstable state the ion cyclotron frequency ω_i is close to the ion–neutral collision frequency ν_i, and the ion Larmor radius ρ_i is a considerable fraction (of the order of 1/2-1/3) of the tube radius a. Under these conditions the ion drift velocity in crossed fields (the electric field of the wave and the constant magnetic field) is significantly different from the electron drift velocity. According to ref. 6, a difference on the drift speeds can lead to low-frequency drift in stabilities in a nonuniform plasma.

An analysis of the behavior of a plasma with a large ion Larmor radius presents considerable mathematical difficulties. In order to simplify the calculations we make use of an expansion in the parameter ρ_i/a, taking the Larmor radius to be small. For $\rho_i/a \sim 1/2$-$1/3$ the results are not highly accurate and are only illustrative. We therefore put most emphasis on the interpretation of the qualitative effects observed in the experiments of the variation in frequency with the magnetic field, the variation of the critical field with density, etc.

The ion component is described by the kinetic equation with the Batnager–Gross–Crook collision integral. It is well known that this collision integral works for a weakly ionized plasma where the denominating collisions are those with neutrals. The use of the kinetic approach is due to the necessity of allowing for the finite Larmor radius. If the plasma is fully ionized the effect of the finite Larmor radius is taken into account in the hydrodynamic treatment by means of the viscosity. However, the normal hydrodynamic treatment is not applicable to a weakly ionized plasma.[7] In the derivation of the hydrodynamic equations it is assumed that collisions do not change the total momentum and energy; however, in collisions with neutrals, neither the momentum nor the energy of the charged particles is observed. The formal use of the hydrodynamic treatment in the present case leads to erroneous results. (Corrections for the effects of finite Larmor radius are ambiguous in sign.)

1. BASIC EQUATIONS.
INITIAL STATE

We describe the ion component of a weakly ionized plasma by the kinetic equation

$$\frac{\partial f}{\partial t}+(\mathbf{v}\nabla)f+\frac{e}{m_i}\left(\mathbf{E}+\frac{1}{c}[\mathbf{v}\mathbf{H}]\right)\frac{\partial}{\partial \mathbf{v}}f=\mathrm{St}(f). \qquad (1)$$

Here, the collision term is taken in a form which allows for the conservation of the number of ions in collisions with neutrals:

$$\mathrm{St}(f)=-\nu_i(f-f_{00})+\nu_i\frac{f_{00}}{n_0}\int(f-f_{00})\,d\mathbf{v}, \qquad (2)$$

where ν_i is the ion–neutral collision frequency,

$$f_{00}=\left(\frac{m_i}{2\pi T_i}\right)^{3/2}n_0(r)\,e^{-\frac{m_i v^2}{2T_i}},$$

T_i is the temperature of the neutral gas. It is assumed that the collisions bring the ions into thermal equilibrium with the neutrals.

Discharge tubes are axially symmetric and in the absence of instabilities the density gradient and the electric field are radial. In order to simplify the problem we introduce an equivalent system with plane symmetry in which OX represents the radial direction and OZ the azimuthal direction. The OZ axis coincides with the magnetic field. Solving (1) under the conditions

$$\left|\rho_i\frac{1}{n_0}n_0'\right|\ll 1,\quad \left|\frac{c}{H}\left(\frac{T_i}{m_i}\right)^{-1/2}\varphi_0'\right|\ll 1,$$

we find

$$f_0=f_{00}\left\{1+\left(\frac{n_0'}{n_0}+\frac{e\varphi_0'}{T_i}\right)(\omega_i v_y-\nu_i v_x)\frac{1}{\omega_i^2+\nu_i^2}+\right.$$

$$+\left(\frac{n_0'}{n_0}\frac{e\varphi_0'}{T_i}+\frac{1}{2}\frac{n_0''}{n_0}+\frac{1}{2}\frac{e\varphi_0''}{T_i}+\frac{1}{2}\left(\frac{e\varphi_0'}{T_i}\right)^2\right)\frac{v_x^2+v_y^2}{\omega_i^2+\nu_i^2}$$
$$-\left(\frac{n_0'}{n_0}\frac{e\varphi_0'}{T_i}+\frac{m_i}{T_i}\left(\frac{e\varphi_0'}{m_i}\right)^2\right)\frac{1}{\omega_i^2+\nu_i^2}\Bigg\}. \tag{3}$$

In the expansion (3) we take only those second-order terms which affect the density.[1] The velocity is defined by the first term of the expansion

$$V_{0ix}=-b_{i\perp}\varphi_0'-D_{i\perp}\frac{n_0'}{n_0}, \tag{4}$$

$$V_{0iy}=b_{i\perp}\varphi_0'-D_{i\perp}\frac{n_0'}{n_0}. \tag{5}$$

Here $b_i = e/m_i\nu_i$ is the mobility of the ions, $D_i = T_i/m_i\nu_i$ is the diffusion coefficient, $b_{i\perp} = b_i(\nu_i^2/\omega_i^2 + \nu_i^2)$; $b_{i\perp} = (\omega_i/\nu_i)b_i$; $D_{i\perp} = D_i(\nu_i^2/\omega_i^2 + \nu_i^2)$; $D_{i\perp} = D_{i\perp}\omega_i/\nu_i$.

It is usually assumed that even with collisions the unperturbed state of the plasma can be described by a function of the integrals of motion v^2, $x + v_y/\omega_i$. In the present case this approach leads to an incorrect expression for the ion velocity.

Since the Larmor radius of the electrons is small, their motion can be described by means of the continuity equation

$$\frac{\partial n}{\partial t}+\operatorname{div}(n\mathbf{V}_e)=0 \tag{6}$$

and the momentum balance equation

$$0=-T_e\nabla n+en\nabla\varphi-\frac{en}{c}[\mathbf{V}H]-m_e n\mathbf{V}_e\nu_e. \tag{7}$$

It is assumed here that the neutrality condition $n_e = n_i = n$ is satisfied and that the temperature (average energy) of the electrons is not changed in the instabilities. By means of (7) we can find an expression for the components of the initial electron velocity and these will differ from (4) and (5) only in the sign in front of the mobility and in the subscript used (i → e).

In dielectric discharge tubes the rate of electron and ion motion to the walls of the tubes must be equal. This condition then defines the ambipolar electric field

$$E_0=\frac{D_{i\perp}-D_{e\perp}}{b_{i\perp}+b_{e\perp}}\frac{n_0'}{n_0}. \tag{8}$$

2. LOW-FREQUENCY DRIFT OSCILLATIONS

The study of drift oscillations usually makes use of the so-called local quasiclassical approximation; we treat small perturbations in the electric field, the ion distribution function, and the density in the form of plane waves traveling in the plane perpendicular to OX, $e^{-i\omega t+ik_z z+ik_y v}$, $k_y \gg \varkappa$, $\varkappa = n'_0/n_0 \sim a^{-1}$.

We consider modes with $k_y \gg k_z$, $\omega \ll \nu_i$. We consider the electrons as magnetized $\omega_e \gg \nu_e$, and the initial electric field as weak $|\varkappa u/\omega_i| \ll 1$. Here $u = (c/H)(d\varphi_0 \cdot dx)^{-1}$, and the conditions $\varkappa\rho_i \ll 1$, $|\varkappa u/\omega_i| \ll 1$ allow us to retain only the first two terms in the expression f_0. Considering the motion of the electrons and ions in the wave field, we get the following relationships between the perturbations in density and potential (remembering that the plasma is neutral):

$$\left.\begin{aligned}&\left(-i\omega+ik_y u+D_e\left(k_y^2\frac{\nu_e^2}{\omega_e^2}+k_z^2\right)\right)\frac{n_1}{n_0}+\\&+\left(-k_y^2\frac{\nu_e}{\omega_e}-k_z^2\frac{\omega_e}{\nu_e}-ik_y\varkappa\right)\frac{c\varphi_1}{H}=0,\\&\left(-i\omega+ik_y u\frac{\omega_i^2}{\omega_i^2+\nu_i^2}(1+\delta)+D_i k_y^2(1-\beta)\frac{\nu_i^2}{\omega_i^2+\nu_i^2}\right)\frac{n_1}{n_0}\\&+\left(k_y^2\frac{\nu_i\omega_i}{\omega_i^2+\nu_i^2}(1-\beta)-ik_y\varkappa\frac{\omega_i^2}{\omega_i^2+\nu_i^2}(1-\alpha)\right)\frac{c\varphi_1}{H}=0,\end{aligned}\right\} \tag{9}$$

and α, β, and δ are corrections related to the finite ion Larmor radius

$$\left.\begin{aligned}\alpha&=1-\frac{\eta_0(z_i)+2\sum\limits_{n=1}^{\infty}\frac{\eta_n(z_i)\nu_i^2}{\nu_i^2+n^2\omega_i^2}}{1-4\sum\limits_{n=1}^{\infty}\frac{\eta_n(z_i)n^2\omega_i^2\nu_i^2}{(\nu_i^2+n^2\omega_i^2)^2}},\\\beta&=1-\frac{1}{z_i}\frac{1-\eta_0(z_i)-2\sum\limits_{n=1}^{\infty}\frac{\eta_n(z_i)\nu_i^2}{\nu_i^2+n^2\omega_i^2}}{1-4\sum\limits_{n=1}^{\infty}\frac{\eta_n(z_i)n^2\omega_i^2\nu_i^2}{(\nu_i^2+n^2\omega_i^2)^2}},\\\delta&=-1+\frac{1+\frac{\nu_i^2}{\omega_i^2}\left(1-\frac{2}{z_i}\sum\limits_{n=1}^{\infty}\frac{\eta_n(z_i)n^2(\nu_i^2+\omega_i^2)}{\nu_i^2+n^2\omega_i^2}\right)}{1-4\sum\limits_{n=1}^{\infty}\frac{\eta_n(z_i)n^2\omega_i^2\nu_i^2}{(\nu_i^2+n^2\omega_i^2)^2}}.\end{aligned}\right\} \tag{10}$$

The following notation has been used in (10): $z_i = k_y^2\rho_i^2$; $\rho_i = \omega_i^{-1}(T_i/m_i)^{1/2}$ is the ion Larmor radius, $I_n(z_i)$ is the Bessel function of imaginary argument, $\eta_n(z_i) = I_n(z_i)e^{-z_i}$. We get the dispersion equation by equating the determinant of (9) to zero. From the dispersion equation we then find the frequency at the instability boundary (Im ω = 0)

$$\omega=\frac{\omega_i^2}{\nu_i^2+\omega_i^2}\left\{k_y u\left(1+\delta+(1-\beta)\left(\frac{k_y}{k_0}\right)^2\frac{\nu_i\nu_e}{\omega_i\omega_e}\right)\right.$$
$$\times\left(1+(1-\beta)\left(\frac{k_y}{k_0}\right)^2\frac{\omega_i\nu_i\nu_e}{\omega_e(\nu_i^2+\omega_i^2)}\right)^{-1}-D_e k_y\varkappa\frac{\nu_e}{\omega_e}$$
$$\left.\times\left(1-\alpha-(1-\beta)\frac{T_i}{T_e}\left(\frac{k_y}{k_0}\right)^2\frac{\nu_i\nu_e}{\omega_i\omega_e}\right)\left(1+(1-\beta)\left(\frac{k_y}{k_0}\right)^2\frac{\omega_i\nu_i\nu_e}{\omega_e(\nu_i^2+\omega_i^2)}\right)^{-1}\right\} \tag{11}$$

and the condition for onset:

$$D_e k_0^2\left(1+\frac{T_i}{T_e}\right)\leqslant-\omega\frac{\varkappa}{k_y}\left(1+\alpha\frac{\omega_i^2}{\nu_i^2}\right)\frac{\nu_i}{\omega_i}(1-\beta)^{-1}$$
$$+\varkappa u\frac{\omega_i}{\nu_i}(\alpha+\delta)(1-\beta)^{-1}. \tag{12}$$

In (11) and (12), $k_0^2 = k_z^2 + k_y^2(\nu_e/\omega_e)^2$.

It is shown in ref. 3 that the drift frequency in a weakly ionized plasma must be greater than the collision frequency of ions with neutrals: $\omega > \nu_i$. It follows from (11) however, that if the plasma is positively charged relative

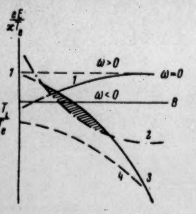

Fig. 1. 1) Electric field for which $\omega = 0$; the frequency (phase velocity) is positive above this curve; 2) characteristic experimental variation of electric with magnetic field; 3) critical electric field; the oscillations are unstable when $E < E_{cr}$; 4) critical field obtained in ref. 4.

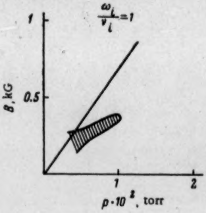

Fig. 3. Calculated stability boundaries for the decreasing frequency branch of the low-frequency mode. $k_{\parallel}$ corresponds to a solenoid with L = 60 cm.

to the walls $\varkappa u > 0$, the frequency of the oscillations can in fact go to zero. The instability condition (12) is then satisfied if the corrections for the effect of a finite Larmor radius (α, δ) in the second term on the right of (12) are large enough. We note that the instability mechanism considered in ref. 4 acts for an electric field of the opposite sign ($\varkappa u < 0$), in which case the first term on the right of (12) is the dominant one.

These ideas are illustrated in Fig. 1. The region of instability is that below the curve 3. As the magnetic field increases (Larmor radius decreases), this curve goes over to 4, which gives the critical field for the instability considered in ref. 4. A typical variation of the electric field with the magnetic field for the conditions of the experiments discussed here is shown by curve 2. The instability region lies between 2 and 3 (shaded area). The frequency (phase velocity) goes to zero on curve 1. Above 1 is the region in which the oscillations have a positive phase velocity, i.e., go over to the electron side (falling branch).

3. NUMERICAL RESULTS.
COMPARISON WITH EXPERIMENT

Expressions are obtained from (9) and (10) for the frequency ω and the growth rate γ. Since these expressions are rather cumbersome, numercial calculations are used to find the dependence of the frequency on the magnetic field. In order to compare the results with experiment the values of the parameters in the dispersion equations are taken to be those in ref. 2 for which the most extensive data are available. We use the experimental values of the stationary electric field. We note that this field exceeds the ambipolar field of (8) by about an order of magnitude. The ions can thus acquire a considerable amount of energy between collisions with neutrals – significantly higher in fact than the thermal energy of the neutrals. The effective ion temperature is calculated from the equation

$$T_{i\,\mathrm{eff}} = T_0 + \frac{eE_0}{l_i^{-1} + \rho_i^{-1}}.$$

Here, T_0 is the neutral temperature, l_i and ρ_i are the mean free path and Larmor radius of the ions. The electron temperature in ref. 2 is 2 eV. The value of $\varkappa \approx -2$ cm^{-1} is determined from the experimental distribution of the initial density n_0. Since we have solved the plane problem rather than the cylindrical of wave number $k_y = |\varkappa|$. The second mode corresponds to $k_y = 2|\varkappa|$, etc.

The waves observed in the experiment represent the fundamental mode in the longitudinal direction, i.e., a single half-wavelength along the axis of the tube. The length of the discharge tube exceeds that of the solenoids so that the length of the plasma along the magnetic field is equal to the length of the solenoid. Thus, the longitudinal wave numbers are 0.156, 0.104 and 0.052 cm^{-1} for solenoid lengths of 20, 40 and 60 cm, respectively.

Figure 2 shows how the frequencies varies with the magnetic field for various pressures and Fig. 3 shows the variation of the instability region with pressure and magnetic field for the decreasing branch of the oscillations. The experimental results are shown[2] in Figs. 4 and 5. For comparison of theory and experiment we have in Figs. 3 and 5 separated out the oscillations on the branch where the frequency decreases with magnetic field. There are two reasons for doing this: First, these modes exist over a narrow range of the parameters and second, it is in these modes that the effects of incomplete ion magnetization, and in particular of finite Larmor radius, are most clearly seen. The oscillations with increasing frequency can build up in a negative electric field of sufficient strength even when the ion Larmor radius is equal to zero.[4] (In Fig. 1, curves 3 and 4 approach each other as $|E|$ increases.) The frequency variation of the unstable modes derived from the theory has the same form as that

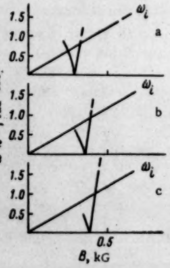

Fig. 2. Theoretical variation of the frequency of unstable oscillations with the magnetic field, calculated for an argon plasma. $k_{\parallel}$ corresponds to a solenoid with L = 60 cm; a) $p = 5 \cdot 10^{-3}$; b) $8 \cdot 10^{-3}$; c) $1 \cdot 10^{-2}$ torr.

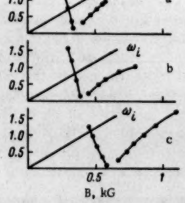

Fig. 4. Experimental variation of the frequency in an argon plasma with magnetic field for L = 60 cm. a) $p = 8 \cdot 10^{-3}$; b) 1.10^{-2}; c) $1.5 \cdot 10^{-2}$ torr.

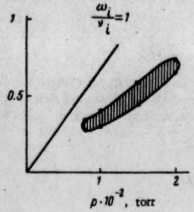

Fig. 5. Experimental boundary for the existence of the decreasing branch of the low-frequency oscillations in an argon plasma in a solenoid with L = 60 cm.

observed in the experiment. However, the whole picture is shifted to lower magnetic field values. This discrepancy is obviously due to the simplified nature of the model. Although the absolute values of the magnetic field and pressure in the instability region differ from the experimental values, there is good agreement in the dimensionless parameter ω_i/ν_i. The fact that this parameter is close to unity is understandable because in this case the ions are sufficiently magnetized as is necessary for the existence of drift instabilities and at the same time the difference in the drift velocities for crossed fields is a maximum. We recall that this quantity plays an important role in the instability.[6]

If we consider the condition $\omega_i/\nu_i \approx 1$ as necessary for the instability, then we have an explanation for the fact that the instability region is bounded on the low-pressure side. In fact, as the pressure decreases, the magnetic field in the instability region must also fall. The instability is quenched when the ion Larmor radius becomes comparable to the radius of the tube. Estimates of the lower limit in pressure made in this way agree with the experimental data.

Electron diffusion along the magnetic field plays a double role. On the one hand, it is necessary for excitation to occur.[6] On the other, it has a stabilizing effect at small longitudinal wavelengths. It is for this second reason, apparently, that the instability is not observed for the smallest solenoid length of 20 cm.

The instabilities have been observed only in the heavy gases Ar, Kr, and Xe and not He and Ne. We take this as direct proof of the important effect of the finite Larmor radius in the instability mechanism.

4. EFFECTS OF THE FINITE ION LARMOR RADIUS ON DRIFT WAVES IN A WEAKLY IONIZED MAGNETIZED PLASMA

In the majority of papers on the instabilities in a weakly ionized plasma, the ions are assumed to be cold. A smaller ion temperature ($T_i \ll T_e$) is characteristic of hf discharges and positive columns. For a discharge plasma, however, the afterglow is isothermal ($T_i \approx T_e$). In this case, as has been noted in ref. 6, the effects of the finite Larmor radius have a considerable influence on the drift waves in strong magnetic fields $\omega_i/\nu_i \gg 1$. When $\omega_i/\nu_i \gg 1$, drift waves can build up under the action of the drift-dissipative mechanism.[3,6] The unstable oscillations are then the "high-frequency" ones with $\omega \gg \nu_i$, and so in what follows we have taken the ion inertia into account.

When $\omega_i/\nu_i \gg 1$, the electrons and ions drift under the action of the stationary radial electric field with almost the same velocities $[|V_{0ey} - V_{0iy}| \approx |(cE_0/H)\,\nu_i^2/\omega_i^2| \ll |cE_0/H|]$. This motion only produces a Doppler frequency shift in the laboratory system. The small difference in the drift velocities causes an azimuthal current which in general can affect the plasma stability.[4] However, if the electric field is ambipolar, its effect is too weak and we can neglect it.

Thus from (A.1) and (2) we have

$$(-i\omega + D_e k_0^2)\frac{n_1}{n_0} + \left(-k_0^2\frac{\omega_e}{\nu_e} - ik_y\varkappa\right)\frac{c\varphi_1}{H} = 0, \tag{13}$$

$$\left(-i\omega + D_i k_y^2 \frac{\nu_i^2}{\omega_i^2}\frac{1-\eta_0(z_i)}{z_i}\right)\frac{n_1}{n_0}$$
$$+\left(k_y^2\frac{\nu_i}{\omega_i}\left(1-\frac{i\omega}{\nu_i}\right)\frac{1-\eta_0(z_i)}{z_i} - ik_y\varkappa\eta_0(z_i)\right)\frac{c\varphi_1}{H} = 0. \tag{14}$$

Here $k_0^2 = k_z^2 + k_y^2\nu_e^2/\omega_e^2$, $\eta_0(z_i) = e^{-z_i}I_0(z_i)$. Equations (13) and (14) give the frequency and the instability boundary ($\mathrm{Im}\,\omega = 0$)

$$\omega = -D_e k_y \varkappa \frac{\nu_e}{\omega_e}\left(\eta_0 - t\left(\frac{k_y}{k_0}\right)^2 \frac{1-\eta_0(z_i)}{z_i}\frac{\nu_i\nu_e}{\omega_i\omega_e}\right)$$
$$\times\left(1 + \left(\frac{k_y}{k_0}\right)^2 \frac{1-\eta_0(z_i)}{z_i}\frac{\nu_i\nu_e}{\omega_i\omega_e} + D_e k_y^2 \frac{1-\eta_0(z_i)}{z_i}\frac{\nu_e}{\omega_i\omega_e}\right)^{-1}, \tag{15}$$

$$D_e k_0^2(1+t) \leqslant \frac{\omega^2}{\nu_i} - \omega\frac{\varkappa}{k_y}z_i\frac{\omega_i}{\nu_i}. \tag{16}$$

Substitution of (15) into (16) gives

$$q \leqslant \xi^2 \frac{\eta_0(z_i) - t\,\dfrac{1-\eta_0(z_i)}{z_i}\,q^{-1}}{\left(1 + \dfrac{1-\eta_0(z_i)}{z_i}\,q^{-1} + \dfrac{1-\eta_0(z_i)}{t}\right)^2}, \tag{17}$$

where

$$q = \left(\frac{k_0}{k_y}\right)^2\frac{\omega_i\omega_e}{\nu_i\nu_e}, \quad \xi^2 = \frac{T_e\varkappa^2}{m_i\nu_i^2}, \quad t = \frac{T_i}{T_e}.$$

The inequality (17) can be written

$$\xi^2 \geqslant \frac{[qz_i(1+t-\eta_0(z_i)) + (1-\eta_0(z_i))\,t]^2}{z_i t^2[z_i\eta_0(z_i)\,q - (1-\eta_0(z_i))\,t]}. \tag{18}$$

An analysis of this inequality has shown that as ξ increases (i.e., as the pressure of the neutral gas decreases), the first modes to become unstable are those which are extended along the magnetic field with $k_z^2 \approx k_y^2(1+2t)(\nu_i\nu_e/\omega_i\omega_e)$. The critical value of ξ is $\xi^* = 2(1+T_i/T_e)^{1/2}$. When T = 0, this result coincides with that in ref. 3. Thus with increase in the ion temperature, the drift instability requires a higher gradient in the plasma density or a smaller neutral gas pressure. The stabilizing effect is apparently due to ion diffusion.

The authors are grateful to B. B. Kadomtsev and B. N. Shvilkin for useful discussions.

APPENDIX

DERIVATION OF THE DISPERSION EQUATION

The kinetic equation for a perturbation in the ion distribution function

$$\frac{\partial f_1}{\partial t}+\frac{e}{m_i}\mathbf{E}_0\frac{\partial f_1}{\partial \mathbf{v}}+\frac{e}{m_i c}[\mathbf{vH}]\frac{\partial f_1}{\partial \mathbf{v}}-\frac{e}{m_i}\nabla\varphi\frac{\partial f_0}{\partial \mathbf{v}}=-\nu_i\left(f_1-n_1 f_{00}(v)\right) \quad (\mathrm{A.1})$$

is obtained by linearizing (1). In (A.1), f_1 is the perturbed distribution function, f_0 is the initial distribution function, φ_1 and n_1 are the potential and ion-density perturbations. The initial electric field is taken to be constant E_0 = const; in the solution of (A.1) it is convenient to go over to a coordinate system in which the initial electric vanishes:

$$v'_y=v_y-u, \qquad v'_x=v_x,$$

v'_x and v'_y are the ion velocity in the new coordinate system and $u_y = -cE_0/H$ in the drift velocity in the crossed fields. Equation (A.1) becomes

$$\frac{\partial f_1}{\partial t}+\frac{e}{m_i c}[\mathbf{v}'\mathbf{H}]\frac{\partial f_1}{\partial \mathbf{v}'}-\frac{e}{m_i}\nabla\varphi_1\frac{\partial f_0}{\partial \mathbf{v}'}=-\nu_i\left(f_1-n_1 f_{00}(\mathbf{v}'+\mathbf{u})\right). \quad (\mathrm{A.2})$$

This equation has been solved by integration along the characteristic

$$v'_x=v_\perp\sin(\omega_i t+\alpha), \qquad v'_y=v_\perp\cos(\omega_i t+\alpha),$$

$$x'=x_0-\frac{v_\perp}{\omega_i}\cos(\omega_i t+\alpha)+\frac{v_\perp}{\omega_i}\cos\alpha,$$

$$y'=y_0+\frac{v_\perp}{\omega_i}\sin(\omega_i t+\alpha)-\frac{v_\perp}{\omega_i}\sin\alpha$$

We now drop the primes with v_x, v_y, x, and y.

The perturbation in the ion distribution function is

$$\frac{df_1}{dt}=\frac{e}{m_i}\nabla\varphi_1\frac{\partial f_0}{\partial \mathbf{v}}-\nu_i f_1+\nu_i n_1 f_{00}(\mathbf{v}+\mathbf{u}). \quad (\mathrm{A.3})$$

The potential and density perturbations $[\varphi_1(\mathbf{r}, t)]$ and $[n_1(\mathbf{r}, t)]$ are taken in the form $e^{-i\omega t+ik_y y+ik_z z}$. By integrating (A.3) we get the following expression for $f_1(\mathbf{r}, t)$:

$$f_1(\mathbf{r},t)=i\nu_i n_1 f_{00}e^{-\frac{m_i u^2}{2T_i}}\sum_{n=-\infty}^{\infty}\frac{J_n\left(\xi(1-\beta_i^2)^{1/2}\right)}{\omega+i\nu_i-k_z v_z-n\omega_i}e^{-i\xi\sin\alpha+in(\alpha+\psi)}$$
$$-\frac{e\varphi_1}{T_i}f_{00}\Big\{n_0\Big(1+\varkappa\Big(x+\frac{v_y}{\omega_i}\Big)\Big)-n_0\Big[\Big(1+\varkappa\Big(x+\frac{v_y}{\omega_i}\Big)\Big)(\omega+i\nu_i)$$
$$-\frac{T_i}{m_i}\frac{k_y\varkappa\omega_i}{(\nu_i^2+\omega_i^2)}\Big(1-\frac{\nu_i^2 m_i u}{\omega_i\varkappa T_i}\Big)\Big]$$
$$\times\sum_{n=-\infty}^{\infty}\frac{J_n(\xi)e^{-i\xi\sin\alpha+in\alpha}}{\omega+i\nu_i-k_z v_z-n\omega_i}-\frac{i\nu_i}{\omega_i}\frac{n_0\varkappa}{\nu_i^2+\omega_i^2}\Big(1+\frac{m_i u\omega_i}{T_i\varkappa}\Big)$$
$$\times v_\perp\Big[\omega_i\omega\sum_{n=-\infty}^{\infty}J'_n(\xi)\frac{e^{-i\xi\sin\alpha+in\alpha}}{\omega+i\nu_i-k_z v_z-n\omega_i}-(\omega_i^2-i\nu_i(\omega+i\nu_i))$$
$$\times\sum_{n=-\infty}^{\infty}\frac{nJ_n(\xi)}{\xi}\frac{e^{-i\xi\sin\alpha+in\alpha}}{\omega+i\nu_i-k_z v_z-n\omega_i}\Big]\Big\}. \quad (\mathrm{A.4})$$

Here $v_\perp^2 = v_x^2 + v_y^2$, $\xi = kv_\perp/\omega_i$, $\beta_i = m_i u\omega_i/kT_i$, $\sin\psi = \beta_i/\sqrt{\beta_i^2-1}$. Integrating (A.4) over velocity, we get

$$\frac{n_1}{n_0}\Big(1-\frac{i\nu_i\sqrt{\pi}}{k_z v_T}\sum_{n=-\infty}^{\infty}I_n\big(z_i\sqrt{1-\beta_i^2}\big)e^{-z_i}W(p_n)\Big(\frac{1-\beta_i}{1+\beta_i}\Big)^{n/2}\Big)$$
$$=-\frac{e\varphi_1}{T_i}\Bigg\{1+i\sqrt{\pi}\,\frac{\omega+i\nu_i-\frac{T_i k_y\varkappa}{m_i\omega_i}\frac{\omega_i^2}{\nu_i^2+\omega_i^2}\Big(1-\frac{\nu_i^2 m_i u}{\omega_i\varkappa T_i}\Big)}{k_z v_T}$$
$$\times\sum_{n=-\infty}^{\infty}I_n(z_i)e^{-z_i}W(p_n)$$
$$+\frac{i\sqrt{\pi}}{k_z v_T}\frac{\omega_i\omega}{\omega_i^2+\nu_i^2}\Big(1+\frac{m_i u\omega_i}{T_i\varkappa}\Big)\frac{\varkappa}{k_y}\Bigg[\omega_i\Bigg(1+\frac{\nu_i^2}{\omega_i^2}\Big(1+\frac{i\nu_i}{\omega_i}\Big)\frac{k_y u}{1+\frac{m_i u\omega_i}{T_i\varkappa}}\Bigg)$$
$$\times\sum_{n=-\infty}^{\infty}nI_n(z_i)e^{-z_i}W(p_n)+i\nu_i\Big(1-\frac{k_y u}{\omega}\frac{T_i\varkappa}{T_i\varkappa+m_i u\omega_i}\Big)$$
$$\times\sum_{n=-\infty}^{\infty}z_i e^{-z_i}\left(I'_n(z_i)-I_n(z_i)\right)W(p_n)\Bigg]\Bigg\}. \quad (\mathrm{A.5})$$

The following notation has been used in (A.5): $W(p_n)$ is the probability integral of the complex argument $p_n = (\omega + i\nu - n\omega_i)/k_z v_T$; $I_n(z_i)$ is the Bessel function of the imaginary argument $z_i = k_y^2\rho_i^2$; $v_T = \sqrt{T_i/m_i}$. When $\omega \ll \nu_i$, $\beta_i \ll 1$, $|(\omega+i\nu_i-n\omega_i)/k_z v_T| \gg 1$, (A.5) can be rewritten as

$$\frac{n_1}{n_0}\Big\{\omega(1-S_2)-k_y u(1+S_3)\frac{\omega_i^2}{\omega_i^2+\nu_i^2}+i\nu_i(1-\eta_0(z_i)-S_1)\Big\}$$
$$=-\Big\{i\nu_i(1-\eta_0(z_i)-S_1)+\frac{T_i}{m_i}\frac{k_y\varkappa}{\omega_i}\frac{\omega_i^2}{\omega_i^2+\nu_i^2}(\eta_0+S_1)\Big\}\frac{e\varphi_1}{T_i}. \quad (\mathrm{A.6})$$

Here

$$\eta_n(z_i)=I_n(z_i)e^{-z_i},$$

$$S_1=2\sum_{n=1}^{\infty}\eta_n(z_i)\frac{\nu_i^2}{\nu_i^2+n^2\omega_i^2},$$

$$S_2=4\sum_{n=1}^{\infty}n^2\eta_n(z_i)\frac{\omega_i^2\nu_i^2}{(\nu_i^2+n^2\omega_i^2)^2},$$

$$S_3=S_2+\frac{\nu_i^2}{\omega_i^2}\Big(1-\frac{2}{z_i}\sum_{n=1}^{\infty}n^2\eta_n(z_i)\frac{\nu_i^2+\omega_i^2}{\nu_i^2+n^2\omega_i^2}\Big).$$

Equation (A.6) is written in the laboratory system of coordinates ($\omega \to \omega' - ku$). For magnetized ions $\omega_i/\nu_i \gg 1$ with $\omega \gtrless \nu_i$, and from (A.5)

$$\Big(-i(\omega-k_y u)+D_i k_y^2\frac{\nu_i^2}{\omega_i^2}\frac{1-\eta_0(z_i)}{z_i}\Big)\frac{n_1}{n_0}$$
$$+\Big(k_y^2\frac{\nu_i^2}{\omega_i^2}\frac{1-\eta_0(z_i)}{z_i}\Big(1-i\frac{\omega-k_y u}{\nu_i}\Big)-ik_y\varkappa\eta_0(z_i)\Big)\frac{c\varphi_1}{H}=0.$$

---

1) The expression for f_0 satisfies the normalization condition. This can be seen by allowing for the connection between the density and potential profiles as found from the continuity equation.

Analysis of the nonlinear stage of the modulation instability shows that the establishment of a steady-state spectrum and a level of modulation waves is accompanied by a change in the direction of spectral pumping; plasmons are transferred from the "condensate" into the Landau-absorption region.

INTRODUCTION

We have previously[1] developed a nonlinear theory for the modulation instability,[2,3] which is driven at a certain level of plasma turbulence and leads to a stochastic heating of the plasma particles. Our purpose here is to analyze the overall energy balance of the plasma under conditions such that the plasma turbulence drives the modulation instability.

The general scheme of the energy fluxes can be described as follows: First, as a result of the conversion of turbulent energy, a "condensate of Langmuir plasmons" arises. This condensate is unstable and drives low-frequency modulation waves at $v_p/v_{Te} \gg 3\sqrt{m_i/m_e}$ with $W/nT > m_e/m_i$. Energy is transferred to low-frequency waves. It is shown below that this energy flux results from a resonance of the plasmons and the (low-frequency) modulation waves when $\omega_1 \approx k_1 v_{\parallel i}$ in the case of a nonlinear balance in which the excitation of waves is balanced by a nonlinear outflow. As a result, low-frequency waves with $\omega/k \ll v_{Te}$ are excited.

The energy subsequently moves through the low-frequency wave spectrum toward increasing phase velocities, up to v_{Te}. At a turbulent-energy level $W/nT > \sqrt[5]{(m_e/m_i)^2}$, the sign of the nonlinear Landau damping changes, i.e., low-frequency waves increase in frequency as a result of the nonlinear resonant interactions with particles. The result is an increase in the phase velocities. Decay processes operate in the same direction.

Finally, there is the energy transfer between low-frequency modulation waves with sufficiently large phase velocities and plasma particles.

We now consider this energy-flux scheme.

1. ENERGY FLUX FROM HIGH FREQUENCIES TO LOW FREQUENCIES

We determine the time rate of change of the total high-frequency energy:

$$\frac{dW^T}{dt}=\int \gamma^T_{k_1,\omega_1} W^T_{k_1,\omega_1} dk_1 d\omega_1, \tag{1}$$

where

$$\gamma^T_{k_1,\omega_1}=-\mathrm{Im}\,\frac{\varepsilon^T_{k_1},\ \omega_1^T}{\frac{\partial}{\partial\omega_1}\mathrm{Re}\,\varepsilon^T_{k_1,\omega_1}}. \tag{2}$$

To find $\gamma^T_{k_1,\omega_1}$ we use the dielectric constant of the high-frequency waves in the presence of modulation waves, found in ref. 1:

$$\varepsilon^T_{k_1,\omega_1}=\frac{\frac{\omega_{pe}^3}{n_0^3 m_e}}{1+\frac{n_0 m_e}{T_e+T_i}d_2}\int \frac{|c_{k,\omega}|^2}{|1+\beta_{k,\omega}|^2}\,\frac{w_{k,\omega}dk d\omega}{\tilde{\varepsilon}(k-k_1,\ \omega-\omega_1)}. \tag{3}$$

We see that the imaginary part of $\varepsilon^T_{k_1,\omega_1}$ is coupled only to the imaginary part of $1/\tilde{\varepsilon}(k-k_1,\omega-\omega_1)$. If we assume the imaginary part of $\varepsilon_{k_1,\omega_1}$ to be small, we can write[1]

$$\mathrm{Im}\,\frac{1}{\tilde{\varepsilon}_{k_1,\omega_1}}\approx-\pi\delta[\tilde{\varepsilon}(k-k_1,\ \omega-\omega_1)].$$

Accordingly, the damping can result from a wave resonance of the plasmons and modulation waves; we can describe this resonance approximately by $\omega_1 \approx k_1 v_{\parallel i}$. It is this resonance which is responsible for the energy flux from high frequencies to low frequencies:

$$\frac{dW^T}{dt}=-\frac{\pi}{2}\,\frac{\frac{\omega_{pe}^3}{n_0^3 m_e}}{1+\frac{n_0 m_e}{T_e+T_i}d_2}\int \frac{|c_{k,\omega}|^2}{|1+\beta_{k,\omega}|^2}W^T_{k_1,\omega_1} \times w^R_{k,\omega}\delta(\tilde{\varepsilon}(|k-k_1|,\ |\omega-\omega_1|))\,dk dk_1 d\omega d\omega_1. \tag{4}$$

We note that in the region of acoustic waves, $\omega \ll \omega_1$, the high-frequency waves are absorbed; if we neglect the nonlinear corrections $\beta_{k,\omega}$ and d_2, we find that this absorption is the same as in ref. 4.

We now treat the true rate of change of the low-frequency energy:

$$\frac{dw^R}{dt}=\int \gamma^R_{k,\omega} w^R_{k,\omega} dk d\omega. \tag{5}$$

Using the dielectric constant of the plasma taking account of the effect of high-frequency plasma waves found in ref. 5,

$$\varepsilon^R_{k,\omega}\simeq\left(\frac{e}{m_e}\right)\frac{\frac{\omega_{pe}^4}{n_0^2}}{1+\frac{n_0 m_e}{T_e+T_i}d_2}\int \frac{|c_{k,\omega}|^2}{|1+\beta_{k,\omega}|^2}\,\frac{J^T_{k_1,\omega_1}dk_1 d\omega_1}{\tilde{\varepsilon}(k_1-k,\ \omega_1-\omega)\,\omega_1^4} \tag{6}$$

taking the imaginary part of (6), and substituting into (5), we find

$$\frac{dw^R}{dt}=\frac{\pi}{2}\,\frac{\frac{\omega_{pe}^3}{n_0^3 m_e}}{1+\frac{n_0 m_2}{T_e+T_i}d_2}\int \frac{|c_{k,\omega}|^2}{|1+\beta_{k,\omega}|^2}W^T_{k_1,\omega_1}w^R_{k,\omega} \times \delta(\tilde{\varepsilon}(|k_1-k|,\ |\omega_1-\omega|))\,dk dk_1 d\omega d\omega_1. \tag{7}$$

We see that Eqs. (7) and (4) are identical. Thus

$$\frac{d}{dt}(W^T+w^R)=0. \tag{8}$$

2. TRANSFER OF PLASMA ENERGY THROUGH THE LOW-FREQUENCY SPECTRUM

To study the energy transfer through the low-frequency spectrum we must first carry out several auxiliary calculations, i.e., we must determine the nonlinear dielectric constant of the plasma in the presence of the modulation instability. Using

$$E^R_{k,\omega}=\frac{4\pi ie}{k}\int f^{Re}_{k,\omega}dkd\omega, \tag{9}$$

multiplying by $E^R_{k',\omega'}$ and averaging over the low frequencies, we find the following equation for the correlation function of the low-frequency waves:[1]

$$w^R_{k,\omega}=i\frac{e}{k}\int\langle E^R_{k',\omega'}f^R_{k,\omega}\rangle_L\,dk'd\omega'dv. \tag{10}$$

The distribution function of the "quasiparticles" (dressed particles) in the plasma $f^R_{k,\omega}$ can be expanded in a series in the field E^R:

$$f^R_{k,\omega}\simeq f^{R(1)}_{k,\omega}+f^{R(2)}_{k,\omega}+f^{R(3)}_{k,\omega}+\ldots, \tag{11}$$

where $f^{R(1)}_{k,\omega}$ describes the linear properties of the plasma, and $f^{R(2)}_{k,\omega}$ and $f^{R(3)}_{k,\omega}$ describe the nonlinear properties. Using[6]

$$f^{R(1)}_{k,\omega}=i\frac{e}{m_e}\frac{E^R_{k,\omega}}{1+\beta_{k,\omega}}\left(\frac{1}{\omega-kv}\frac{\partial\Phi}{\partial v}+\frac{\beta_{k,\omega}}{k}\frac{\partial^2\Phi}{\partial v^2}\right) \tag{12}$$

and substituting into (10), we find an equation for the linear dielectric constant of the plasma which incorporates the renormalization under the influence of the high-frequency plasma fluctuations ($\beta_{k,\omega}$):

$$\varepsilon^{Re}_{k,\omega}\approx\frac{\frac{\omega^2_{pe}}{k^2v^2_{Te}}}{1+\beta_{k,\omega}}. \tag{13}$$

To find the nonlinear dielectric constant we use[1]

$$\begin{aligned}f^{R(2)}_{k,\omega}={}&i\frac{e}{m_e}\frac{1}{\omega-kv}\frac{\partial}{\partial v}\int\left(E^R_{k_1,\omega_1}f^{R(1)}_{k_2,\omega_2}-\langle E^R_{k_1,\omega_1}f^{R(1)}_{k_2,\omega_2}\rangle_L\right)\\&\times\delta(k-k_1-k_2)\,\delta(\omega-\omega_1-\omega_2)\,dk_1dk_2d\omega_1d\omega_2\\&+i\frac{e}{m_e}\frac{a}{1+\beta_{k,\omega}}\frac{1}{\omega-kv}\frac{\partial}{\partial v}(\omega-kv)\frac{\partial\Phi}{\partial v}\int\frac{dv}{\omega-kv}\frac{\partial}{\partial v}\\&\times\left(E^R_{k_1,\omega_1}f^{R(1)}_{k_2,\omega_2}-\langle E^R_{k_1,\omega_1}f^{R(1)}_{k_2,\omega_2}\rangle_L\right)\delta(k-k_1-k_2)\\&\times\delta(\omega-\omega_1-\omega_2)\,dk_1dk_2d\omega_1d\omega_2,\end{aligned} \tag{14}$$

$$\begin{aligned}f^{R(3)}_{k,\omega}={}&i\frac{e}{m_e}\frac{1}{\omega-kv}\frac{\partial}{\partial v}\int\left(E^R_{k_1,\omega_1}f^{R(2)}_{k_2,\omega_2}-\langle E^R_{k_1,\omega_1}f^{R(2)}_{k_2,\omega_2}\rangle_L\right)\\&\times\delta(k-k_1-k_2)\,\delta(\omega-\omega_1-\omega_2)\,dk_1dk_2d\omega_1d\omega_2-\left(\frac{e}{m_e}\right)^2\frac{1}{\omega-kv}\frac{\partial}{\partial v}\\&\times\int\frac{\omega-kv}{(\omega_1-k_1v)(\omega_2-k_2v)}\left(\langle E^{T(0)}_{k_1,\omega_1}E^{T(3)}_{k-k_1,\omega-\omega_1}+E^{T(1)}_{k_1,\omega_1}E^{T(2)}_{k-k_1,\omega-\omega_1}\rangle_L\right)\\&\times\frac{\partial\Phi}{\partial v}\delta(k-k_1-k_2)\,\delta(\omega-\omega_1-\omega_2)\,dk_1dk_2d\omega_1d\omega_2.\end{aligned} \tag{15}$$

Solving the integral equation for the correlation function $\langle E^{T(0)}_{k_1,\omega_1}E^{T(3)}_{k-k_1,\omega-\omega_1}\rangle_H$, which is of the same order as $\langle E^{T(1)}_{k_1,\omega_1}E^T_{k-k_1,\omega-\omega_1}\rangle_H$, i.e.,

$$\begin{aligned}&\varepsilon(k-k_1,\ \omega-\omega_1)\langle E^{T(0)}_{k_1,\omega_1}E^{T(3)}_{k-k_1,\omega-\omega_1}\rangle_H-\left(\frac{e}{m_e}\right)^2J_{k_1,\omega_1}\\&\times\int dk'_2d\omega'_2\langle E^{T(0)}_{k'_2,\omega'_2}E^{T(3)}_{k-k'_2,\omega-\omega'_2}\rangle_H\left[\Sigma_{k-k_1,\omega-\omega_1;\,k'_1,\omega'_1;\,-k_1,-\omega_1;\,k-k'_2,\omega-\omega'_2}\right.\\&\left.+\Sigma_{k-k_1,\omega-\omega_1;\,k-k'_2,\omega-\omega'_2;\,-k_1,-\omega_1;\,k'_1,\omega'_1}\right]\\&-\left(\frac{e}{m_e}\right)^2\int\langle E^{T(0)}_{k_2,\omega_2}E^{T(1)}_{k'-k_2,\omega'-\omega_2}\rangle_H\left(\langle E^{T(0)}_{k'_2,\omega'_2}E^{T(2)}_{k''-k'_1,\omega''-\omega'_1}\rangle_H\right.\\&\left.+\langle E^{T(1)}_{k'_2,\omega'_2}E^{T(1)}_{k''-k'_1,\omega''-\omega'_1}\rangle_H\right)\left[\Sigma_{k-k_1,\omega-\omega_1;\,k'_1,\omega'_1;\,k''-k'_1,\omega''-\omega'_1;\,k'-k_1,\omega'-\omega_1}\right.\\&\left.+\Sigma_{k-k_1,\omega-\omega_1;\,k''-k'_1,\omega''-\omega'_1;\,k'_1,\omega'_1;\,k'-k_1,\omega'-\omega_1}\right]\\&\times\delta(k-k'-k'')\,\delta(\omega-\omega'-\omega'')\,dk'dk''d\omega'd\omega''=G,\end{aligned} \tag{16}$$

where

$$\begin{aligned}G={}&-\frac{\omega^2_{pe}}{n_0}\int\frac{J_{k_1,\omega_1}dk_1d\omega_1}{(k-k_1)[\omega-\omega_1-(k-k_1)v]}\frac{\partial f^{R(3)}_{k,\omega}}{\partial v}\\&-\frac{\omega^2_{pe}}{n_0}\int\frac{dv}{(k-k_1)[\omega-\omega_1-(k-k_1)v]}\\&\times\left(\frac{\partial f^{R(1)}_{k'',\omega''}}{\partial v}+i\frac{e}{m_e}E^R_{k'',\omega''}\frac{\partial}{\partial v}\frac{1}{\omega'-\omega_1-(k'-k_1)v}\frac{\partial\Phi}{\partial v}\right)\langle E^{T(0)}_{k_1,\omega_1}E^{T(2)}_{k'-k_1,\omega'-\omega_1}\rangle_H\\&\times\delta(k-k'-k'')\,\delta(\omega-\omega'-\omega'')\,dk'dk''d\omega'd\omega''\\&-\frac{\omega^2_{pe}}{n_0}\int\frac{dv}{(k-k_1)[\omega-\omega_1-(k-k_1)v]}\frac{\partial f^{R(2)}_{k'_2,\omega'_2}}{\partial v}\langle E^{T(0)}_{k_1,\omega_1}E^{T(1)}_{k'_1,\omega'_1}\rangle_H\\&\times\delta(k_2-k'_1-k'_2)\,\delta(\omega_2-\omega'_1-\omega'_2)\,dk'_1dk'_2d\omega'_1d\omega'_2,\end{aligned} \tag{17}$$

we find the following equation for $f^{R(3)}_{k,\omega}$:

$$\begin{aligned}f^{R(3)}_{k,\omega}={}&i\frac{e}{m_e}\frac{1}{\omega-kv}\frac{\partial}{\partial v}\int\left(E^R_{k_1,\omega_1}f^{R(2)}_{k_2,\omega_2}-\langle E^R_{k_1,\omega_1}f^{R(2)}_{k_2,\omega_2}\rangle_L\right)\\&\times\delta(k-k_1-k_2)\,\delta(\omega-\omega_1-\omega_2)\,dk_1dk_2d\omega_1d\omega_2+i\frac{e}{m_e}\frac{a}{1+\beta_{k,\omega}}\\&\times\frac{1}{\omega-kv}\frac{\partial}{\partial v}(\omega-kv)\frac{\partial\Phi}{\partial v}\int\frac{dv}{\omega-kv}\frac{\partial}{\partial v}\left(E^R_{k_1,\omega_1}f^{R(2)}_{k_2,\omega_2}\right.\\&\left.-\langle E^R_{k_1,\omega_1}f^{R(2)}_{k_2,\omega_2}\rangle_L\right)\delta(k-k_1-k_2)\,\delta(\omega-\omega_1-\omega_2)\,dk_1dk_2d\omega_1d\omega_2.\end{aligned} \tag{18}$$

Substituting (18) and (14) into (10) and carrying out some straightforward calculations, we find

$$\begin{aligned}\varepsilon^{RN}_{k,\omega}\approx{}&-\left(\frac{e}{m_e}\right)^2\frac{1}{|1+\beta_{k,\omega}|^2}\frac{1}{1+\beta_{k-k_1,\omega-\omega_1}}\\&\times\int\Sigma_{k,\omega;\,k_1,\omega_1;\,k,\omega;\,-k_1,-\omega_1}w^R_{k_1,\omega_1}dk_1d\omega_1\\&-\left(\frac{e}{m_e}\right)^2\frac{\frac{\beta_{k,\omega}}{k}}{|1+\beta_{k,\omega}|^2}\frac{1}{1+\beta_{k-k_1,\omega-\omega_1}}\frac{\omega^2_{pe}}{n_0}\\&\times\int\frac{dv}{(\omega-kv)^2}\left[\frac{2k}{\omega-kv}+\frac{k-k_1}{\omega-\omega_1-(k-k_1)v}\right]\\&\times\frac{1}{\omega-\omega_1-(k-k_1)v}\frac{\partial^2\Phi}{\partial v^2}w^R_{k_1,\omega_1}dk_1d\omega_1.\end{aligned} \tag{19}$$

Equation (19) which gives the electric constant of the plasma, takes account of the nonlinear interaction of low-frequency waves. Equation (19) can be used to calculate the nonlinear growth rate:

$$\gamma^{RN}_{k,\omega}=-\frac{\operatorname{Im}\varepsilon^{RN}_{k,\omega}}{\frac{\partial}{\partial\omega}\operatorname{Re}\varepsilon^{RN}_{k,\omega}}. \tag{20}$$

Neglecting the influence of the modulation waves, i.e., setting $\beta_{k,\omega}=0$, we find the following equation for the induced scattering by ions, $\omega-\omega_1<|k-k_1|v_{Ti}$ (ref. 6):

$$\gamma_1^{RN} \simeq \frac{1}{30}\left(\frac{\omega_{pe}}{kv_{Te}}\right)^2 \frac{w}{n_0 T}\frac{m_e}{m_i}, \tag{21}$$

which gives the energy transfer toward low frequencies.

Taking account of the nonlinear corrections $\beta_{k,\omega}$ for this case, we find that the term which arises from the second term in (19) is the predominant term, i.e., the predominant term is

$$\operatorname{Im} \varepsilon_{k,\omega}^{RN} \approx -\left(\frac{e}{m_e}\right)^2 \frac{\frac{\operatorname{Re} \beta_{k,\omega}}{k}}{|1+\beta_{k,\omega}|^2} \frac{\operatorname{Im} \beta^*_{k-k_1,\,\omega-\omega_1}}{|1+\beta_{k-k_1,\,\omega-\omega_1}|^2} \operatorname{Re} J_1, \tag{22}$$

where

$$J_1 = \frac{\omega_{pe}^2}{n_0} \int \frac{dv}{(\omega - kv)^2}\left[\frac{2k}{\omega - kv} + \frac{k - k_1}{\omega - \omega_1 - (k - k_1)v}\right]$$
$$\times \frac{1}{\omega - \omega_1 - (k - k_1)v} \frac{\partial^2 \Phi}{\partial v^2} w^R_{k_1,\omega_1} dk_1 d\omega_1. \tag{23}$$

Using (22) and (23) we can find the growth rate governing the energy transfer toward high frequencies:

$$\gamma_2^{RN} \approx -8\sqrt{\frac{\pi}{2}}\left(\frac{\omega_{pe}}{kv_{Te}}\right)^5 \frac{w}{nT}\frac{\xi^3}{|1+\xi|^4}, \tag{24}$$

where

$$\xi = \frac{n_0}{v_{Te}^2}\alpha = \frac{\frac{n_0 m_e}{T_e} d_1}{1 + \frac{n_0 m_e}{T_e + T_i} d_2} \approx \frac{1}{1 + \frac{\omega^2}{k^2 v_\sim^2}},$$

and $v_\sim^2 = 3W/4n_0 m_e$.

When we take $\beta_{k,\omega}$ into account in (21) we find a factor $1/|1 + \xi|^3$. Comparing Eqs. (21) and (24) we see that the transfer of plasma energy undergoes a change when the plasma turbulence reaches a level

$$\left(\frac{\omega_{pe}}{kv_{Te}}\right)^3 \frac{\xi^2}{|1+\xi|} > \frac{m_e}{m_i}. \tag{25}$$

Introducing $\lambda = \omega/kv_{Te}$ and $\lambda_0^2 = 3W/4n_0T$, we can rewrite inequality (15) as

$$\frac{\lambda^3}{\left(1 + \frac{\lambda^2}{\lambda_0^2}\right)\left(2 + \frac{\lambda^2}{\lambda_0^2}\right)} > \frac{m_e}{m_i}. \tag{26}$$

In the case $\lambda \gg \lambda_0$

$$\frac{W}{nT} > \left(\frac{m_e}{m_i}\right)^{2/5}. \tag{27}$$

The decay processes taken into account in ref. 4 also lead to transfer toward high frequencies.

3. ENERGY BALANCE OF THE LOW-FREQUENCY PARTICLE OSCILLATIONS

To determine the change in the total particle energy per unit time we use a quasilinear equation describing the motion of particles in the presence of the modulation instability:[1]

$$\frac{\partial \Phi}{\partial t} + v\frac{\partial \Phi}{\partial z} = I_1, \tag{28}$$

where

$$I_1 = i\frac{4\pi e^2}{m_e^2}\frac{\partial}{\partial v}\int \frac{w^R_{k,\omega}}{1+\beta_{k,\omega}} \frac{dk d\omega}{\omega - kv}\frac{\partial \Phi}{\partial v}. \tag{29}$$

Multiplying Eq. (28) by $mv^2/2$ and integrating over v, we find

$$\frac{dE}{dt} = \int I_1 \frac{mv^2}{2} dv = -i\frac{4\pi e^2}{m_e}\int \frac{\omega}{k}\frac{w^R_{k,\omega}}{1+\beta_{k,\omega}}$$
$$\times \frac{1}{\omega - k\omega}\frac{\partial \Phi}{\partial v} dv dk d\omega = -i\frac{4\pi e^2}{m_e}\frac{\omega}{k}\frac{c_{k,\omega}}{1+\beta_{k,\omega}} w^R_{k,\omega} dk d\omega, \tag{30}$$

where

$$\beta_{k,\omega} = \alpha k c_{k,\omega};\ c_{k,\omega} = \int \frac{1}{\omega - kv}\frac{\partial \Phi}{\partial v} dv.$$

Since the left-hand side of Eq. (30) is real, we find

$$\operatorname{Im}\frac{c_{k,\omega}}{1+\beta_{k,\omega}} = \operatorname{Im}\frac{c_{k,\omega}(1+\beta^*_{k,\omega})}{|1+\beta_{k,\omega}|^2} = \operatorname{Im}\frac{c_{k,\omega} - \alpha k|c_{k,\omega}|^2}{|1+\beta_{k,\omega}|^2}. \tag{31}$$

The second term vanishes since it is of odd parity. We can thus write

$$\frac{dE}{dt} = \frac{4\pi e^2}{m_e}\int \frac{\omega}{k}\frac{\operatorname{Im} c_{k,\omega}}{|1+\beta_{k,\omega}|^2} w^R_{k,\omega} dk d\omega. \tag{32}$$

On the other hand, the change in the energy of the low-frequency oscillations per unit time is

$$\frac{dw^R}{dt} = \int \gamma^R_{k,\omega} w^R_{k,\omega} dk d\omega. \tag{33}$$

Using

$$\gamma^R_{k,\omega} = \frac{-\operatorname{Im}\varepsilon^R_{k,\omega}}{\frac{\partial}{\partial \omega}\operatorname{Re}\varepsilon^R_{k,\omega}} \approx -\frac{4\pi e^2}{m_e}\frac{\omega}{k}\frac{\operatorname{Im} c_{k,\omega}}{|1+\beta_{k,\omega}|^2} \tag{34}$$

for the damping by electrons, we find

$$\frac{dw^R}{dt} = -\frac{4\pi e^2}{m_e}\int \frac{\omega}{k}\frac{\operatorname{Im} c_{k,\omega}}{|1+\beta_{k,\omega}|^2} w^R_{k,\omega} dk d\omega, \tag{35}$$

which, in particular, is the same as (32).

We thus find that the energy exchange occurs only between low-frequency oscillations and particles:

$$\frac{d}{dt}(E + w^R) = 0. \tag{36}$$

---

[1] In principle, there could also be cases in which this imaginary part is not small.

---

Energy of charged particles accelerated by electromagnetic waves in a plasma with a spatially decreasing density

V. Ya. Davydovskii and A. S. Ukolov

Taganrog Radiotechnical Institute

(Submitted October 26, 1973; resubmitted February 6, 1974)
Zh. Tekh. Fiz., 44, 2101-2108 (October 1974)

The energies of charged particles trapped by an electromagnetic wave propagating in a plasma are found when the electron density decreases exponentially in the direction of propagation. It is shown that an adiabatic treatment, in which the wave velocity is a slowly varying function, is valid for the entire acceleration process. Two mechanisms are considered for the loss of particles from the trapped state: the reduction in the amplitude of the wave and collisions. In the latter case the shape of the energy spectrum coincides with the spectrum observed for cosmic rays. The existence of a lower limit of the spectrum is indicated.

The motion of charged particles trapped by plane electromagnetic waves is considered in refs. 1 and 2 in the adiabatic approximation, in which the variation in wave parameters over a period can be neglected. The acceleration of particles by waves with an increasing propagation velocity is proposed in ref. 3 as a mechanism for the acceleration of cosmic particles. This mechanism can even operate in the solar atmosphere. Long-range Coulomb collisions do not untrap particles (the numerical estimates for the sun are given in ref. 4), and the mean free path of the particles, calculated on the basis of an impact parameter of the order of the classical electron radius e^2/mc^2, is much larger than the solar radius $R_\odot$, even for electron densities corresponding to the lower layers of the corona.

In the present work we investigate a possible shape for the energy spectrum of particles accelerated by the mechanism under discussion. It is assumed below that the medium is a plasma with an electron density that varies as

$$N(z)=N_0 e^{-\alpha z}.$$

Such a medium is fairly typical of cosmic conditions. For the sun, depending on height, the parameter $1/\alpha$ varies from 0.01-0.5 $R_\odot$.

The electromagnetic wave is described by the vector potential

$$\left.\begin{array}{l} A_x=\lambda\cos\omega\theta,\ A_y=-\lambda\sin\omega\theta,\ A_z=0,\\ \lambda=\dfrac{eE}{mc\omega},\ \omega=\text{const},\ \theta=t-\displaystyle\int_0^z n(z)\,dz, \end{array}\right\} \qquad (1)$$

where E is the electric field of the wave, and n(z) is a function which plays the role of the refractive index, being related to the group velocity by the expressions

$$n(z)=\frac{1}{v(z)}=\left[1-\frac{4\pi e^2}{m\omega^2}N(z)\right]^{-1/2}=\left[1-\frac{\omega_0^2}{\omega^2}e^{-\alpha z}\right]^{-1/2}, \qquad (2)$$

where ω_0 is the plasma frequency at the point z = 0. All velocities are expressed in units of c and distances in units of light seconds.

In the numerical estimates we set $E = 10^{-4}$ V/cm, which is twice the values observed for radio emission from the quiet sun calculated back to the source. Amplitudes have been observed in radio bursts that are four to five orders of magnitude higher than the value assumed here. The wave frequency ω is taken to be $2\cdot10^9$ sec^{-1}, which corresponds to the meter range. Also, $\lambda\simeq5\cdot10^{-9}$ for electrons, and $\lambda\simeq2.5\cdot10^{-12}$ for protons.

It is pointed out in ref. 5 that it is not necessary to choose the wave in the form of (1); it is only necessary that the field of the wave confine the particle.

The adiabatic treatment of the particle motion is valid if

$$\left|\frac{dn}{dz}\right|\ll\frac{n}{Z}, \qquad (3)$$

where Z is the distance the particle is displaced during a period.[1,2] It is easy to verify that condition (3) is satisfied in the solar corona for waves in the meter range.

The parameter τ is related to the amplitude of phase oscillations of the particle $\Delta\theta_{\max}$ by the relation[1,2]

$$\tau=\sin^2\frac{1}{2}\omega\Delta\theta_{\max}. \qquad (4)$$

With $\tau = 0$ there are no phase oscillations; when $\tau > 1$ the particles are not confined by the wave.

For wave propagation along the z axis the average energy of the trapped particles increases as

$$\beta=n\left[\frac{4C\lambda\tau+1+(C-\lambda)^2}{n^2-1}\right]^{1/2}=\frac{\omega}{\omega_0}\sqrt{4C\lambda\tau+1+(C-\lambda)^2}\,e^{\frac{\alpha z}{2}}. \qquad (5)$$

The particle energy β is divided by the rest energy mc^2. We will assume that the energy spectrum of particles accelerated by the described mechanism is determined by the following consideration: The final energy of the particle is related by Eq. (5) to the value of n(z) at the point at which the particle becomes untrapped. For simplicity we assume everywhere that the constant C is the same for all the particles. In the estimates we set C = 1.

The desired energy spectrum is determined by mechanisms that break down the confinement of the particle by the wave. We will show, first, that the violation of adiabaticity cannot be such a mechanism. Using (2) and (4), and setting $\tau = 0$ we write instead of (3)

$$\sqrt{\frac{1+(C-\lambda)^2}{C\lambda}}\ll\frac{\omega}{4\alpha}, \qquad (6)$$

which is satisfied for the assumed values. If condition (6) is not satisfied, an adiabatic treatment is impossible for any values of τ. Otherwise, there exists a $\tau_{\max}$ determined by

$$K(\tau_{\max})\sqrt{\tau_{\max}+\frac{1+(C-\lambda)^2}{4C\lambda}}=\frac{\omega}{4\alpha}$$

such that when $\tau \ll \tau_{\max}$, there exists an adiabatic invariant[1,2]

$$\tau B(\tau)\sqrt{\frac{\lambda}{n^2-1}}=I=\text{const.} \tag{7}$$

In our case it is practical to set $\tau_{\max} = 1$.

It follows from (7) that for a decrease in n the parameter τ only decreases if $\lambda(z)$ does not decrease faster than n^2-1. In this case condition (6) is only enhanced, which means that it is impossible for the particles to escape from the trapped state as a result of a violation of adiabaticity. We note also that on the basis of the above discussion the parameter τ decreases for trapped particles as the acceleration increases.

The particles escape from the trapped state due to a decrease in the wave amplitude, collisions with the particles of the medium, and a change in wave mode due to dispersion. Assuming that the particles attain high energies for values of n close to unity, when the electron density is small and dispersion is negligible, we restrict the investigation to the first two mechanisms. For this reason we neglect damping of the wave due to interaction with the medium, assuming that the decrease in wave amplitude results from energy transfer between the wave and the particles. The latter effect is considered in ref. 5 under the assumption that the particles have the same initial parameters and therefore that they are untrapped simultaneously. If this assumption is not made then the accelerated particles have an energy distribution.

We assume that condition (3) is satisfied, so that there is an adiabatic invariant (7). Then at the point of untrapping, for which $\tau = 1$, we have

$$\sqrt{\frac{E}{n^2-1}}=A_1\tau_0 B(\tau_0). \tag{8}$$

Here, $A_1=\sqrt{E_0/(n_0^2-1)}$ and the subscript 0 denotes quantities at some initial reference point.

Assume that the wave imparts energy only to trapped particles whose flux j decreases. Then we have

$$d(S+j\beta)=\beta dj, \tag{9}$$

where S(n, E) is the wave energy flux density.

We introduce the function $f(\tau_0)$, which characterizes the initial distribution of particles over the parameter τ_0: $dj_0 = f(\tau_0)d\tau_0$. In the interval corresponding to a change in the refractive index by dn, particles with values of τ_0 within the interval $d\tau_0$ escape from the trapped state. The number of such particles in the flux j is $f(\tau_0)d\tau_0$. Thus,

$$dj=f(\tau_0)\,d\tau_0. \tag{10}$$

Assuming that the particle energy at untrapping time is related to n by (5), where we set $\tau = 1$,

$$\beta=n\left[\frac{1+(C+\lambda)^2}{n^2-1}\right]^{1/2}=\frac{\omega}{\omega_0}\sqrt{1+(C+\lambda)^2}\,e^{\alpha z/2}, \tag{11}$$

we can, theoretically, use Eqs. (8)-(10) to find the energy spectrum of the accelerated particles. We solve this problem under the following assumptions, which are fairly realistic:

1. We assume $n \gg 1$ since particle acceleration becomes important for values of n close to unity. On the basis of (2), this assumption is equivalent to $\exp(\alpha z) \gg (\omega_0/\omega)^2$.

2. The form of the wave energy flux density is $S = A_2E^2n^{-1}$, $A_2 = 1.2\cdot10^{12}$ sec/g-cm. Throughout, the estimates are satisfactory with regard to protons. Under these assumptions, equality (9) becomes

$$2A_2\frac{E}{n}\,dE+j\,d\beta=0. \tag{12}$$

Here, the change in wave amplitude related to the increase in wave velocity is neglected; only the change due to the increase in particle energy is considered. Obviously, this procedure is valid when $n \to 1$. Substituting into (12) the value of j obtained from (10), $j=\int_0^{\tau_0} f(x)dx$, expressing τ_0 in terms of E and n through (8), where $B(\tau_0) = 1$ [actually, B(x) varies from $\pi/4$ to 1 when x varies from 0 to 1], and finding $d\beta$ from (11), we obtain a differential equation for E(n):

$$2A_2EdE-\sqrt{1+(C+\lambda)^2}\,\frac{dn}{(n^2-1)^{3/2}}\int\limits_0^{\frac{1}{A_1}\sqrt{\frac{E}{n^2-1}}} f(x)\,dx. \tag{13}$$

It is evident from this equation that the shape of the spectrum depends essentially on the shape of $f(\tau_0)$, which is determined by a number of factors that are hard to evaluate: the trapping mechanism, the behavior of the flux and the wave up to the point chosen as the initial point, etc. Therefore, certain assumptions will be made with regard to the shape of $f(\tau_0)$.

The trapped particle represents an oscillator[1] with a maximum energy

$$\beta_{\max}=\beta+\sqrt{\frac{C\lambda\tau}{n^2-1}}$$

that obviously coincides with the total energy. Assuming that at the initial time the oscillators are governed by Boltzmann statistics, we write

$$dj_0=2A_3e^{-\gamma\sqrt{\tau_0}}d(\sqrt{\tau_0}),\ A_3=\text{const},\ f(\tau_0)=A_3\frac{e^{-\gamma\sqrt{\tau_0}}}{\sqrt{\tau_0}}, \tag{14}$$

after which E(n), given by (13), takes the form

$$A_2 d(E^2)+\frac{A_3}{\gamma}\sqrt{1+(C+\lambda)^2}$$

$$\times\left\{\exp\left[-\frac{\gamma E^{1/4}}{A_1^{1/4}(n^2-1)^{1/4}}\right]-1\right\}\frac{d(n^2)}{(n^2-1)^{3/2}}=0. \qquad (15)$$

We take $A_3 = 10^4$ sec^{-1}, which corresponds to fluxes observed near the earth, which are of order 1 cm^{-2}. sec^{-1}. To integrate (15) we assume $\sqrt{1+(C+\lambda)^2}$ = const since usually $\lambda \ll 1$.

In (15) we take

$$\tau_1 \ll \frac{1}{\gamma^2}, \qquad (16)$$

which is valid not only for small τ_0 for any temperature of excitation of phase oscillations $1/\gamma$, but also for $\gamma \ll 1$ for any values of τ_0. Integrating (15) and using (16), we find E(n) for n ~ 1:

$$E=\left\{E_0^{7/4}+\frac{7A_3}{6A_2}\sqrt{\frac{1+(C+\lambda)}{A_1}}\,[(n_0^2-1)^{-3/4}-(n^2-1)^{-3/4}]\right\}^{4/7}. \quad (17)$$

It is evident that for n → 1 a value of n is reached such that the wave amplitude vanishes and confinement becomes impossible. Introducing the notation

$$a=E_0^{7/4}+(n_0^2-1)^{-3/4}\frac{7A_3}{6A_2}\sqrt{\frac{1+(C+\lambda)^2}{A_1}}$$

and expressing n in terms of β with the aid of (11), where it is assumed that $n \approx 1$, we rewrite (17) in the form

$$E=\left\{a-\frac{7A_3}{6A_2\sqrt{A_1}}\frac{\beta^{3/4}}{[1+(C+\lambda)^2]^{1/4}}\right\}^{4/7}.$$

It follows that there exists a limiting energy β_{lim} for which the wave vanishes:

$$\beta_{\text{lim}}=\left\{\frac{6A_2\sqrt{A_1}\,a\,[1+(C+\lambda)^2]^{1/4}}{7A_3}\right\}^{4/3}.$$

The larger β_{lim} the larger E_0, the later the particles are captured (the smaller $n_0^2 - 1$), and the smaller the initial particle flux (the smaller A_3).

Assuming $n_0^2 - 1 = 1$, we obtain $\beta_{\text{lim}} \simeq 1.3$; this corresponds to 300 MeV protons, which is comparable to the energy of protons of solar origin.

It is also easy to establish the lower limit of the spectrum; this is determined by the vanishing of the derivative of the expression $[E(n^2-1)^{-1}]^{-1/2}$; at this point the increase due to the reduction in $n^2 - 1$ is offset by the reduction due to the decreasing wave amplitude E caused by the fact that the energy of the wave is absorbed by the accelerated particles. At this point the reduction in τ [as can be seen from (7)] becomes an increase and when τ = 1 the particles escape from the trap. Therefore, the lower boundary of the particle energies in the spectrum is β_{low}, which is determined by $\beta_{\text{low}} = (0.7)^{2/3}\beta_{\text{lim}} \simeq 0.7884 \cdot \beta_{\text{lim}}$, which follows from

$$\frac{d}{d\beta}\left(\frac{E}{n^2-1}\right)=0.$$

Assuming (14) in the limiting case (16) the differential energy spectrum of the accelerated particles $F(\beta)$ with $\beta \leqslant \beta_{\text{lim}}$ is

$$F(\beta)=\text{const}\,\beta\left[1-\left(\frac{\beta}{\beta_{\text{lim}}}\right)^{3/4}\right]^{-4/7}. \qquad (18)$$

In the opposite limiting case to (16),

$$\gamma^2 \gg \frac{1}{\tau_0}, \qquad (19)$$

the wave amplitude is

$$E=\left\{E_0^2+\frac{2A_3}{A_2\gamma}\sqrt{1+(C+\lambda)^2}\,[(n_0^2-1)^{-1/2}-(n^2-1)^{-1/2}]\right\}^{1/2}.$$

In this case the limiting energy at which the field vanishes is

$$\beta_{\text{lim}}=\frac{A_2\gamma b}{2A_3},$$

where

$$b=E_0^2+\frac{2A_3}{A_2\gamma}\sqrt{\frac{1+(C+\lambda)^2}{n_0^2-1}}.$$

When $\gamma \simeq 10$ we obtain $\beta_{\text{lim}} \simeq 1.4$. The lower boundary of the spectrum is $\beta_{\text{low}} = 0.8\beta_{\text{lim}}$. Obviously, the limiting case (19) is realized at low excitation temperatures, in which case γ is large; this holds when there are no particles with small τ_0 in the initial distribution over τ_0. Assuming that the spectrum only contains particles with $\tau_0 \simeq 1$ we find the following differential spectrum for $\beta \sim \beta_{\text{lim}}$:

$$F(\beta)=\text{const}\,\beta^{1/2}\left(1-\frac{\beta}{\beta_{\text{lim}}}\right)^{-1/2}. \qquad (20)$$

Equations (18) and (20) do not coincide with the spectrum observed for cosmic radiation. We now find the form of $f(\tau_0)$ for which the energy spectrum of the accelerated particles is like the observed power spectrum:

$$j=A_4\beta^{-x},\ A_4=\text{const}. \qquad (21)$$

Taking n ~ 1 in (12), we find

$$E=E_0\left[1-\left(\frac{\beta}{\beta_{\text{lim}}}\right)^{1-x}\right]^{1/2}\left[1-\left(\frac{\beta_0}{\beta_{\text{lim}}}\right)^{1-x}\right]^{-1/2}, \qquad (22)$$

$$\beta_{\text{lim}}^{1-x}=\frac{E_0^2A_3(1-\gamma)}{A_4}+\beta_0^{1-x}. \qquad (23)$$

Thus, if the particles are accelerated by the mechanism under consideration, their energy spectrum is not expressed by (21) but has the form

$$j(\beta)=\begin{cases} A_4\beta^{-x} & \text{for } \beta\leqslant\beta_{\text{lim}} \\ A_4\beta^{-x} & \text{for } \beta>\beta_{\text{lim}}. \end{cases}$$

For (21), the lower boundary is

$$\beta_{\text{low}}^{1-x}=\beta_{\text{lim}}^{1-x}\frac{4}{5-x}.$$

The form of $f(\tau_0)$ is determined by (8), (10), and (11). Setting x = 3 and $B(\tau_0) = 1$ we obtain

$$f(\tau_0)=\frac{6A_3}{\beta^3_{\text{lim}}}\frac{1+(C+\lambda)^2}{n_0^2-1}(\beta^2_{\text{lim}}-\beta_0^2)\tau_0^3. \tag{24}$$

Here, $\beta_{\text{low}} = \beta_{\text{lim}}/\sqrt{2}$. Equation (24) is valid when

$$2\frac{1+(C+\lambda)^2}{n_0^2-1}(\beta^2_{\text{lim}}-\beta_0^2)^{1/2}\tau_0^2\ll\beta^3_{\text{lim}},$$

i.e., for small τ_0 and, thus, high energies.

Equations (22) and (23) become

$$E=E_0\frac{\beta_0}{\beta}\sqrt{\frac{\beta^2_{\text{lim}}-\beta^2}{\beta^2_{\text{lim}}-\beta_0^2}},\quad \beta^2_{\text{lim}}=\frac{A_4\beta_0^2}{A_4-2S_0}. \tag{25}$$

If the initial amplitude is large and the initial flux of trapped particles is small, $2S_0 > A_4$ the latter expression is meaningless, and thus total absorption of the wave is impossible and there is a limiting value of the amplitude:

$$E_{\text{lim}}=E_0\left(1-\frac{\beta^2_{\text{lim}}}{\beta_0^2}\right)^{-1/2}=E_0\sqrt{1-\frac{A_4}{2S_0}}.$$

In this case the entire spectrum is described by (21). Collisions can also cause untrapping of particles. The relation describing the decrease in particle density due to collisions can be written

$$dj=-g(z)\,j\,dz, \tag{26}$$

where g(z) is a function which acts as the reciprocal mean free path. As a first approximation we take

$$g(z)=g_0=\text{const}, \tag{27}$$

and find from (11)

$$j=j_0\left(\frac{\omega\sqrt{1+(C+\lambda)^2}}{\omega_0}\right)^{\frac{\alpha}{2g_0}}\beta^{-\frac{2g_0}{\alpha}},$$

i.e., a power spectrum with exponent $2g_0/\alpha$; in the differential energy spectrum the exponent is $i = 2g_0/\alpha + 1$.

Acceleration of charged particles in waves with an increasing propagation velocity is obviously effective when the mean free path of the trapped particles $1/g_0$ is comparable to or larger than the distance of the characteristic change in energy $1/\alpha$. When $1/2 < g_0/\alpha < 2$ agreement is obtained with the spectrum observed for cosmic radiation of galactic or solar origin, for which i = 2–5.

When particles escape from the trap due to collisions the function g(z) theoretically cannot be considered constant since a decrease in the density of the medium is necessary for particle acceleration, and the function g(z) must decrease along with the decrease in density. Therefore, we set $g(z) = g_0 \exp(-qz)$, and q can coincide with α, which characterizes the decrease in medium density. Then, from (26), we have

$$j=j_0\exp\left[\frac{g_0}{q}(e^{-qz}-1)\right]. \tag{28}$$

From (11), it is easy to find the spectrum

$$j=j_0e^{g_0/q}\exp\left\{\frac{g_0}{q}\left(\frac{\omega_0{}^3}{\omega\sqrt{1+(C+\lambda)^2}}\right)^{-2q/\alpha}\right\}. \tag{29}$$

We now consider the form of the energy spectrum of accelerated particles for different assumptions. The spectrum concides with the experimentally observed spectrum only for (26) and (27). However, we feel that the most realistic picture of the acceleration of charged particles is given by a combination of the two mechanisms under consideration. At first, when the wave has not yet imparted its energy to the trapped particles, it is fairly powerful and confines the particles well. This feature is indicated by the fact that the parameter τ decreases according to (7) with decreasing n in spite of the decrease in the wave amplitude. For a value of n corresponding to a particle energy equal to the lower limit of the spectrum β_{low}, the parameter τ begins to increase. When $\tau \simeq 1$ particles can escape from the trapped state by collisions. Therefore the collision mechanism comes into play only at a certain value of the z coordinate. In this case there is a more or less sharp lower boundary of the spectrum. The parameters g_0 and q depend not only on the kind of collision and the density of the medium, but also on the portion of the trapped particles for which τ has reached values close to unity.

In any case, it can be seen from (29) that a necessary condition for a substantial decrease in the initial particle flux is $g_0 \gg q$, which means that the average mean free path of the trapped particles should vary slowly. In (28) we take

$$z\gg\frac{1}{q}\ln\frac{g_0}{q}, \tag{30}$$

and expand the exponential

$$j=j_0e^{-g_0/q}\left(1+\frac{g_0}{q}e^{-qz}\right).$$

If the coordinates for particle untrapping satisfy the condition $z \gg 2/\alpha$ as well as (30), the trapped particles are effectively accelerated by the mechanism in question. For the hard part of the spectrum, for which (30) is valid, a power differential spectrum is obtained with an exponent $i = 2q/\alpha + 1$. This exponent coincides with that observed for $q \sim \alpha$ and is fairly realistic since it means that substantial variation of the mean free path of the trapped particles and the electron density of the medium occurs at comparable distances.

The maximum energies that can be attained by protons in the sun are easy to estimate from the following considerations. The particle energy is related to n by (5), which for $n \sim 1$ can be written as $\beta = \text{const}(n^2-1)^{-1/2}$. Using (2), we obtain $\beta/\beta_0 = (N/N_0)^{1/2}$. Setting $\beta_0 \simeq 1$ and $N_0 \simeq 10^9$ cm^{-3} (the lower corona layers), for the upper corona, where $N \simeq 10^5$ cm^{-3}, we have $\beta \simeq 10^2$ and this corresponds to energies of $\sim 10^{11}$ eV. Energies of the same order of magnitude have been observed for the most energetic protons from the sun (for example, see ref. 6).

If the flux of trapped particles encounters a magnetic inhomogeneity they are untrapped. The synchrotron radiation of these particles can generate radio bursts.

In conclusion, we summarize results that are of interest for astrophysical problems.

1. Violation of the adiabatic condition is not an important mechanism for particle untrapping.

2. If a fairly large portion of the particles in the initial flux have low phase oscillation amplitudes, when $\tau_0 \ll 1$ the wave is strongly absorbed. If there are many trapped particles, the acceleration is negligible. Thus, high-energy trapped particles accelerated by the wave can appear unaccompanied by electromagnetic radiation.

3. The mechanism explains the existence of a lower boundary in the spectrum.

4. Fairly realistic assumptions are used to obtain a form of the spectrum that coincides with the spectrum observed for cosmic particles of galactic or solar origin.

5. Numerical estimates indicate that even under solar conditions with amplitudes corresponding to radio emission from the quiet sun the mechanism in question can generate particles over a very broad energy range. Energies corresponding to the hardest protons of solar origin are attained through acceleration by waves generated by powerful chromospheric flares.

Nonmonotonic potential distribution in the electrode region

A. I. Loshkarev

(Submitted October 25, 1973)
Zh. Tekh. Fiz., 44, 2109-2115 (October 1974)

Low-voltage arcs with a nonmonotonic potential distribution in the electrode sheath are examined. The inclusion of electron and ion scattering is important because it provides correct matching to the neutral plasma. Simple analytic expressions are obtained for the potential drop near the cathode; these agree with the experimental data. The space charge at the minimum potential is fairly small, making it possible to match the solution to the neutral plasma at the minimum. This matching is equivalent to the existence of a solution with fixed striations, which have been observed experimentally in cesium discharges. Moving striations are also discussed.

The nonmonotonic potential distribution in the electrode sheath has attracted the attention of many investigators. As a rule, the solution is obtained from the Vlasov (collisionless) equation or from the beam approximation. Difficulties arise with regard to correct matching of the kinetic equation to the diffusion equation at the boundary of a dense neutral plasma. In certain cases formal satisfaction of the boundary conditions, i.e., zero first derivative of the potential at the minimum near the electrode and at the boundary of the diffusion region, means that the square of the derivative of the potential, obtained as the first integral of the Poisson equation, must be negative over most or all of the region in which the potential varies in the electrode sheath. A detailed review of the literature involving this problem is contained in ref. 1. That paper also emphasizes the difficulties involved in matching and the resulting error in the sign of the second derivative of the potential at the minimum. Consideration of charged-particle scattering allows us to obtain a correct solution which can be matched to the diffusion equation.

We will use transport equations in hydrodynamic form. The accuracy of these equations is no worse than that of the kinetic equations if the frictional forces, viscous terms, etc. are determined appropriately.

The conservation of momentum for electrons and ions can be written

$$\frac{dn_e}{dx}+n_e\left(\frac{d\ln T_e}{dx}-\frac{e}{T_e}\frac{d\varphi}{dx}\right)=\frac{1}{T_e}\left(R_e-\frac{d\tau_{exx}}{dx}-m_e\Gamma_e\frac{du_e}{dx}\right)\equiv\frac{R_e^*}{T_e}, \tag{1}$$

$$\frac{dn_i}{dx}+n_i\left(\frac{d\ln T_i}{dx}+\frac{e}{T_i}\frac{d\varphi}{dx}\right)=\frac{1}{T_i}\left(R_i-\frac{d\tau_{ixx}}{dx}-m_i\Gamma_i\frac{du_i}{dx}\right)\equiv\frac{R_i^*}{T_i}, \tag{2}$$

where $m_{e,i}$ is the electron (ion) mass, $n_{e,i}$ is the electron (ion) density, $T_{e,i}$ is the electron (ion) temperature, φ is the electric potential, $R_{e,i}$ is the electron (ion) frictional force produced by interactions with the other plasma particles, $\tau_{e,ixx}$ is the viscous stress component, $\Gamma_{e,i} \equiv n_{e,i}u_{c,i}$ is the electron (ion) flux expressed in terms of the density and the average drift velocity $u_{e,i}$. The quantities are expressed in terms of moments of the distribution function and the collision integrals.[2]

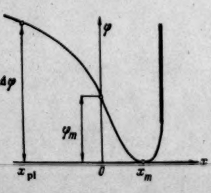

Fig. 1. Potential distribution in the electrode sheath.

In Eqs. (1) and (2), generalized frictional forces $R_{e,i}^*$ are introduced which include viscous and inertial terms. The formal solutions of the equations are:

$$n_e=\frac{T_{e0}}{T_e}\exp\left(\int_0^x\frac{e}{T_e}\frac{d\varphi}{dx'}\,dx'\right)\left[n_{e0}+\int_0^x\frac{R_e^*}{T_{e0}}\exp\left(-\int_0^{x'}\frac{e}{T_e}\frac{d\varphi}{dx''}dx''\right)dx'\right],$$

$$n_i=\frac{T_{i0}}{T_i}\exp\left(-\int_0^x\frac{e}{T_i}\frac{d\varphi}{dx'}\,dx'\right)\left[n_{i0}+\int_0^x\frac{R_i^*}{T_{i0}}\exp\left(\int_0^{x'}\frac{e}{T_i}\frac{d\varphi}{dx''}\,dx''\right)dx'\right].$$

These relations show that the inclusion of the comparatively weak temperature variation across the electrode sheath should not lead to qualitative (or significant quantitative) changes in the solutions. For simplicity therefore, we assume below that the electron and ion temperatures in the sheath are constant.

It is convenient to choose the origin at the point of inflection of the potential curve (Fig. 1), where $n_e = n_i = n_0$; the potential calculated from the minimum is φ_m. Introducing the notation

$$\eta=\frac{e(\varphi_m-\varphi)}{T_i};\ \xi=\frac{x}{r_i};\ r_i=\sqrt{\frac{T_i}{4\pi e^2n_0}},$$

we write the Poisson equation

$$\frac{d^2\varphi}{dx^2}=4\pi e\,(n_e-n_i)$$

in dimensionless form:

$$\frac{d^2\eta}{d\xi^2}+\left\{\frac{1}{\eta}\left[e^{-\frac{\eta}{\theta}}\left(1+\int_0^\xi a_e^*e^{\frac{\eta}{\theta}}d\xi'\right)-e^{\eta}\left(1+\int_0^\xi a_i^*e^{-\eta}d\xi'\right)\right]\right\}\eta=0, \tag{3}$$

where $a_{e,i}^* = R_{e,i}^*r_i/T_{e,i}n_0$; $\theta = T_e/T_i$.

Using the continuity equation in the form

$$\frac{d\Gamma_{e,i}}{dx}=\frac{d\,(n_{e,i}u_{e,i})}{dx}=0,$$

i.e., assuming that volume production and recombination can be neglected in the sheath, we obtain the following relations for the dimensionless generalized frictional forces:

$$a_e^*\left(1-\frac{m_e\Gamma_e^2}{T_en_e^2}\right)=\frac{\left(R_e-\frac{d\tau_{exx}}{dx}\right)r_i}{T_en_0}-\frac{m_e\Gamma_e^2}{T_en_e^2}\frac{n_e}{n_0}\frac{1}{\theta}\frac{d\eta}{d\xi}, \tag{4}$$

$$a_i^*\left(1-\frac{m_i\Gamma_i^2}{T_i n_i^2}\right)=\frac{\left(R_i-\frac{d\tau_{ixx}}{dx}\right)r_i}{T_i n_0}+\frac{m_i\Gamma_i^2}{T_i n_i^2}\frac{n_i}{n_0}\frac{d\eta}{d\xi}. \qquad (5)$$

The electron and ion fluxes at the boundary of the quasineutral plasma, expressed in terms of random fluxes, are

$$\Gamma_e=\frac{b_e}{4}n_{\mathrm{pl}}v_{eT};\ \Gamma_i=\frac{b_i}{4}n_{\mathrm{pl}}v_{iT}. \qquad (6)$$

Here, $b_{e,i}$ must be negative if the corresponding flux is directed away from the electrode. Note that in these relations n_{pl} does not coincide with n_{el}, which is the analytic continuation (extrapolation) of the solution of the neutral diffusion equations to the electrode surface.

Using (6), we obtain

$$\frac{m_i\Gamma_i^2}{T_i n_{\mathrm{pl}}^2}=\frac{b_i^2}{2\pi};\ \frac{m_e\Gamma_e^2}{T_e n_{\mathrm{pl}}^2}=\frac{b_e^2}{2\pi}\approx\frac{1}{2\pi}\left[\frac{\Gamma_e}{\Gamma_{\mathrm{et}}-\Gamma_e}\exp\left(-\frac{e\Delta\varphi}{T_e}\right)\right]^2,$$

where Γ_{et} is the portion of the electron flux emitted by the cathode that passes through the potential barrier into the plasma.

In order that the ion density drop off from the boundary of the neutral plasma to the regions of strong fields, where the field term in the right side of (5) is decisive, it is necessary that at least the following condition be satisfied:

$$b_i^2>2\pi.$$

It follows from (1) and (2) that at the boundary of the neutral plasma ($n_e = n_i = n_{\mathrm{pl}}$)

$$\left.\frac{d\eta}{d\xi}\right|_{\xi=\xi_{\mathrm{pl}}}=(a_e^*-a_i^*)_{\mathrm{pl}}\frac{n_0}{n_{\mathrm{pl}}}\left(1+\frac{1}{\theta}\right)^{-1}. \qquad (7)$$

We transform (7), taking (4) and (5) into account:

$$\left[\frac{2\pi}{2\pi-b_e^2}\left(R_e-\frac{d\tau_{exx}}{dx}\right)\frac{1}{T_e}-\frac{2\pi}{2\pi-b_i^2}\left(R_i-\frac{d\tau_{ixx}}{dx}\right)\frac{1}{T_i}\right]\frac{r_i}{n_{\mathrm{pl}}}\left.\frac{d\xi}{d\eta}\right|_{\xi=\xi_{\mathrm{pl}}}$$
$$=1+\frac{1}{\theta}+\frac{b_e^2}{2\pi-b_e^2}+\frac{b_i^2}{2\pi-b_i^2}. \qquad (8)$$

Since Coulomb scattering can be neglected at the boundary, with the introduction of effective frequencies for electron and ion collisions with atoms $\tau_{e,ia}^{-1} = v_{e,iT}/\lambda_{e,i}$

$$R_e\approx-\frac{\Gamma_e m_e}{\tau_{ea}}\ll|R_i|\approx\left|-\frac{\Gamma_i m_i}{\tau_{ia}}\right|,$$

and $b_e^2 \ll 1$, for the derivative of the dimensionless potential at the boundary to be positive $d\eta/d\xi|_{\mathrm{pl}} > 0$ it is necessary that

$$1+\frac{1}{\theta}+\frac{b_i^2}{2\pi-b_i^2}<0.$$

This condition determines the upper limit of b_i, which is thus restricted by the relations

$$(1+\theta)2\pi>b_i^2>2\pi.$$

It is interesting to note that in the limiting case $\theta \ll 1$, $b_i^2 = 2\pi$. This result agrees with the result obtained in ref. 3 for a kinetic treatment of the neutral electrode sheath for $\theta \ll 1$.

Under the above-mentioned conditions with $n_{e,i} \leq n_0 \ll n_{\mathrm{pl}}$

$$\left.\begin{aligned}a_e^*&\approx\frac{r_i}{T_e n_0}\left(R_e-\frac{d\tau_{exx}}{dx}\right)-\frac{m_e\Gamma_e^2}{T_e n_{\mathrm{pl}}^2}\frac{n_{\mathrm{pl}}^2}{n_e^2}\frac{n_e}{n_0}\frac{1}{\theta}\frac{d\eta}{d\xi},\\ a_i^*&\approx-\frac{r_i}{T_i n_0}\left(R_i-\frac{d\tau_{ixx}}{dx}\right)\left(\frac{m_i\Gamma_i^2}{T_i n_{\mathrm{pl}}^2}\frac{n_{\mathrm{pl}}^2}{n_i^2}\right)^{-1}-\frac{n_i}{n_0}\frac{d\eta}{d\xi},\end{aligned}\right\} \qquad (9)$$

since

$$\frac{m_e\Gamma_e^2}{T_e n_{\mathrm{pl}}^2}\frac{n_{\mathrm{pl}}^2}{n_e^2}\ll 1;\ \frac{m_i\Gamma_i^2}{T_i n_{\mathrm{pl}}^2}\frac{n_{\mathrm{pl}}^2}{n_i^2}\gg 1. \qquad (10)$$

We denote the term in curly brackets in (3) by $C^2(\xi)$ which is permissible for the postulated potential distribution. A formal approximate solution of (3) with boundary condition

$$\eta=0 \text{ for } \xi=0$$

can be found by the WKB method[4] and written in the form

$$\eta=\frac{A}{\sqrt{C(\xi)}}\sin\int_0^{\xi}C(\xi')\,d\xi', \qquad (11)$$

where $A = \eta_m C_m^{1/2}\left[\sin\int_0^{\xi_m}C(\xi')d\xi'\right]^{-1}$ (the subscript indicates that the term is taken at the corresponding point).

Note that the solution in the form of (11) is exact if $C^2(\xi) = (D\xi + B)^{-4}$, where D and B are arbitrary constants, i.e., this solution is also applicable for rapidly varying $C^2(\xi)$ in the range in question. To satisfy the second boundary condition

$$\frac{d\eta}{d\xi}=0 \text{ for } \xi=\xi_m$$

it is necessary that

$$-\frac{1}{2C_m^2}\left.\frac{dC}{d\xi}\right|_m\sin\int_0^{\xi_m}C(\xi')\,d\xi'+\cos\int_0^{\xi_m}C(\xi')\,d\xi'=0. \qquad (12)$$

It is easy to see that when (9) is used

$$C_0^2=(a_e^*-a_i^*)_0\left.\frac{d\xi}{d\eta}\right|_0-\left(1+\frac{1}{\theta}\right)$$
$$\approx\left[\frac{r_i}{T_e n_0}\left(R_e-\frac{d\tau_{exx}}{dx}\right)+\frac{r_i}{T_i n_0}\left(R_i-\frac{d\tau_{ixx}}{dx}\right)\left(\frac{m_i\Gamma_i^2}{T_i n_0^2}\right)^{-1}\right]_0\left.\frac{d\xi}{d\eta}\right|_0-\frac{1}{\theta}.$$

If viscous terms are neglected and it is assumed that $R_i < 0$, to obtain a nonmonotonic potential distribution it is necessary that $R_e > 0$, i.e., the total electron flux must move from the electrode into the plasma and must be fairly large.

Substituting the derivative calculated from (11) into the expression for C_0^2, we obtain

$$\frac{\eta_m C_m^{1/2}}{\sin\int_0^{\xi_m}C(\xi')\,d\xi'}\left(C_0^{3/2}+\frac{1}{\theta}C_0^{1/2}\right)\approx a_e+a_i\left(\frac{m_i\Gamma_i^2}{T_i n_0^2}\right)^{-1}, \qquad (13)$$

where

$$a_e = \frac{R_e r_i}{T_e n_0} \approx \frac{2}{\pi} \frac{\exp\left[-\frac{1}{\theta}\left(\eta_m + \frac{\eta_{\text{pl}}}{2}\right)\right]}{\frac{\Gamma_{\text{et}}}{\Gamma} - 1} \frac{11}{\theta^{1/2}} \frac{r_e}{\lambda_e} \ll 1; \quad r_e = \sqrt{\frac{T_e}{4\pi e^2 n_{\text{pl}}}},$$

$$a_i = \frac{R_i r_i}{T_i n_0} \approx -\frac{2}{\pi} \frac{b_i}{\theta^{1/2}} \exp\left(-\frac{3}{2}\frac{\eta_{\text{pl}}}{\theta}\right)\frac{r_e}{\lambda_i}; \quad \frac{n_0}{n_{\text{pl}}} \approx \exp\left(\frac{\eta_{\text{pl}}}{\theta}\right).$$

It will be shown later that $\eta_{\text{pl}} \approx -3$ and the second term on the right side of (13) is considerably smaller than the first.

When the basic variation in the potential is concentrated in a region of the order of the Debye radius (ξ_m is the order of unity), it is necessary that C_0 also be of the order of unity. [For $C^2(\xi)$ = const it follows from (12) that $C\xi_m = \pi/2$.] Then, (13) should be satisfied for $C_m^{1/2} \sim a_e$, i.e., for small space charge at the minimum potential. To restrict the first term in (12) it is necessary that

$$\left.\frac{dC}{d\xi}\right|_m \sim a_e^4.$$

Differentiation of $C^2(\xi)$ leads to

$$2C\frac{dC}{d\xi} = \left\{C^2 - \frac{1}{\eta}\left[C^2 + \left(1 + \frac{1}{\theta}\right)\frac{n_e}{n_0}\right]\right\}\frac{d\eta}{d\xi} + \frac{1}{\eta}(a_e^* - a_i^*), \tag{14}$$

and to within terms $\sim a_e^6$

$$(a_e^* - a_i^*)_m = 0. \tag{15}$$

Relation (15) again indicates that for a potential minimum to exist in the sheath the electron and ion fluxes must move in opposite directions.

If viscous terms are neglected, using (9) we have

$$\frac{|\Gamma_e|}{\Gamma_i}\left(\frac{m_e}{m_i}\right)^{1/2} = \theta^{-1/2}\frac{\sigma_{ia}}{\sigma_{ea}}\frac{\sqrt{2}\pi}{b_i^2}\frac{n_{im}^2}{n_{\text{pl}}^2} \ll 1. \tag{16}$$

The value of n_{im} can be determined when the dimensionless space charge at the minimum is

$$\frac{(n_e - n_i)_m}{n_0} = C_m^2 \eta_m \sim a_e^4.$$

The electron density at the minimum n_{em}, with the distribution function approximated by the sum of two semi-Maxwellian functions and with the usual expression for the electron flux

$$|\Gamma_e| = \Gamma_{\text{et}} - \frac{1}{4} n_{\text{pl}} v_{eT} \exp\left(-\frac{e\Delta\varphi}{T_e}\right) = \Gamma \tag{17}$$

is represented in the form

$$n_{em} = \frac{1}{2} n_{\text{pl}}\left(1 + \theta^{1/2}\frac{\frac{\Gamma_{\text{et}}}{\Gamma}}{\frac{\Gamma_{\text{et}}}{\Gamma} - 1}\right)\exp\left(-\frac{e\Delta\varphi}{T_e}\right).$$

The following equality is valid to within terms $\sim a_e^4$:

$$\frac{n_{im}}{n_0} \approx \frac{n_{em}}{n_0} \sim \exp\left(-\frac{\eta_m}{\theta}\right) \gg a_e^4,$$

and (15) can be rewritten

$$2\left(\frac{\sigma_{ea}}{\sigma_{ia}}\frac{b_i}{\sqrt{2}\pi}\right)^{1/2}\exp\left(\frac{e\Delta\varphi}{2T_e}\right) = \frac{1 + \theta^{1/2}}{\theta^{1/2}}\sqrt{\frac{\Gamma_{\text{et}}}{\Gamma} - 1} + \frac{1}{\sqrt{\frac{\Gamma_{\text{et}}}{\Gamma} - 1}}. \tag{18}$$

The error introduced by the assumptions does not exceed the error of the ratio σ_{ia}/σ_{ea} and is therefore negligible.

The right side of (18) has a lower limit and the minimum value of the electrode jump in the presence of the virtual cathode is

$$\frac{e\Delta\varphi_{\min}}{T_e} = \ln\left(\frac{1 + \theta^{1/2}}{\theta^{1/2}}\frac{\sqrt{2}\pi}{b_i}\frac{\sigma_{ia}}{\sigma_{ea}}\right), \tag{19}$$

which is realized for

$$\left(\frac{\Gamma_{\text{et}}}{\Gamma}\right)_{\Delta\varphi_{\min}} = 1 + \frac{\theta^{1/2}}{1 + \theta^{1/2}}.$$

A unique determination of $\Delta\varphi$ requires the use of the energy balance equation for the electron gas. If the electron distribution function at the boundary of the neutral plasma is approximated by the sum of two semi-Maxwellian functions with temperature T_e, then the energy balance equation[5] takes the simple form

$$\frac{e\Delta\varphi}{2T_e} = \frac{\Gamma_{\text{et}}}{\Gamma}\left(1 - \frac{1}{\theta}\right). \tag{20}$$

A joint solution of (19) and (20) allows us to determine $e\Delta\varphi/T_e$ and $(\Gamma_{\text{et}}/\Gamma)_{\Delta\varphi}$ which in this approximation depend only on θ and $b_i\sigma_{ea}/\sigma_{ia}$.

The dependence of $e\Delta\varphi/T_e$, $e\Delta\varphi_{\min}/T_e$, $(\Gamma_{\text{et}}/\Gamma)_{\Delta\varphi}$ and $(\Gamma_{\text{et}}/\Gamma)_{\Delta\varphi_{\min}}$ on θ is shown in Figs. 2 and 3. Comparison of the theoretical values of $\Delta\varphi$ with the appropriate experimental results[6] indicates good agreement between theory and experiment.

We consider the magnitude of the basic parameters at the boundary of the neutral plasma. It follows from (7) and (14) that at the boundary

$$\frac{\eta_{\text{pl}} - 1}{\eta_{\text{pl}}}\left.\frac{d\eta}{d\xi}\right|_{\text{pl}} = \frac{2}{C_{\text{pl}}}\left.\frac{dC}{d\xi}\right|_{\text{pl}}.$$

The differential expression (11) gives

$$\frac{1}{A}\frac{d\eta}{d\xi} = -\frac{1}{2C^{3/2}}\frac{dC}{d\xi}\sin\int_0^\xi C(\xi')\,d\xi' + C^{1/2}\cos\int_0^\xi C(\xi')\,d\xi'.$$

Excluding $dC/d\xi$ we obtain

$$\eta_{ux} = -3 + 4\eta_m C_m^{1/2} C_{\text{pl}}^{1/2}\,\mathrm{ctg}\left[\int_0^{\xi_{\text{pl}}} C(\xi')\,d\xi'\right]\left.\frac{d\xi}{d\eta}\right|_{\text{pl}}. \tag{21}$$

However, it follows from (8) that

$$\left.\frac{d\xi}{d\eta}\right|_{\text{pl}} = \frac{\theta^{1/2}}{4b_i}\left[\left(1 + \frac{1}{\theta}\right)(2\pi - b_i^2) + b_i^2\right]\exp\left(\frac{\eta_{\text{pl}}}{2\theta}\right)\frac{\lambda_i}{r_e}.$$

Since

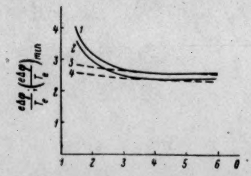

Fig. 2. $e\Delta\varphi/T_e$ (solid lines) and $(e\Delta\varphi/T_e)_{min}$ (dashed) as functions of θ. 1,3) $\alpha \equiv [(\sigma_{ea}/\sigma_{ia})b_i/\sqrt{2\pi}]^{1/2} = 0.325$; 2,4) 0.364.

$$A = \eta_m \frac{C_m^{1/2}}{\sin\int_0^{\xi_m} C(\xi')\,d\xi'} = \eta_{pl} \frac{C_{pl}^{1/2}}{\sin\int_0^{\xi_{pl}} C(\xi')\,d\xi'},$$

relation (13) gives $C_{pl}^{1/2} \sim a_e$, i.e., a small value for the space charge, as expected. Thus, the second term on the right side of (21) is of order a_e^2 and can be neglected. An interesting result is that the potential drop from the point of inflection to the boundary of the neutral plasma is almost constant and equal to $3T_i/e$.

If the results of ref. 3 are used, the relationship between n_{pl} and n_{el} at a nonemitting electrode is given by the following expression which is obtained by assuming $\theta \ll 1$:

$$n_{el} = \frac{\sqrt{2}}{1+\theta}\left(1.016 + \frac{\theta}{\sqrt{2}}\right) n_{pl}; \quad b_i = \sqrt{2\pi} \approx 2.5.$$

To obtain correct results for $\theta \approx 1$ we have recommended[11] that T_i be replaced by T_e, which corresponds to $\theta = 1$ in the expression obtained above. Then $n_{el} \approx 1.22 n_{pl}$ and $b_{i\,el} \approx 2$, i.e., we obtain the usual relation for the particle flux to the nonemitting wall, which is twice the random flux.

We now give certain results. An electrode sheath with a nonmonotonic potential distribution can occur only at an emitting electrode operating in the cathode mode with small ion emission. An electrode sheath with a nonmonotonic potential distribution cannot be produced in the working quadrant even with a hot anode with a uniform work function over its surface, although such a distribution can appear if the reverse currents are eliminated. The latter feature is confirmed by the experimental voltage–current characteristic curves given in Fig. 45 of ref. 7, which have an intermediate plateau in the reverse-current branch; this is due to the nonmonotonic potential distribution at the hot anode working in the cathode mode.[8] An important role can be played by the "spottiness" of the electrode in which a monotonic potential jump is "attached" to the spots with an increased work function, and the virtual electrodes are aligned over the spots with a reduced work function. Since the space charge is close to zero at the potential minimum, the solution is well matched to the neutral plasma at the minimum. This corresponds to the striations in a cesium discharge that are observed experimentally in ref. 9. A mode with a sharp variation in the potential within the limits of the Debye radius can be interpreted as a shock wave produced by the interaction between oppositely traveling electron and ion fluxes in a scattering medium.

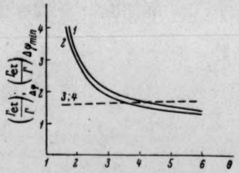

Fig. 3. $(\Gamma_{et}/\Gamma)_{\Delta\varphi}$ ($1 - \alpha = 0.325$, $2 - 0.364$) and $(\Gamma_{et}/\Gamma)_{\Delta\varphi\min}$ (3, 4) as functions of θ.

The simplest energy balance equation for the electron gas (20) is an approximation. Near the cathode of an arc discharge or at the head of a striation, thermal conductivity processes[10] that should reduce the value of Γ_{et}/Γ to obtain the given θ can be important. Thus, calculation of the detailed potential distribution and the density and temperature distributions requires that the appropriate closed system of diffusion equations be solved using the expression obtained for the potential drop in the Debye sheath as the boundary condition. However, if we only calculate the total potential drop across the gap or across a striation up to the head of the next striation, then correct results can be obtained by writing the voltage and energy balance equations for the interval as a whole under the assumption of constant T_e over the entire interval (see refs. 5 and 11). In analyzing the striations in the positive column of a long discharge tube, the two-dimensional problem should be solved with the escape of ions and hot electrons to the wall of the discharge tube taken into account. Moving striations can be obtained if the solution is found in a coordinate system coupled to the striation. Also, in the equations of conservation of momentum it is necessary to change the expression for $R_{e,i}$ in the appropriate manner since the neutral gas cannot be considered at rest in this coordinate system.

Nonlinear effects for the "kink" instability in an electron-ion ring

G. P. Berman

Novosibirsk University

(Submitted July 11, 1973; resubmitted December 18, 1973)
Zh. Tekh. Fiz., 44, 2116-2125 (October 1974)

The influence of a nonlinear polarization force on damping of the "kink" instability in an electron–ion ring is investigated. An explicit expression is found for the polarization force produced by relative displacement of the beam centers of gravity. Conditions are found for which there is no nonlinear stabilization at low amplitudes. Nonlinear saturation amplitudes are estimated for different instability regions.

In an electron–ion ring an instability can be produced by relative transverse displacement of the center of gravity of the electrons with respect to the ions without changing the shape of the transverse cross section of the beams ("kink" instability).[1,2] This problem is considered in detail in ref. 2 in the linear approximation. In particular, it is shown that an instability always exists for a continuous wave-number spectrum. For a discrete spectrum $k_n = n/R$ (R is the radius of the ring, and $n = \pm 1, \pm 2, \ldots$), it follows from the results of ref. 2 that an instability is possible only for certain wave numbers k_n (in Fig. 1, the boundaries of the instability region are denoted by k_- for the lower boundary and by k_+ for the upper boundary).

However, the exponential increase in the amplitude $a(t)$ predicted by linear theory is valid only for the initial stage of the instability, when the oscillation amplitudes are small. Therefore, a nonlinear treatment is necessary to estimate the maximum amplitude.

The transverse instability is considered in ref. 3 in the approximation of a small nonlinear polarization force for a single unstable mode with $n \geq 1$. The beam parameters are chosen near the upper boundary of the instability region. In ref. 3 a solution is obtained in the form of a nonlinear stationary wave in the absence of external focusing [$\lambda = 0$, see (1.5)]. The oscillation saturation amplitude is found in the presence of an external focusing field and is small compared to the characteristic beam dimensions.

However, the approximation for a small nonlinearity is valid only near the boundary of the instability region, where the maximum oscillation amplitudes, which are proportional to γ (the growth rate), are small. Furthermore, as will be shown later, there are conditions for which nonlinear stabilization is impossible, even for small γ. This situation occurs for wave numbers near the lower boundary of the instability region ($k \geqslant k_-$), where the weakly nonlinear polarization force leads to an increase in the growth rate of the displacement between the electrons and ions. This result comes from the approximate treatment of the problem: Physically, it is clear that the interaction between beams is attenuated as $y - x$ increases (x and y are the electron and ion displacements, respectively). As a result the instability should be damped, although possibly not for small amplitudes of the electron and ion displacements. Therefore, further investigation of the instability requires that the explicit form of the interaction force produced by transverse displacements of the beam be known. Furthermore, it is necessary to investigate the instability without the assumption of a small nonlinearity. The explicit form of the interaction force is also necessary for estimates of the maximum oscillation amplitudes near the boundary of the instability region.

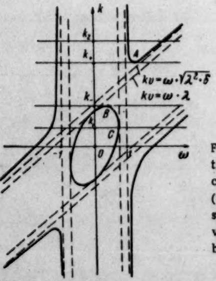

Fig. 1. Form of the dispersion relation $k = k(\omega)$ given by Eq. (1.8). The coordinates of point C are: $\bar{\omega} = \bar{k}v = (1 + \delta/\Lambda^2)^{-1/2}$. The boundaries of the stability region are: $A(k_+)$, $B(k_-)$. The vectors k_1 and k_2 are in the linear stability region.

In the present paper, the transverse instability of an electron–ion ring is considered in a rigid-beam model with a Gaussian distribution of the particle density over the cross section. An explicit expression is found for the interaction force between the beams $F(y - x)$. An expression is obtained for the complex amplitude $\Phi(\xi, \tau)$ for a single mode (ξ and τ characterize the slow variation of the amplitude with z and t, respectively); the time development is also investigated (see Sec. 2). Physically, the situation is the following: The electron beam makes many turns during the change in oscillation amplitude; therefore, the spatial evolution of the oscillation amplitude is not considered in the present paper. The effect of nonlinearity on damping of instabilities corresponding to different areas of the instability region is investigated. Near the lower boundary of the instability region ($k \geqslant k_-$) conditions are found for the absence of stabilization due to nonlinearity at small amplitudes. Near the upper boundary of the instability region ($k \leq k_+$) estimates are obtained for the maximum amplitudes and the saturation amplitudes of oscillation due to nonlinearity.

1. FUNDAMENTAL EQUATIONS

We consider two interpenetrating beams: an electron beam and an ion beam; the particle density over the transverse cross sections is a Gaussian:

$$n_{e,i}(r_\perp) = n_{e,i}^{(0)} \exp\left(-\frac{r_\perp^2}{a^2}\right), \tag{1.1}$$

where a characterizes the beam radius. The beams can be displaced with respect to each other in the vertical direction (the X axis). The polarization force resulting from the relative displacement, calculated for one particle, is

$$F_{e,i}(\Delta_1, \Delta_2) = -\frac{\frac{\partial U(\Delta_1, \Delta_2)}{\partial \Delta_1 (\partial \Delta_2)}}{N_{e,i}}, \tag{1.2}$$

where Δ_1 and Δ_2 are the electron and ion displacements, respectively; $U(\Delta_1, \Delta_2)$ is the beam interaction energy

$$U(\Delta_1, \Delta_2) = \int \frac{dv_1 dv_2 n_e(x_1 - \Delta_1, y_1, z_1)\, n_i(x_2 - \Delta_2, y_2, z_2)}{|\mathbf{r}_1 - \mathbf{r}_2|}, \tag{1.3}$$

$$N_{e,i} = \int n_{e,i} dv_{e,i}.$$

The calculation of $F_{e,i}$ is fairly laborious and will not be given here. We note only that it is convenient to differentiate the expression for $U(\Delta_1, \Delta_2)$ in (1.3) with respect to $\Delta_1(\Delta_2)$ and then to integrate. We give the final result of the calculations

$$\left.\begin{aligned} F_{e,i}(\Delta) &= \pm \frac{2\pi e^2 n_{i,e}^{(0)} a^2}{\Delta}\left(1 - e^{-\Delta^2/2a^2}\right), \\ \Delta &= \Delta_2 - \Delta_1. \end{aligned}\right\} \tag{1.4}$$

In addition to the polarization force (1.4), there are external focusing forces which act on the electrons; these are proportional$^{1-3}$ to Δ_1: $f_{ex} = -\gamma m_e \lambda^2 \Delta_1$ where $\gamma = (1 - v^2/c^2)^{-1/2}$ c is the velocity of light, v is the velocity of the electron beam along the Z axis, m_e is the electron rest mass, and λ is the electron oscillation frequency in the external focusing field. Taking account of the polarization and focusing forces acting on the particle, we write the Lagrangian equation for the displacements Δ_1 and Δ_2

$$\left.\begin{aligned} m_e\gamma\ddot{\Delta}_1 + m_e\gamma\lambda^2\Delta_1 &= F_e(\Delta_2 - \Delta_1), \\ m_i\ddot{\Delta}_2 &= F_i(\Delta_2 - \Delta_1), \end{aligned}\right\} \tag{1.5}$$

where m_i is the ion rest mass. The dots in (1.5) denote the total derivative with respect to time: $d/dt = \partial/\partial t + v\partial/\partial z$. As noted above, the system (1.5) is used in refs. 1 and 2 to investigate stability in an approximation linear in $\Delta_{1,2}$ for perturbations of the form $\Delta_{1,2} \sim \exp i(kz - \omega t)$. Here, we consider the nonlinear stage of such perturbations.

We only consider a weak nonlinearity: $\Delta_{1,2}/a \ll 1$. Substituting (1.4) into (1.5) and expanding $F_{e,i}(\Delta)$ in a series in the parameter Δ/a (we only keep the first two terms of the expansion), we obtain a system of equations for the dimensionless displacements $x = \Delta_1/a$, $y = \Delta_2/a$:

$$\left.\begin{aligned} \ddot{x} + \lambda^2 x &= \delta\omega_0^2 (y - x)\left[1 - \frac{1}{4}(y - x)^2\right], \\ \ddot{y} &= -\omega_0^2 (y - x)\left[1 - \frac{1}{4}(y - x)^2\right], \end{aligned}\right\} \tag{1.6}$$

where $\omega_0 = (\pi e^2 n_e^{(0)}/m_i)^{1/2}$ is the ion oscillation frequency in the electron field (below we take $\omega_0 = 1$); $\delta = n_i^{(0)} m_i \cdot (\gamma n_e^{(0)} m_e)^{-1}$.

The solution of (1.6) is sought by using the method of stretched coodinates developed in refs. 4-6. We introduce the slowly varying variables

$$\tau = \varepsilon t; \quad \xi = \varepsilon^2 z; \quad \varepsilon \ll 1$$

and seek the solution of (1.6) in the form of a series in powers of the parameter ε

$$\begin{pmatrix} x \\ y \end{pmatrix} = \sum_{j=1}^{\infty} \varepsilon^j \sum_{l=1}^{\infty} \begin{pmatrix} x_l^{(j)} & (\xi, \tau) \\ y_l^{(j)} & (\xi, \tau) \end{pmatrix} e^{il(kz - \omega t)} + \text{c.c.}, \tag{1.7}$$

Here, k and ω are the wave vector and the frequency.

To first order in E we obtain the dispersion relation of the linear theory^2

$$F(\omega) = \frac{1}{\omega^2} + \frac{\delta}{(\omega - kv)^2 - \lambda^2} = 1. \tag{1.8}$$

We also obtain the relation: $\alpha x_1^{(1)} = y_1^{(1)} \equiv \Phi(\xi, \tau)$, $\alpha \equiv 1 - \omega^2$. Below we will obtain an equation for $\Phi(\xi, \tau)$ near the boundary of the instability region, i.e., for the additional condition $\partial F(\omega)/\partial\omega = 0$. From the latter condition and (1.8), we obtain a condition that is valid at the boundary of the instability region

$$1 - \frac{kv}{\omega} = -\frac{\delta}{\alpha^2}\bigg|_{A;\,B}. \tag{1.9}$$

The relation $k = k(\omega)$ given by (1.8) is plotted in Fig. 1. The points A and B denote the boundaries of the instability region: A the upper boundary (k_+), corresponds to the electron-ion resonance; B, the lower boundary (k_-) corresponds to resonance at electron Doppler oscillation frequencies in the magnetic field. These frequencies appear because electrons oscillate with frequency λ in the external focusing field. Terms refering to points A(B) will henceforth be denoted by the subscripts "+" and "-", respectively.

To order E^2, with (1.9) taken into account, we have

$$x_1^{(2)} - \alpha y_1^{(2)} = -2i\omega\frac{\partial\Phi}{\partial\tau}. \tag{1.10}$$

We introduce the parameter μ

$$\mu = \frac{v_0 - v}{v_0}; \quad |\mu| \ll 1, \tag{1.11}$$

where v_0 is the velocity at the boundary (at point A or B). By changing the sign of μ we shift from the boundary A (or B) either to the region of linear stability or to the region of linear instability. Near the boundary of the instability region we can assume $\mu \sim \varepsilon^2$ (see Ref. 6). The relationship between μ and the shift in the wave number k: $\delta k = k - k_\pm$ will be seen from the equation for Φ. Assuming $\mu \sim E^2$ we obtain the equation for Φ to order E^3:

$$i\frac{\partial\Phi}{\partial\xi} = q\frac{\partial^2\Phi}{\partial\tau^2} - (b|\Phi|^2 + c)\Phi, \tag{1.12}$$

$$q = -\frac{\left(\frac{4\omega^2\delta}{\alpha} + \frac{\alpha^2 k v_0}{\omega}\right)}{2v_0\omega\delta},$$

$$b = -\frac{3}{4v_0\omega}(1 - \alpha)^4; \quad c = \frac{\mu}{|\mu|}k. \tag{1.13}$$

An equation similar to (1.13) is obtained in ref. 3 for the two-stream instability in a plasma.

We note that displacement from boundary A or B can occur not through a shift of the beam [see (1.11)] from the equilibrium value v_0 at the boundary ($k_\pm$ is taken at the boundary), but through a direct shift of the wave number $k = k_\pm + \delta k$ (the beam velocity is assumed to be v_0 at the boundary). Actually, it can be seen from (1.13) that the linear term in parentheses can be obtained without representing the electron beam velocity by (1.11), but by using the formal substitution

$$\Phi = \bar{\Phi}\exp\left(-i\frac{\mu}{|\mu|}k\xi\right) = \bar{\Phi}\exp\left(-i\frac{\mu}{|\mu|}k\varepsilon^2 z\right). \tag{1.14}$$

Thus, the displacement from the boundary of the stability region with respect to k is given by $\delta k \approx (\mu/|\mu|)\, E^2 k_\pm$. Depending on the sign of μ, in the linear approximation we have

$$\operatorname{sign} \mu = \begin{cases} +, \text{ instability near point A, stability near point B} \\ -, \text{ stability near point A, instability near point B.} \end{cases}$$

2. TIME EVOLUTION

We consider the effect of the nonlinearity on the time evolution near the instability boundary. The solution of (1.12) is sought in the form

$$\Phi(\xi, \tau) = A(\tau) \exp(-i\psi(\tau)). \tag{2.1}$$

Solution (2.1) is obviously a particular solution of (1.12). This solution only reflects the time evolution of the complex oscillation amplitude. As noted in the introduction, physically this means that the electron beam executes many turns during the change in oscillation amplitude. A similar solution is considered, for example, in ref. 5 for the beam–plasma instability. In the present paper, we only consider solutions like (2.1) type for Eq. (1.12).

We substitute (2.1) into (1.2), separate the real and imaginary parts, and use conservation of "momentum"

$$A^2 \frac{d\psi}{d\tau} = M = \text{const}, \tag{2.2}$$

to integrate the equation for $A(\tau)$. We obtain

$$\frac{1}{2}\left(\frac{dA}{d\tau}\right)^2 + V(A) = H = \text{const}, \tag{2.3}$$

where H is a constant of integration and

$$V(A) = -\frac{M^2}{A^2} - \frac{b}{4q} A^4 - \frac{c}{2q} A^2. \tag{2.4}$$

Thus, the time evolution can be interpreted as the motion of a "particle" of unit mass in the potential V(A), which is axially symmetric with respect to the phase ψ. Oscillations with M = 0 are of interest since the potential (2.4) gives a deep "well" at the origin for $M \neq 0$.

We consider two cases: a narrow instability region with respect to k, i.e., $\sqrt{\delta/\lambda} \ll 1$, $\lambda \gg 1$ or $\lambda \sim 1$ (see the Appendix, case $I_\pm$), and a broad instability region with respect to k, $\lambda^2/\delta^{2/3} \ll 1$ (see the Appendix, case $II_\pm$).

The terms q and b in the coefficients of (1.13) are calculated for cases I and II in the Appendix.

The solutions of (2.3) for cases I_+ and II_+ have the form:

for $V_0 \leq H \leq 0$ (trajectory 1 in Fig. 2a)

$$\left.\begin{aligned} &A(\tau) = \sqrt{1+\theta_1}\, A_0 \operatorname{dn}\left[\sqrt{\frac{1}{2}\left|\frac{c}{q}\right|}(2+\theta_1)\tau,\ \frac{2\theta_1}{1+\theta_1}\right], \\ &\theta_1 = \sqrt{1 - \left|\frac{H}{V_0}\right|};\ V_0 = -\frac{c^2}{4|qb|};\ A_0 = \sqrt{\left|\frac{c}{b}\right|}. \end{aligned}\right\} \tag{2.5}$$

for $H \geq 0$ (trajectory 2 in Fig. 2a)

$$A(\tau) = A_1 \operatorname{cn}\left[\sqrt{\frac{1}{2}\left|\frac{b}{q}\right|(A_1^2 + A_2^2)}\,\tau,\ \theta_2\right],$$

$$A_{1,2} = A_0\left[\left(1 + \frac{H}{|V_0|}\right)^{1/2} \pm 1\right]^{1/2};\quad \theta_2 = \frac{A_1}{\sqrt{A_1^2 + A_2^2}}.$$

Thus, we have stabilized the linearly unstable oscillations near the upper boundary of the instability region produced by the nonlinearity of the polarization force. The maximum value of the amplitude A is $A_{\max} = \sqrt{2|c/b|}$. In the linear theory the growth rate γ is related to E by [see (1.2)] $\gamma = E\sqrt{|c/q|}$; thus $A_{\max} = (\gamma/E)\sqrt{2|q/b|}$. Calculations give

$$A_{\max}(I_+) \approx 2\sqrt{\frac{2}{3}}\,\frac{\gamma}{E\sqrt{\varepsilon}};\quad \varepsilon = \sqrt{\frac{\delta}{\lambda}} \ll 1, \tag{2.6}$$

$$A_{\max}(II_+) \approx \frac{\gamma}{E}\,\frac{1}{\delta^{1/3}};\quad \delta \gg 1. \tag{2.7}$$

Since $(y-x)_{\max} \approx E(1-\alpha)\Phi + \text{c.c.} \approx 2E(1-\alpha)A_{\max}$ we find the expressions for $(y-x)_{\max}$

$$I_+)\quad (y-x)_{\max} \approx 4\sqrt{\frac{2}{3}}\,\frac{\gamma}{\sqrt{\varepsilon}}, \tag{2.6'}$$

$$II_+)\quad (y-x)_{\max} \approx \frac{2\gamma}{\delta^{1/3}}. \tag{2.7'}$$

In case I_+, $\gamma_{\max} = (1/2)\varepsilon$ (see ref. 2); therefore, near point A the condition $(y-x)_{\max} \ll 1$ is satisfied. Thus, near point $A(k_+)$ the nonlinearity damps the instability at small amplitudes proportional to γ. Note that substitution of the parameters for the upper boundary of the instability region in case I_+ gives saturation amplitude as found by another method in Ref. 3, which coincides with (2.6) to within a numerical factor of order unity.

We now consider the effect of nonlinearity on damping of instability near the lower boundary of the instability region (point B). In this wave-number region the nonlinearity does not damp the instability; indeed, the nonlinearity acts to destabilize. For $\mu < 0$ $(k \gtrsim k_-)$ under these conditions we have $b/q > 0$, i.e., the nonlinear term in potential (2.4) has a negative sign (Fig. 2b). It follows that damping due to the nonlinearity does not occur at small amplitudes near the lower boundary of the instability region; hence the approximation of a small nonlinearity $x, y \ll 1$, used above, is not applicable here.

We now consider the behavior inside the instability region for $k_- \lessapprox k \lessapprox k_+$. We represent ω in (1.7) in the form $\omega = \mathrm{Re}\,\omega + i\gamma$ and make use of the following situation: Far from the boundary A there is a wave-number region for which damping begins at $(y-x)_{\max} \sim \sqrt{\gamma}$. On

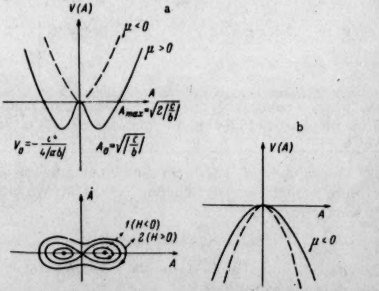

Fig. 2. a) Shape of the potential and phase trajectories for cases I_+ and II_+ (nonlinear stabilization near point A); b) shape of the potential for cases I_- and II_- (nonlinear enhancement near point B shown by dashed curve).

the other hand, near A: $(y-x)_{\max} \sim \gamma$. We take this into account by introducing the slow time evolution (as before, we assume $\gamma \ll 1$) according to the equation $\tau = E^2 t$. We obtain the dispersion relation (1.8) to within ε. To order E^2 we have

$$\left.\begin{aligned} -2i(\omega-kv)\frac{\partial x_1^{(1)}}{\partial\tau}+\frac{\delta}{\alpha}x_1^{(2)}-\delta y_1^{(2)}=-\frac{3}{2}|y_1^{(1)}|^2 y_1^{(1)} \\ \times(1-\alpha)|1-\alpha|^2 e^{2\gamma t}, \\ -2i\omega\frac{\partial y_1^{(1)}}{\partial\tau}+\alpha y_1^{(2)}-x_1^{(2)}=\frac{3}{2}|y_1^{(1)}|^2 y_1^{(1)}(1-\alpha)|1-\alpha|^2 e^{2\gamma t}, \end{aligned}\right\} \quad (2.8)$$

where $\alpha = 1-\omega^2(\operatorname{Im}\alpha \neq 0)$. We multiply the first equation in (2.8) by α/δ and combine it with the second, obtaining

$$\frac{d\Phi}{d\tau}=\frac{3i\delta|1-\alpha|^2(1-\alpha)^2 e^{\frac{2\gamma\tau}{E^2}}|\Phi|^2\Phi}{4[\alpha^2(\omega-kv)+\delta\omega]}. \quad (2.9)$$

The solution of (2.9) is sought in the form of (2.1). Separating the real and imaginary parts, we obtain the equation for $A(\tau)$:

$$\frac{dA}{d\tau}=-\frac{3\delta|1-\alpha|^2\Lambda_{im}}{4}A^3\exp\left(\frac{2\gamma\tau}{E^2}\right), \quad (2.10)$$

where

$$\Lambda=\frac{(1-\alpha)^2}{[\alpha^2(\omega-kv)+\delta\omega]};\quad \Lambda_{im}=\operatorname{Im}\Lambda.$$

Integrating (2.10) with the initial condition $A(0) = A_0$, we obtain

$$A(\tau)=A_0\left[1+E^2\frac{3\delta|1-\alpha|^2\Lambda_{im}}{2\gamma}\left(e^{\frac{2\gamma\tau}{E^2}}-1\right)\right]^{-1/2}. \quad (2.11)$$

Thus, (2.11) gives the expression for the saturation amplitude

$$A_{\text{sat}}=\frac{1}{E}\sqrt{\frac{2\gamma}{3\delta|1-\alpha|^2\Lambda_{im}}}. \quad (2.12)$$

An estimate of Λ_{im} near point A for cases I_+ and II_+ gives

$$\Lambda_{im}(I_+)=\frac{\varepsilon}{\gamma\delta};\quad \Lambda_{im}(II_+)\approx\frac{1}{\gamma\delta^{1/2}}.$$

The saturation amplitudes are

$$A_{\text{sat}}(I_+)=\frac{1}{E}\sqrt{\frac{2}{3}}\frac{\gamma}{\sqrt{\varepsilon}};\quad \varepsilon=\sqrt{\frac{\delta}{\lambda}}\ll 1, \quad (2.13)$$

$$A_{\text{sat}}(II_+)\approx\frac{1}{E}\frac{\gamma}{\delta^{1/4}};\quad \delta\gg 1. \quad (2.13')$$

Expressions (2.13) and (2.13') are the same order of magnitude as (2.6) and (2.7), respectively.

In the middle section of the instability region, for case I_+ [setting $\gamma = \gamma_{\max} = (1/2)E$]: $\Lambda_{im} \approx \gamma/\delta$ so that we find from (2.12): $A_{\text{sat}} \approx 1/E$. Similarly for $(y-x)_{\text{sat}}$ we obtain a value of the order of unity. This means that in the middle section of the instability region (case I_+, $\gamma = \gamma_{\max}$) stability does not occur at small amplitudes and the approximation of a small nonlinearity is not applicable.

Thus, the entire instability region can be divided into three parts (beginning with the upper boundary): 1) $\gamma < (y-x)_{\max} < \sqrt{\gamma}$, 2) $\sqrt{\gamma} < (y-x)_{\max} < 1$, and 3) $(y-x)_{\max} \gtrsim 1$. The wave vector corresponding to $EA_{\max} = \sqrt{\gamma}$ is found from the solution for the expression (the point $p = p_0$, see the Appendix)

$$\Lambda_{im}(p_0)=\left[\frac{3}{2}|1-\alpha(p_0)|^2\right]^{-1}. \quad (2.14)$$

For wave numbers corresponding to $p_0 < p < 1$, stabilization by the nonlinearity occurs at small amplitudes. For $-1 < p < p_0$, we obtain the amplitudes $(y-x)_{\max} \gtrsim 1$. An exact solution has not been obtained for p_0. Analysis of (2.14) indicates that p_0 is close to zero for case I. Consequently, starting from the lower boundary of the instability region (point B in Fig. 1) up to the middle section, ($\gamma = \gamma_{\max}$, $p = 0$), the instability is damped at amplitudes of the order of the beam radius. And only in fairly close proximity to the upper boundary (point A in Fig. 1) is the transverse instability damped at amplitudes $(y-x)_{\max} \ll 1$. The fact that damping by the nonlinearity does not occur at small amplitudes near the lower boundary of the instability region follows formally from the consideration that the value of Λ_{im} in (2.11) near point B is negative (for example, when I_+ $\Lambda_{im} = -\varepsilon/\gamma\delta$).

To investigate the region $p < p_0$, it is necessary to solve the problem with a polarization force (1.4) without assuming a small nonlinearity. We consider the case of a relative displacement $\Delta \gg a$ (this occurs, naturally, during a limited time interval). Then the exponent in (1.4) can be neglected, and we obtain $F(\Delta) \sim 1/\Delta$. But then the system of equations for the displacements give a stable solution. Actually,

$$\left.\begin{aligned} \ddot{x}+\lambda^2 x=\frac{2\delta}{(y-x)}, \\ \ddot{y}=-\frac{2}{(y-x)}. \end{aligned}\right\} \quad (2.15)$$

We write an approximate solution of system (2.15)

$$x \sim \exp i(kz-\Omega_k t);\quad y\approx 0,$$
$$\Omega_k = kv \pm \lambda.$$

It is clear that the expression for Ω_k is real. Thus, there exists a region of amplitudes of the order of the beam radius at which the instability ceases to develop.

Note that system (1.5) with a polarization force (1.4) has a solution when $\lambda = 0$ in the form of a nonlinear stationary wave, where all the terms are functions of one variable $\eta = kz - \omega t$. Actually, in this case we obtain for the dimensionless displacement $\bar{\Delta} = \Delta/a$

$$\frac{d^2\bar{\Delta}}{d\eta^2}=-\frac{T}{\bar{\Delta}}(1-e^{-\bar{\Delta}^2/2}), \quad (2.16)$$

where

$$T=\frac{\delta}{(\omega-kv)}+\frac{1}{\omega^2}>0.$$

Integration of (2.16) leads to the equation of motion of the nonlinear oscillator

$$\frac{1}{2}\left(\frac{d\bar{\Delta}}{d\eta}\right)^2+U(\bar{\Delta})=\bar{H}=\text{const}, \quad (2.17)$$

where $\bar{H}$ is a constant of integration, and

$$U(\bar{\Delta}) = \int_0^{\bar{\Delta}} \frac{(1 - e^{-\Delta^2/2})}{\Delta} d\Delta = U(-\bar{\Delta}). \qquad (2.18)$$

It is easy to show that in the potential (2.18) the motion is finite for any finite values of $\bar{H}$ in (2.17), i.e., the expression for $\bar{\Delta}(\eta)$ has the form of a nonlinear wave with a definite period.

CONCLUSION

We have considered the damping of a transverse instability in an electron–ion ring produced by a nonlinear polarization force. It has been shown that the nonlinear polarization force does not always damp the instability at small amplitudes. In particular, the instability is not damped at small amplitudes near the lower boundary of the instability region. The appearance of instability at the lower boundary is due to resonance at Doppler electron oscillation frequencies, and at small amplitudes the nonlinear polarization force enhances the instability growth rate. Investigation of the equations for high amplitudes indicates that damping of the instability begins in this case at amplitudes of the order of the beam radius.

We thank V. I. Kurilko and B. V. Chirikov for their interest.

APPENDIX

The parameters are calculated at points A and B

$$F(\omega) = \frac{1}{\omega^2} + \frac{\delta}{(\omega - kv)^2 - \lambda^2} = 1, \qquad (A.1)$$

$$\frac{\partial F}{\partial \omega} = 0. \qquad (A.2)$$

We introduce the notation $Y = \omega^2 - 1$. From (A.1) and (A.2) we obtain the equation for Y

$$\left(1 + \frac{\lambda^2}{\delta}\right) Y^4 + Y^3 - \delta Y - \delta = 0, \qquad (A.3)$$

and

$$\omega = \sqrt{1 + Y}; \quad \omega = kv = -\frac{\delta\sqrt{1+Y}}{Y^2}.$$

Case I $(\varepsilon = \sqrt{\delta/\lambda} \ll 1;\ \lambda \gg 1$ or $\lambda \sim 1)$

$$Y = p\varepsilon + \frac{1}{4}\varepsilon^2,$$

$$\omega = 1 + \frac{p}{2}\varepsilon,$$

$$q_\pm = \frac{2k}{(1+\lambda)\varepsilon},$$

$$kv = 1 + \lambda + \frac{p}{2}\varepsilon - \frac{\lambda}{16}\varepsilon^2,$$

$$b_\pm = -\frac{3k}{2(1+\lambda)},$$

$$\alpha = -p\varepsilon - \frac{1}{4}\varepsilon^2,$$

$$\gamma = \frac{1}{2}\varepsilon\sqrt{1 - p^2} \text{ (see ref. 2)}$$

$$p = \begin{cases} +1, \text{at point } A, \\ -1, \text{at point } B. \end{cases}$$

Case II $(\lambda^2/\delta^{2/3} \ll 1)$

$$Y_+ = \delta^{1/3}; \quad Y_- = -\left(1 + \frac{\lambda^2}{\delta}\right)^{-1},$$

$$\omega_+ = \sqrt{1 + \delta^{1/3}}; \quad \omega_- = \left(1 + \frac{\delta}{\lambda^2}\right)^{-1/2},$$

$$(kv)_+ = (1 + \delta^{1/3})^{3/2}; \quad (kv)_- = \frac{\left[1 + \delta\left(1 + \frac{\lambda^2}{\delta}\right)\right]}{\sqrt{\left(1 + \frac{\delta}{\lambda^2}\right)}},$$

$$\alpha_+ = -\delta^{1/3}; \quad \alpha_- = \left(1 + \frac{\lambda^2}{\delta}\right)^{-1}.$$

The values of $q_\pm$ and $b_\pm$ are not given for Case II because of their awkwardness.

Instabilities in interpenetrating electron and ion beams

I. A. Soloshenko and L. P. Katsubo

Institute of Physics of the Ukrainian SSR, Kiev

(Submitted October 30, 1973; resubmitted April 10, 1974)
Zh. Tekh. Fiz., 44, 2126-2131 (October 1974)

Collective oscillations are investigated in a synthesized plasma consisting of interpenetrating electron and ion beams. Instabilities are excited as in the case in which the electron component is at rest and when its velocity v_e exceeds that of the ion component v_i. The experimentally measured frequencies, growth rates, and phase velocities are found to be in qualitative agreement with theory. An effect is detected in which trapping of electrons by the wave field limits the amplitudes of the oscillations; this mechanism accelerates the electrons when $v_e = 0$ and retards them when $v_e > v_i$.

The literature contains a number of experimental investigations of the interaction between a fast ion beam and a stationary electron background. In refs. 1 and 2 an electron plasma instability is observed in such a system, and in refs. 2-4, the linear and nonlinear stages of the interaction are investigated. In the present paper the collective interaction between ions and electrons is investigated in the case in which both components have drift velocities.

The dispersion relation in a system consisting of cold electron and ion beams is

$$\frac{\omega_e^2}{(\omega-kv_e)^2}+\frac{\omega_i^2}{(\omega-kv_i)^2}=1, \tag{1}$$

where ω_e and ω_i are the plasma frequencies; v_e and v_i are the velocities of the electron and ion beams, respectively. It follows from (1) that the system is unstable when $v_e \neq v_i$. The maximum instability growth rate obtains for $k \approx \omega_{pe}/(v_i - v_e)$ and is given by

$$\gamma \approx \frac{\sqrt{3}}{2^{4/3}}\,\omega_e^{1/3}\omega_i^{2/3}. \tag{2}$$

The frequency corresponding to the maximum growth rate is

$$\omega \approx \frac{\omega_e v_i}{v_i-v_e}-\frac{1}{2^{4/3}}\,\omega_e^{1/3}\omega_i^{2/3}. \tag{3}$$

It follows from (3) that ω depends on the relationship between the electron and ion velocities. When $v_e = 0$, $\omega \approx \omega_e$ and for increasing v_e, ω increases until $v_e = v_i$, at which point the system is stable; for $v_e > v_i$ the frequency decreases as v_e increases, and for very high electron velocities ω is roughly equal to the frequency of the Buneman instability [the second term in Eq. (3)]. Below we only consider the case

$$\frac{|v_e-v_i|}{v_i} \ll 2^{4/3}\left(\frac{\omega_e}{\omega_i}\right)^{2/3}.$$

Also,

$$\omega \approx \frac{\omega_e v_i}{v_i-v_e}, \tag{4}$$

and the phase velocity of the excited waves is close to the ion beam velocity.

As in refs. 3 and 4, the exponential growth in a system consisting of an ion beam and a stationary electron background ceases at amplitudes of the potential sufficient for trapping and entrainment of the electrons by the wave field. In a system with interpenetrating electron and ion beams the amplitudes of the potential oscillations should also be restricted by this effect; thus the maximum amplitude of the wave potential $\tilde{\varphi}$ should be

$$\tilde{\varphi} \sim \frac{m\,(v_{\text{ph}}-v_e)^2}{4e} \approx \frac{m\,(v_i-v_e)^2}{4e}. \tag{5}$$

It should be noted that the electron trapping effect should lead to the equalization of the average electron and ion velocities: For $v_e < v_i$ the electrons should be accelerated and for $v_e > v_i$ they should be retarded.

A schematic diagram of the experimental apparatus is given in Fig. 1. The helium or hydrogen ions are extracted from the duoplasmatron 1, accelerated by the field of the electrode 2, and then focused by a magnetic lens 3 into a beam 4. The maximum beam current is $I_i = 40$, maximum energy $eU_0 = 40$ keV, particle density $n_i \sim 10^7$ cm^{-3}, and the beam radius $r_0 \approx 5$ cm. The electrons enter the system from the thermoionic emitter 8 located at the chamber entrance. (The pressure in the chamber $p = 5 \cdot 10^{-6}$ mm Hg, and the contribution of electrons produced by beam ionization of the gas can be ignored). The thermionic emitter–neutralizer consists of a series of tungsten

150 cm.

needles heated to emission temperature; it is held at a potential close to the wall potential. A double-grid modulator[5] is also located at the beam entrance to the chamber and is connected to an external generator. The amplitudes of the potential oscillations are measured by insulated probes[5] 7; the signals from the probes are amplified and displayed on a spectrum analyzer. The static space potential is measured by thermionic probes located along a radius. The phase velocity of the excited waves is measured by an electronic interferometer system with a delay line.

The electron beam is formed in the sheath in which there is a potential drop between the emitter and synthesized plasma. The potential of the system can be regulated by the potential of the target 6, which is 500 cm from the neutralizer. Figure 2 gives the time-averaged space potential in the center of the beam (curve 1) and the electron current from the neutralizer (curve 2) as functions of the target potential. The beam current $H_2^+ I_i$ = 15 mA, and the energy eU_0 = 30 keV. For modest target potentials the plasma potential increases as U_T increases, and φ_P and U_T are of nearly the same order of magnitude in this region. For larger target potentials, φ_P is independent of U_T. In the latter case a sheath is formed near the target; this is the region in which the potential drop between the plasma and the target occurs. The dependence of the emitter current I_{em} on U_T behaves in similar fashion. For small U_T, according to ref. 6, $I_{em} \sim \sqrt{\bar{\varphi}}$, where $\bar{\varphi}$ is the potential difference between the emitter and the plasma averaged over the radius; with a further increase in U_T the electron current ceases to change because the space potential ceases to change.

The experiments indicate that, depending on the target potential, oscillations can be excited in the system in two spectral regions. For zero target potential, oscillations are excited at frequencies close to the electron plasma frequency (Fig. 3a); this result agrees with theory since the electrons do not have a drift velocity in this case. As the target potential increases, the oscillation amplitude drops sharply, and oscillations are not excited for U_T equal to the floating potential (Fig. 3b); this result is also consistent with theory since the average electron velocity is close to the ion velocity,[7] in this case. With a further increase in the target potential, oscillations are generated in the system at frequencies below the electron frequency (Fig. 3c). Figure 4 gives the dependence of the amplitude of these oscillations on U_T, and Fig. 5 shows the dependence of the frequency on the beam velocity, which is calculated according to $v_e = \sqrt{2e\varphi_0/m}$ where φ_0 is the static space potential in the center of the ion beam [the points are the experimental data, and the curve is calculated from Eq. (4) under the assumption that f_e = 25 MHz]. The experimental frequencies are of the same order as the calculated frequencies. Some of the difference is possibly due to the reduction in electron density at higher target potentials. The absence of oscillations at small target potentials and the increase in the amplitude with increasing U_T are evidently due to the presence of an appreciable potential drop within the ion beam. As the measurements indicate (see ref. 6), for small U_T this drop is of the same order as the potential in the beam center φ_0; therefore, the spread of electron velocities within the ion beam is of the same order as the electron drift velocity. For large U_T the radial potential drop is less than 30% of the potential φ_0 and thus the electron drift velocity exceeds the spread.

Thus, instabilities are only observed experimentally for $v_e \approx 0$ and $v_e > v_i$; the case $v_e < v_i$ has not been real-

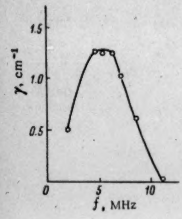

Fig. 8. Growth rate as a function of frequency. Ion current $H_2^+I_i$ = 20 mA, energy eU_0 = 30 keV, target potential U_T = 160 V.

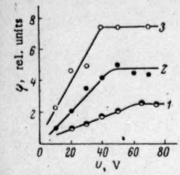

Fig. 9. Amplitude as a function of the generator voltage. 1) Target potential U_T = 0; 2) 40; 3) 80 V. Ion current $H_2^+I_i$ = 20 mA, energy eU_0 = 30 keV, distance to the neutralizer z = 150 cm, modulation frequency f = 4 MHz.

ized because of the large electron velocity spread at small target potentials.

The amplitudes of oscillations excited at large U_T increase exponentially along the beam (Fig. 6). The growth distance, which is determined from the slope of the line shown in Fig. 6, is ~100 cm; this same quantity can be estimated from Eq. (2): $l \sim v_0/\gamma \approx 25$ cm. The difference may be due to the electron velocity spread.

As expected, the instabilities are highly damped in the spectral region investigated when gas is admitted to the chamber, i.e., thermal electrons are produced due to shock ionization of the gas by the beam. Also, plasma oscillations of thermal electrons are driven by the electron current from the emitter.[2]

The instabilities are also damped when the electron current from the emitter decreases; in this case ω_e, and the instability growth rate, decreases. Figure 7 shows the emitter current (curve 1) and the oscillation amplitudes (curve 2) as functions of the filament current of the neutralizer.

To obtain the dependence of the growth rate frequency, to measure the phase velocity, and to investigate the nonlinear stage of the interaction, the ion beam is premodulated. This allows us to measure the magnitude and frequency of the initial perturbation. Figure 8 shows the measured dependence of the growth rate on the modulation frequency. The curve is resonant, and the maximum growth rate is reached at a frequency corresponding to the calculated frequency. [It follows from Eq. (4) that when f_e = 25 MHz, the maximum growth rate should correspond to f = 10 MHz].

Interferometer measurements indicate that when f = 4 MHz and U_T = 160 V the wavelength of the excited oscillations is λ = 42 cm; thus, the phase velocity is $v_{ph} = 1.68 \cdot 10^8$ cm/sec, in agreement with the calculated value for this quantity $v_{ph} \approx v_i = 1.7 \cdot 10^8$ cm/sec.

To detect the nonlinear effect of electron trapping by a wave, the oscillation amplitude is measured as a function of generator voltage. Figure 9 gives these relationships at a distance of ~200 cm from the modulator for different target potentials. In all cases the region with a linear increase in amplitude is replaced by a saturation region, and $\tilde{\varphi}$ is independent of the modulation frequency in the saturation region. It is pointed out in refs. 3 and 4 that when the electron component is at rest (U_T = 0), the maximum amplitude of the potential oscillations is $\tilde{\varphi} \approx (1/4)mv_i^2$. It follows from Eq. (4) that the maximum amplitude for the two other cases (U_T = 40 and 80 V) should increase by a factor of ~2.1 and 4.2, respectively. As can be seen from Fig. 9, the experimental ratios, 1.8 and 3, are close to the calculated ratios. The discrepancy may be due to the method of measuring the amplitude. As the target potential increases the relationship between the probe and the plasma deteriorates since the electron density, and thus the capacitance of the probe–plasma interface, decreases.

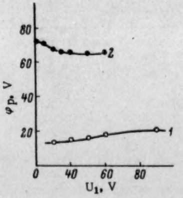

Fig. 10. Space potential in the center of the beam as a function of the generator voltage. 1) U_T = 0; 2) 160 V. Ion current $H_2^+I_i$ = 15 mA, energy eU_0 = 30 keV, f = 4 MHz.

Since the trapping of electrons changes their average velocity and average density in the region of the ion beam, a marked change in the degree of neutralization of the ion beam is to be expected with the excitation of a high-amplitude wave. Figure 10 shows the experimental dependences of the average potential in the center of the beam on the generator voltage for $v_e = 0$ (curve 1) and $v_e > v_i$ (curve 2). At a modulation amplitude sufficient for electron capture at a given point the beam potential begins to change markedly. In the first case the potential increases due to the increase in both the longitudinal and transverse electron velocity;[7] in the second case, electron capture leads to an enhanced neutralization since the average electron velocity decreases.

The present paper represents the first investigation of collective oscillations in a two-component system consisting of interpenetrating ion and electron beams. The fundamental nature of the instability has been established. An effect has been detected in which trapping of electrons restricts the amplitudes of the potential oscillations, and accelerates the electrons for $v_e = 0$ and retards them for $v_e > v_i$. The experimental results agree with theory.

In conclusion we thank M. D. Gabovich for discussion.

(Submitted July 10, 1973)
Zh. Tekh. Fiz., 44, 2132-2145 (October 1974)

The initial stage of the electrical explosion of a copper wire is studied theoretically and experimentally; the wire is heated to the boiling point by a high-density current obtained by discharging a capacitor bank.

INTRODUCTION

The electrical explosion of a wire is usually understood to mean the reaction of a comparatively thin wire of given configuration and geometrical dimensions to the short-term effect of a high-density electrical current. Despite its seeming simplicity, the exploding wire phenomenon is in actuality very complex and there is no theoretical model at the present which explains it completely.

In this work we consider the initial stage of the electrical explosion of a wire (its heating to the boiling point) which is arbitrarily divided[1-3] into three phases:[1)] heating of the wire to its fusion temperature T_f, fusion, and subsequent heating of the fused wire to the boiling point T_b.

Figure 1a gives a simplified diagram of the discharge circuit which consists of the condenser C_0 charged to a voltage V_0 by the high-voltage source HVS, the spark gap P, and the exploding wire EW. Initiation of discharge is accomplished at the time $t = t_0$, for example, by applying a high-voltage pulse to one of the electrodes of the three-electrode gap P. Despite the existing nonlinearity of the initial portion of the volt–ampere characteristic for an air spark gap, it is assumed[8-10] that such a circuit containing an air gap can be replaced by an equivalent circuit with lumped parameters and that the resultant resistance of the circuit is constant (except for the resistance of the exploding wire).

The introduction of the equivalent averaged resistance R_{0k} for the spark gap and circuit conductors and the total inductance of the discharge circuit L_{0k} (excluding the inductance L_w of the exploding wire), as we have done in Fig. 1b, is obviously correct only when the time to heat the wire to its fusion temperature is greater than $0.5\pi\sqrt{L_{0k}C_0}$ since the nonlinearity of the volt–ampere characteristic of the discharge gap is insignificant from that time on.[8-12] From the work of Keilhacker[7] and Haussler,[13-14] the exploding wire is replaced by its equivalent inductance L_w and resistance R_w (Fig. 1b), the values of which vary during the flow of a discharge current along the EW.

1. HEATING EXPLODING WIRE FROM T_0 TO T_f

As shown previously,[3,15] the energy expended in radiation and heat transfer between the EW and the surrounding medium is insignificant in the initial stage of the EWP; these are neglected below. The distribution of the temperature, T, over the cross section of the EW is assumed to be uniform. It is assumed that the classical thermodynamic properties and empirical data on the temperature dependence of thermophysical characteristics of materials are also valid for the conditions obtaining in the electrical explosion of a wire.

At the high rates of energy introduction into an EW the current in the EW is initially distributed over its surface because of the skin effect and arrives at the symmetry axis of a cylindrical conductor only after a small (but finite) period of time determined by the diffusion process.[16] The relative increase R_ω/R_0 in the resistance of a cylindrical conductor because of the skin effect based on the approximation[17]

$$\frac{R_\omega}{R_0}=\begin{cases} 1+\frac{n^4}{3} & \text{for } n<1, \\ 0.997n+0.277 & \text{for } 1.5<n<10, \\ n+\frac{1}{4}+\frac{3}{64n} & \text{for } n>10, \end{cases} \tag{1}$$

depends strongly on the parameter n, the values of which for an exploding cylindrical wire can be calculated in the following manner:

$$n=\frac{r_0}{2}\left(\frac{\rho_0 T_0^*}{\pi\mu\mu_0}\right)^{-0.5}, \tag{2}$$

where r_0 is the initial radius of the EW; μ_0 is the magnetic permeability of a vacuum; μ is the relative permeability of the EW material; ρ_0 is its specific electrical resistance of an EW of radius r_0 and length l at the temperature T_0; $T_0^* = 2\pi\sqrt{(L_{0k} + L_w)C_0}$ is the period of the natural oscillations of the discharge circuit.

If we require that the inequality

$$\left|\frac{R_\omega}{R_0}-1\right|\leqslant\varepsilon, \tag{3}$$

be satisfied for $\varepsilon = 0.01$-0.1, relations are easily established, by using Eqs. (1)-(3), between the parameters of

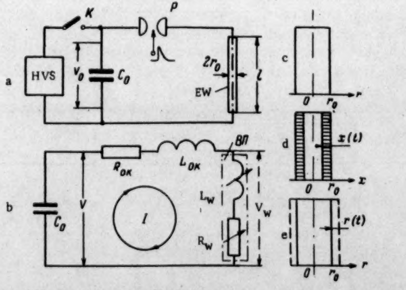

Fig. 1. a) Electrical diagram of exploding wire connected into a discharge circuit; b) equivalent circuit; c-e) choice of coordinate systems associated with the exploding wire; c) heating EW from T_0 to T_f; d) fusion; e) heating EW from T_f to T_b.

the discharge circuit and EW dimensions and materials for which the skin effect need not be considered in the initial stage of the EWP and for which the distribution of the current I can be considered uniform over the cross section of the EW. For example, the period T_0^* of the natural oscillations of the discharge circuit must not be less than $3 \cdot 10^{-5}$ sec for $\varepsilon = 0.05$ in the explosion of copper wires with diameters from 0.1 to 1 mm.

One can then write the following equations describing the transient processes in the discharge circuit and the dynamics of heating the EW from T_0 to T_f during flow of a high-density current I:

$$\frac{d}{dt}(L_{0k}+L_{w1})I+(R_{0k}+R_{w1})I-V=0, \tag{4}$$

$$\frac{dV}{dt}=-\frac{1}{c_0}I, \tag{5}$$

$$\frac{d}{dt}(mcT)=R_{w1}I^2, \tag{6}$$

where t is the time; V is the condenser voltage at time t; I is the current in the discharge circuit; c is the heat capacity of the EW material; m is the EW mass; R_{w1} and L_{w1} are the resistance and inductance of the EW in the first phase of the explosion.

The factors R_{w1}, L_{w1}, and c in Eqs. (4)-(6) are generally complex functions of time

$$c=\Phi[T(t)], \tag{7}$$

$$R_{w1}=G[T(t),\ r(t)], \tag{8}$$

$$L_{w1}=F[r(t)], \tag{9}$$

where r(t) is the radius of the thermally expanding EW at the time t.

At the present time there is no single point of view as to which heat capacity c (c_v or c_p) should be used in the numerical integration of the equation system (4)-(6).[1-7,15,18-20] Thus, Tucker[1] and Keilhacker[7] use c_p while Bennett[18,19] and Vermij[20] use c_v.

The relative increase of the EW radius r(t) with respect to its initial value r_0 during this first phase[21,22] does not exceed 5%. Therefore in Eqs. (4)-(6) with Eqs. (7)-(9) taken into account, empirical data for the specific heat capacity at constant volume c_v are used for the EW material and the variation in radius is neglected in calculations of R_{w1} and L_{w1}. The value of the density γ_0 in this phase is assumed to be constant.2)

Since it does not appear possible to establish the form of the temperature dependence $c_v(T) = \Phi(T)$ directly from the meager experimental data in the literature on measurements of the heat capacity c_v for metals, we use the approximate relation3) for c_p/c_v[23]

$$\frac{c_p(T)}{c_v(T)}=1+\frac{\alpha_v(T)\,T}{a}, \tag{10}$$

where a is the relative atomic packing density (a = 0.74 for a cubic face-centered lattice and a = 0.68 for a body-centered lattice); $\alpha_v(T)$ is the volume coefficient of expansion which to a first approximation, is equal to three times the linear coefficient of expansion α_l and increases in proportion to the first power of the increase in the temperature T.

For a copper wire, the experimental data[25,26] for α_l, converted to the corresponding values of α_v, are closely approximated by the following relation

$$\alpha_v(T)=(44.995+0.016\,T^\circ\,\mathrm{K})\,10^{-6}\ \mathrm{deg}^{-1}, \tag{11}$$

as shown by our computer calculations, with the relative error of the approximation being no more than 5% in the temperature range 293-1356°K. Computer-calculated coefficients for the relation

$$c_p(T)=a_0+a_1T+a_2T^2+a_3T^3\ \ (\mathrm{J/kg\cdot deg}), \tag{12}$$

which approximates the experimental data (on the measurement of c_p) of more than 20 authors have the following values: a_0 = 348.41, a_1 = 0.136, $a_2 = -3.35 \cdot 10^{-5}$, $a_3 = 1.19 \cdot 10^{-8}$. The relative error of this approximation is less than 3.0%.

The values of $c_v(T)$ calculated from Eq. (10) using Eqs. (11) and (12) are approximated by the linear relation

$$c_v(T)=c_v(T_0)[1+B_1(T-T_0)], \tag{13}$$

where $B_1 = 17.07 \cdot 10^{-5}\ \mathrm{deg}^{-1}$, and

$$c_v(T_0)=348.48+0.114T_0 -0.47\cdot10^{-4}T_0^2+0.117\cdot10^{-7}T_0^3\ \ (\mathrm{J/kg\cdot deg}), \tag{14}$$

with the relative error of this approximation being no more than 3-4%.

The experimental data for the specific resistance $\rho(T)$ of copper in the temperature range $T_0 - T_f$, as shown by calculation, are closely approximated by

$$\rho(T)=\rho(T_0)[1+C_1(T-T_0)], \tag{15}$$

where $C_1 = 40.151 \cdot 10^{-4}\ \mathrm{deg}^{-1}$, and

$$\rho_0=\rho(T_0)=(0.5641+30.85\cdot10^{-4}T_0+34.57\cdot10^{-7}T_0^2 +82.65\cdot10^{-11}T_0^3)\,10^{-8}\ \ (\Omega\cdot\mathrm{m}). \tag{16}$$

The EW inductance L_{0w} for this phase is calculated as[27]

$$L_{0w}=\frac{\mu_0 l}{2\pi}\ln\left(\frac{2l}{r_0}-0.75\right), \tag{17}$$

and the EW resistance R_{0w} at T_0 is calculated from

$$R_{0w}=\rho_0\frac{l}{\pi r_0^2}, \tag{18}$$

where μ_0 in Eq. (17) is the magnetic permeability of a vacuum.

Considering Eqs. (13)-(18) along with the relations

$$L_0=L_{0K}+L_{0w},\quad R_0=R_{0k}+R_{0w}, \tag{19}$$

and introducing dimensionless variables for the time τ, temperature, Θ, current in the discharge circuit, i, voltage on the condenser plates, u, and EW radius, ν, through the relations

$$\left.\begin{aligned} &u=\frac{V}{V_0},\quad \Theta=\frac{T}{T_0},\quad \tau=\frac{t}{\sqrt{L_0C_0}},\\ &i=\frac{I}{V_0}\sqrt{\frac{L_0}{C_0}},\quad \nu=\frac{r}{r_0}, \end{aligned}\right\} \tag{20}$$

the equation system (4)-(6) can be transformed to the following form:

$$\frac{dl}{d\tau}=\frac{1}{l_K+l_c}\{(u-la_0\{a_s+a_c[1+c_1(\theta-1)]\}\}, \tag{21}$$

$$\frac{du}{d\tau}=-l, \tag{22}$$

$$\frac{d\theta}{d\tau}=\frac{2\alpha_0 a_c}{q_0[1+b_1(2\Theta-1)]}[1+c_1(\Theta-1)]\,l^2, \tag{23}$$

$$\frac{d\nu}{d\tau}=0, \tag{24}$$

where $l_k, l_c, \alpha_0, a_K, a_c, q_0, c_1$, and b_1 are dimensionless parameters which are defined in terms of the parameters of Eqs. (4)-(6) in the following way:

$$\left.\begin{gathered} l_K=\frac{L_{0K}}{L_0},\quad l_c=\frac{L_{0W}}{L_0},\quad a_c=\frac{R_{0K}}{R_0},\quad a_c=\frac{R_{0W}}{R_0},\\ \alpha_0=R_0\sqrt{\frac{C_0}{L_0}},\quad q_0=\frac{2l\gamma_0\pi r_0^2c_v(T_0)\,T_0}{C_0V_0^2},\\ b_1=B_1T_0,\quad c_1=C_1T_0. \end{gathered}\right\} \tag{25}$$

The initial conditions for the solution of Eqs. (21)-(24) are given in the form

$$\text{at}\quad \tau=0\begin{cases} u=1,\ \Theta=1,\\ l=0,\ \nu=1. \end{cases} \tag{26}$$

Numerical integration of the system of (21)-(24) with the initial conditions (26) is cut off at the time τ_1, which is determined by the following condition:

$$\text{at}\quad \tau=\tau_1\ \Theta=\Theta_f=\frac{T_f}{T_0}. \tag{27}$$

The fusion process beings after the heating of the EW to the temperature Θ_f.

2. FUSION OF THE EXPLODING WIRE

It is assumed fusion of the EW occurs isothermally ($T = T_f$) and its thermal expansion is negligibly small. Fusion of the EW begins simultaneously over its entire lateral surface.[28] The solid metal−melt interface moves toward the symmetry axis of the wire during fusion (Fig. 1d), and its total resistance R_{w2} is given by

$$R_{w2}=\frac{k_f\,l\rho_0[1+C_1(T-T_0)]}{\pi(r_0-x)^2+k_f\,\pi x^2}, \tag{28}$$

where k_f is the relative increase in the resistance of the fused EW material relative to the EW resistance in the solid state at $T = T_f$; x is the coordinate of the moving solid metal−melt interface.

The equation of energy balance for the EW during fusion can be written

$$H_m\frac{dm(t)}{dt}=-R_{w2}I^2, \tag{29}$$

where H_m is the specific heat of fusion for the EW material; m(t) is the mass of the wire still in the solid state.

Since

$$m(t)=\pi x^2 l\gamma, \tag{30}$$

Eq. (29) can be rewritten in the form

$$\frac{dx}{dt}=-\frac{R_{w2}I^2}{2H_m l\gamma\pi x}, \tag{31}$$

where γ is the value of the density of the EW material assumed in the first phase.

The system of equations (4), (5), and (31) describing EW fusion and reduced to canonical form with Eqs. (25) and (28) taken into account takes the following form in terms of the dimensionless variables (20):

$$\frac{dl}{d\tau}=\frac{1}{l_k+l_c}\left\{u-\alpha_0 l\left[a_s+k_f\,a_c\frac{1+c_1(\Theta_f-1)}{(1-\xi)^2+k_f\,\xi^2}\right]\right\}, \tag{32}$$

$$\frac{du}{d\tau}=-l, \tag{33}$$

$$\frac{d\Theta}{d\tau}=0, \tag{34}$$

$$\frac{d\xi}{d\tau}=-\frac{\alpha_0 a_c k_f[1+c_1(\Theta_f-1)]}{\xi[(1-\xi)^2+k_f\,\xi^2]\,h_{\theta f}}\,l^2, \tag{35}$$

$$\frac{d\nu}{d\tau}=0, \tag{36}$$

where the following dimensionless variables and coefficients are used:

$$\xi=\frac{x}{r_0},\ h_{\theta f}=\frac{2H_m\pi r_0^2 l\gamma_0}{C_0V_0^2}. \tag{37}$$

The initial conditions for the solution of (32-(36) are determined from the results of a solution of (21)-(24) at time τ_1 and have the following form

$$\text{at}\quad \tau=\tau_1\begin{cases} u=u_{\tau_1},\ l=l_{\tau_1},\ \Theta=\Theta_f\\ \nu=1,\ \xi=1. \end{cases} \tag{38}$$

Numerical integration of (32)-(36) under the initial conditions (38) is cut off at the time τ_2 when the condition

$$\int_{\tau_1}^{\tau_2} a_0 k_f\,a_c\frac{1+c_1(\Theta_f-1)}{(1-\xi)^2+k_f\,\xi^2}\,l^2 d\tau=\frac{h_{\theta f}}{2}, \tag{39}$$

is satisfied, which corresponds to the condition

$$\xi=0\ \text{at}\ \tau=\tau_2. \tag{40}$$

3. HEATING OF THE FUSED WIRE FROM T_f TO THE BOILING POINT T_h

In considering the phase of EW heating above the fusion temperature, only its radial expansion is taken into account along with the variation of EW inductance, which is defined as[27]

$$L_W=L_{0W}+\frac{\mu_0 l}{4\pi}\ln\frac{r_0}{r(t)}, \tag{41}$$

where r(t) is the EW radius during heating from T_f to T_b (Fig. 1e).

From the condition for mass balance, one can write

$$r(t)=\frac{r_0}{\sqrt{\frac{\gamma(T)}{\gamma_0}}}, \tag{42}$$

where $\gamma(T)$ is the density of the EW material in the liquid state and in the temperature range $T_f - T_b$.

The temperature dependence of $\gamma(T)$ and $\rho(T)$ for liquid copper, as shown by our computer analysis of the experimental data of many authors, can be approximated by the following expressions:

$$\text{at} \quad T_f \leqslant T \leqslant T_b \quad \begin{cases} \gamma(T) = \gamma_l(T_f)[1 - K_\gamma(T - T_0)], & (43) \\ \rho(T) = \rho_p(T_f)[1 + C_2(T - T_0)], & (44) \end{cases}$$

where $K_\gamma = 12.81 \cdot 10^{-5}\ \text{deg}^{-1}$; $C_2 = 33.62 \cdot 10^{-5}\ \text{deg}^{-1}$; $\gamma_l(T_f)$ and $\rho_l(T_f)$ are respectively the density and specific resistance of liquid copper at T_f.

The value of $\rho_l(T_f)$ in Eq. (44) is calculated from

$$\rho_p(T_f) = \rho_0[1 + C_1(T_f - T_0)]k_f. \tag{45}$$

The relative error of approximation (43) is less than 0.6% and that of approximation (44) is less$^{4)}$ than 3%.

The temperature dependence of the heat capacity of liquid metals cannot be considered to be sufficiently investigated at the present time.[24] In a number of papers on the experimental measurement of $c_p(T)$, an increase in heat capacity with increasing temperature is noted; in others there is a reduction and in some papers the heat capacity is almost constant, and in some it varies nonmonotonically. Therefore it does not seem possible to establish the form of the temperature dependence $c_v(T)$ for metals in the liquid state, particularly for copper. In the calculations we assume a constant value for the $c_v(T)$ for copper in the temperature range $T_f - T_b$.

Using Eqs. (42) and (43) we can convert Eq. (6) for this phase of the explosion can be the following form:

$$\pi r_0^2 l \gamma_0 c_v(T_0)[1 + B_1(T_f - T_0)]\frac{dT}{dt} = k_f R_{0w}[1 + C_1(T_f - T_0)] \times [1 + C_2(T - T_0)][1 - K_\gamma(T - T_0)]I^2. \tag{46}$$

Note that Eqs. (42) and (46) indicate that

$$\frac{dr}{dt} = \frac{K_\gamma k_f R_{0w}[1 + C_1(T_f - T_0)][1 + C_2(T - T_0)]}{2\pi r_0 l c_v(T_0)[1 + B_1(T_f - T_0)]\gamma_0\sqrt{1 - K_\gamma(T - T_0)}}I^2. \tag{47}$$

Using Eqs. (46) and (47), the dimensionless variables (20) and (37), the coefficients (25) and (37), and the fact that

$$\left.\begin{aligned} \frac{L_w}{L_0} &= l_c + \frac{\Delta l_w}{2}\ln[1 - K_\gamma(T - T_0)], \\ k_\gamma &= K_\gamma T_0, \quad c_2 = C_2 T_0, \end{aligned}\right\} \tag{48}$$

where

$$\Delta l_w = \frac{\mu_0 l}{2\pi L_0}, \tag{49}$$

we can write the system of equations describing heating of the fused wire from T_f to T_b in the form

$$\frac{di}{d\tau} = \frac{1}{l_k + l_c + \frac{\Delta l_w}{2}\ln[1 - k_\gamma(\theta - 1)]} \times \Big\{u - \alpha_0 i \Big\{a_x + a_c k_f[1 + c_1(\Theta_f - 1)] \times [1 + c_2(\Theta - 1)][1 - k_\gamma(\Theta - 1)] \times \Big[1 - \Delta l_w \frac{k_\gamma}{[1 - k_\gamma(\Theta - 1)][1 + b_1(2\Theta_f - 1)]q_0} i^2\Big]\Big\}\Big\}, \tag{50}$$

$$\frac{du}{d\tau} = -i, \tag{51}$$

$$\frac{d\theta}{d\tau} = \frac{2a_0 a_c k_f[1 + c_1(\Theta_f - 1)][1 + c_2(\Theta - 1)][1 - k_\gamma(\Theta - 1)]}{q_0[1 + b_1(2\Theta_f - 1)]}i^2, \tag{52}$$

$$\frac{d\nu}{d\tau} = \frac{a_0 a_c k_f k_\gamma[1 + c_1(\Theta_f - 1)][1 + c_2(\Theta - 1)]}{q_0[1 + b_1(2\Theta_f - 1)]}i^2. \tag{53}$$

The solution of (50)-(53) under the initial conditions

$$\text{at} \quad \tau = \tau_2 \left\{\begin{matrix} u = u_{\tau_2}, & i = i_{\tau_2}, \\ \Theta = \Theta_f, & \nu = 1 \end{matrix}\right\} \tag{54}$$

should be carried out up to the time τ_3 for which the following condition

$$\text{at} \quad \tau = \tau_3 \quad \Theta = \frac{T_b}{T_0} = \Theta_b. \tag{55}$$

is satisfied.

4. RESULTS OF NUMERICAL INTEGRATION OF THE EQUATION SYSTEMS

Integration of the equation systems (21)-(24), (32)-(36), (50)-(53) under the corresponding initial conditions (26), (38), (54) is carried out numerically on a computer by the Runge–Kutta method. For this purpose the (21)-(24), (32)-(36), and (50)-(53) are formally reduced to the following system:

$$\frac{di}{d\tau} = \frac{1}{l_K + l_w}\left[u - \alpha_0 i\left(a_K + z_w + \frac{\Delta l_w}{R}k_\gamma M i^2\right)\right], \tag{56}$$

$$\frac{du}{d\tau} = -i, \tag{57}$$

$$\frac{d\theta}{d\tau} = 2B\alpha_0 M i^2, \tag{58}$$

$$\frac{d\nu}{d\tau} = +\frac{k_\gamma a_0}{\sqrt{R^3}}M i^2 - A\frac{a_0 a_c k_f P}{\nu N h_{\Theta f}}i^2, \tag{59}$$

where

$$\left.\begin{aligned} P &= 1 + c_1(n_\Theta\Theta - 1); \quad Q = 1 + c_2(n_\Theta\Theta - 1), \\ R &= 1 - k_\gamma(n_\Theta\Theta - 1), \quad z_w = a_c k_f\frac{PQR}{N}, \\ N &= [(1 + k_f)\nu^2 - 2\nu]D + 1, \quad l_w = l_c + \frac{\Delta l_w}{2}\ln R, \\ M &= \frac{z_w}{q_0[1 + b_1(2n_\Theta\Theta - 1)]}, \end{aligned}\right\} \tag{60}$$

with the following conditions being satisfied: a) in the first phase ($0 \le \tau \le \tau_1$), $A = 0$, $B = 1$, $D = 1$, $n_\Theta = 1$, and it is formally assumed $\Delta l_w = 0$, $k_\gamma = 0$, $c_2 = 0$, and $k_f = 1$; b) for the second phase ($\tau_1 \le \tau \le \tau_2$), $A = 1$, $B = 0$, $D = 1$, $n_\Theta = \Theta_f/\Theta$, and it formally assumed $\Delta l_w = 0$, $k_\gamma = 0$, and $c_2 = 0$; c) for the third phase ($\tau_1 \le \tau \le \tau_3$), $A = 0$, $B = 1$, $D = 0$, and $n_\Theta = \Theta_f/\Theta$.

Figures 2 and 3 present the results of a numerical solution of the equation system (59)-(60) under the initial conditions (26), (38), and (54) for the following values of the dimensionless coefficients (25) and (37): $l_K = 0.9828$, $l_c = 0.0172$, $a_K = 0.9155$, $a_c = 0.0845$, $\alpha_0 = 0.1304$, $q_0 = 0.001790$, and $h_{\Theta f} = 0.003735$, which correspond to the parameters of our experimental device where $C_0 = 9\,\mu F$, $L_{0k} = 3.58\,\mu H$, and $R_{0k} = 0.075\,\Omega$ for the electric explosion of a bare copper wire with a diameter $2r_0 = 0.38$ mm and a length of 50 mm at $V_0 = 25$ kV. In the calculations it is assumed $T_0 = 293°K$, $T_f = 1356°K$, $T_b = 2855°K$, $\gamma_0 = 8.93 \cdot 10^3\ kg/m^3$, $H_m = 21.39 \cdot 10^4$ J/kg, $\mu_0 = 12.57 \cdot 10^{-7}$ H/m, and $k_f = 2.5$.

5. METHOD OF MEASUREMENT AND RESULTS

A simplified block diagram of the experimental device used in our work on the electrical explosion of wires in water is shown in Fig. 4. The bank of high-voltage capacitors C1-C3 consists of three IM-50-3 capacitors with a total capacity of $9\,\mu F \pm 1\%$; the three-electrode spark gap p, the construction of which is shown in Fig. 5, is used as a switch. A study of this spark gap using a method described earlier[12] shows that the nonlinearity of the initial portion of its volt–ampere characteristic is significant only for 0.05-0.1 T_0^* at maximum discharge currents of 5-50 kA, which is somewhat different from the values given.[12] Initiation of the discharge is accomplished by a high-voltage pulse from the control panel of the SFR-2M photodetector which is fed through the split condenser 4 to electrode 15 of the gap P. Connection to the condenser bank is made with RK-50-9-11 coaxial cable.

The discharge chamber consists of two cylindrical copper electrodes submerged in a water-filled tank with the metal wire under study stretched between them. The discharge chamber is connected to the gap P by an RKG-15 cable 2.8 m long.

To measure the discharge current during electrical explosion of a wire, a noninductive coaxial current shunt is used which is similar in construction to one previously proposed[29] and which has a resistance of $(55 \pm 0.05) \cdot 10^{-4}$ Ω.

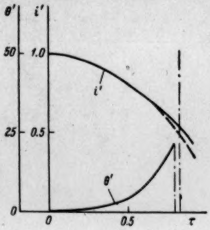

Fig. 3. Dependence of the dimensionless time rates of change for current, $i' = di/d\tau$, and for temperature, $\theta' = d\theta/d\tau$, on the dimensionless time τ.

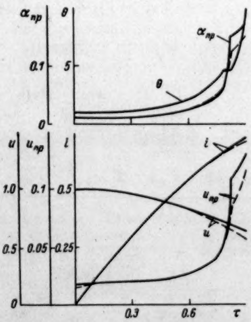

Fig. 2. The dimensionless condenser voltage u, voltage u_w across EW current i, resistance α_w, and EW temperature θ as functions of the dimensionless time τ. Here, and in Fig. 3, the solid curves are the theoretical curves and the dashed curves are experimental curves.

The voltage $V_w(t)$ on the EW is measured with a low-inductance, frequency-compensated TVO-10 resistance voltage divider (scale factor, 38.46; rise time, 10^{-7} sec at most) and is simultaneously recorded with the current I(t) on RF-3 35-mm film by photographing the screen of the cathode ray tube in the OK-17M dual-beam oscilloscope. Note that serious experimental difficulties arise in the determination of $V_w(t)$ because of the induced voltage $V_m(t)$ resulting from the presence of parasitic inductance L_m in the measuring circuit (even though the path is very short) and the high rates of change in the current flowing through it. Thus with L_m of the order of 20 mH and the current rate change of 10^7-10^{10} A/sec, the voltage $V_m(t)$ can reach several hundred volts and completely destroy the useful signal taken from the voltage divider.

The quantity $V_m(t)$ is allowed for by means of a compensation loop using a differential amplifier ahead of the oscilloscope input, as described earlier.[30] To compensate for $V_m(t)$ induced in the measuring circuit, the discharge chamber is shorted by a cylindrical copper rod in place of the exploding wire and the compensating circuit is adjusted so that the recorded time variations in voltage correspond to those which are calculated from current changes and from the resistance and inductance of the copper rod with surface effect included.

Measures are taken, similar to those described previously,[22] to reduce the nonlinearity with respect to amplitude and time in commerical models of the OK-17M oscilloscope. The amplitude nonlinearity over the working portion of the screen does not exceed 2% and the sweep non-

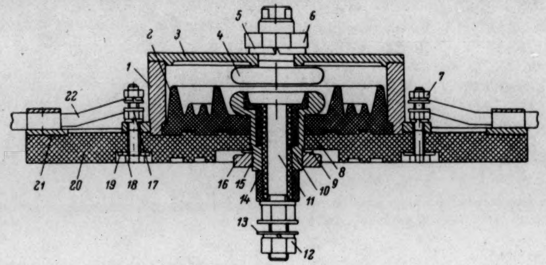

Fig. 5. Construction of spark gap. 1) Housing; 2, 8, 10, 14) insulating bushings; 3) top cover; 4, 11, 15) electrodes; 5, 9, 13, 17) washers; 6, 7, 12, 16) nuts; 18) bolt; 19) circular bus; 20) bottom cover and base; 21) cable-fastening clip; 22) high-voltage cable.

linearity is less than 0.5%. A precision calibrator using silicon stabilitrons for the production of pulses of calibrated height is used to calibrate the pulse-height and time scale factors for the oscilloscope display of $V_W(t)$ and I(t).

Because of all the measures enumerated above, we have managed to increase the accuracy of current and voltage measurements in comparison with our earlier measurements.[31] The relative error in current measurement is no more than 4%; for the voltage $V_W(t)$, it is 7-10%.

The current and voltage oscilloscope traces obtained are put in tabular form by means of an MMI-2 measuring microscope. Inclusion of the inductive component of the voltage on the EW

$$\left[L_W(t)\frac{dI(t)}{dt}+I(t)\frac{dL_W(t)}{dt}\right]$$

in calculations of the ohmic component of the voltage on the EW, and of the resistance and the energy introduced into the EW, is accomplished numerically on a computer.

The total initial circuit inductance L_{0k} and resistance R_{0k} calculated from a current trace for a short-circuited discharge chamber are the following: 3.58 μH and 0.075 Ω. The voltage V_0 on the plates of the condensers C1-C3 during charging is established with an error of no more than 1.5%.

The volume of the tank 2 (Fig. 4), which is filled with tap water, is 1.7 m^3. The water in the tank is replaced after each explosion of a wire. In the experiments, type PEL copper wire is used, the enamel insulation of which is removed with formic acid. For all bare copper-wire samples studied, the diameter and surface cleanliness are checked before installation in the discharge chamber, and the length is checked after installation.

Averaged results from five measurements of the voltage on an EW 0.19 ± 0.01 mm in radius and 50 ± 0.5 mm long, of the current in the discharge circuit and its rate of rise, and of the EW resistance, reduced to dimensionless form using (20) and (25) are shown in Figs. 2 and 3 by the dashed lines. The maximum deviation of individual measurements from the averaged curves is within the limits of accuracy of the measurements (the initial portion at τ = 0-0.1, where the maximum deviation is larger by a factor of 1.5-2, is an exception). Using the experimentally determined values for i, $di/d\tau$, and u_W, the value of the voltage on the condenser plates is calculated as

$$u=l_K\frac{di}{d\tau}+\alpha_0\alpha_K i+u_W$$

from the balance condition for the voltage in the discharge circuit.

Good agreement is observed between the calculated and experimentally measured values for α_W, i, u_W, and u, which are compared in Fig. 2, over the time period corresponding to the first phase of the EWP — heating of an EW from T_0 to T_f. As the figure indicates, theory gives a more rapid increase in the resistance of the two-phase solid metal—melt system during fusion of an EW than is observed experimentally. At time τ_2, our experimentally measured value for the ratio $\alpha_{W\tau_2}/\alpha_{W\tau_1} = k_f$ is 2-2.2 for copper, which is considerably different from the measured value of 1.83 for k_f for copper[22] in the explosion of a copper EW in air. Note that data in the literature on the measurement (or calculation) of k_f for copper by other methods is also contradictory. The value k_f = 2.5 used by us for the integration of (56)-(60) is determined by averaging independent experimental data from many authors for measurement of the specific resistance of copper in the solid and liquid states at the fusion temperature. This value is in satisfactory agreement with other data.[32,33]

As Fig. 2 indicates, the experimentally measured EW resistance α_W increases more rapidly in the time period $\tau_2 - \tau_3$ than the calculated value from the integration of equation system (56)-(60).

Better agreement with experiment than that in Fig. 2 can be obtained by assuming k_f = 2.1, as shown by calculation. Despite this, our view is that the existing considerable differences between experimentally measured and assumed values of k_f cannot be explained merely by the inaccuracy of the k_f values used in the calculations but is more likely evidence that the assumed model of isothermal fusion is very approximate (the fact that thermal expansion of the EW and the external forces opposing this expansion are not taken into account in the consideration of the first two phases of the EWP tends to reinforce this conclusion).

For this electrical explosion of a copper wire in water, we make an experimental check of the Vermij hypothesis[20] about the nonisothermal nature of the fusion process in an EWP which he observed in a study of the electrical explosion of silver wires in air. For this purpose, we compare the duration $\tau_2 - \tau_1$ of the fusion phase which is obtained by numerical solution of equation system (56)-(60) with the value calculated from the experimental curves for $u_w(\tau)$ and $i(\tau)$. The end of EW fusion (the time τ_2) is characterized by a clearly defined sharp bend in the $u_w(\tau)$ curve and therefore is comparatively simple to determine (Fig. 2). The time τ_1 is determined from the experimental curve for $\alpha_w(\tau)$ since for $T = T_f$ and $\tau = \tau_1$, the resistance of the EW is known and is

$$\alpha_{w\tau} = a_c \alpha_0 [1 + c_1 (\Theta_f - 1)].$$

In addition, the value of the energy introduced into the EW in the time $\tau_2 - \tau_1$

$$W_{J_{EW}} = \int_{\tau_1}^{\tau_2} \alpha_w i^2 d\tau,$$

is calculated.

A comparison of the indicated durations $\tau_2 - \tau_1$ shows that the experimental values of $\tau_2 - \tau_1$ are greater than the calculated values, and the experimentally determined energy $W_{J_{EW}}$ is 15-20% greater than the energy which would be expended in isothermal fusion[5] of the EW. The latter indicates that apparently the energy $W_{J_{EW}}$ will be used in part to heat the EW.

A possible reason for the nonisothermal nature of the EW fusion process may be the fact that the magnetic pressure increases as x decreases[20] ($0 \le x \le r_0$, Fig. 1d). This should lead to a dependence of the fusion temperature on the x coordinate in accordance with the Clapeyron equation even for uniform current distribution over the EW cross section and neglect of heat transfer to the surrounding medium. Then during subsequent heating of the EW, the above mentioned temperature nonuniformity over the EW cross section should lead to an "anomalous" rise in EW resistance in the time period $\tau_2 - \tau_3$, which is also observed experimentally (Fig. 2). At large current densities ($j > 10^{10}$ A/m^2), a situation is apparently possible where the boiling point can be reached on the surface of the EW even before the solid metal−melt interface reaches the EW symmetry axis (x [illegible] 0).

However, there are other points of view with respect to the reasons for the anomalous rise in EW resistance. Thus some assume[18,19] that with uniform distribution of current over the EW cross section there is observed no connection whatever between magnetic pressure and the thermodynamic processes taking place in the EW and that the anomalous rise in the resistance of a fused wire during subsequent heating results from a vaporization wave which arises even at temperatures only slightly greater than the EW fusion temperature.

Our experimental results do not allow an answer to the question of which point of view should be adopted for a description of the nonisothermal nature of the fusion and of the anomalous rise in EW resistance although the analysis performed definitely establishes the existence of a radial temperature distribution during the electrical explosion of a wire in water.

Although the proposed model for the initial stage of the EWP also does not take account of the radial distribution of temperature and is based on certain simplifying assumptions, it gives a good description of heating of the EW to its fusion temperature and gives satisfactory results for the description of the subsequent phases, for which refined models may be proposed only after additional experimental studies.

---

[1] Note that such a subdivision of the exploding wire phenomenon (EWP) into stages (or phases) is not unique or generally accepted. Thus Bennett takes as the end of the initial stage of the EWP the striking of an arc in the expanding metal vapor.[4] Manka and Hobson[5] assume the initial stage of the EWP to be one fifth of the natural oscillation period T_0^* of the discharge circuit, which corresponds approximately to the development of the EWP up to the point where fusion of the wire beings. Nash and Olsen[6] divide the explosion of a wire into three stages including in the first stage the development of the process to the point where a current break is created. Keilhacker[7] takes as the end of the first stage of the EWP the completion of fusion of the wire. Thus the duration of the initial stage of the EWP discussed here agrees with that assumed in refs. 1-3, is less than that in refs. 4 and 6, and is greater than that in refs. 5 and 7.

[2] The variation of γ does not exceed 5% during heating of a copper wire in the solid state from 293 to 1356°K.

[3] In the opinion of L. P. Filippov,[24] calculations using the equation of B. N. Oshcherin lead to better agreement with calculations based on the rigorous thermodynamic equation $c_p - c_v = \beta^{-1} v T \alpha_v^2$ than calculations using the empirical relation of Nernst and Lindemann $c_p - c_v = a c_p^2 T$, which is employed in most papers (β is the isothermal compressibility, v is atomic volume, and a is a constant.

[4] In the preceding first and second phases of the electrical explosion of a copper wire the radial expansion of the EW is neglected; hence it is necessary to substitute the value of γ_0 in place of $\gamma_l(T_f)$ in Eq. (43) in order to conserve the initial mass of the EW, which leads to an increase in the relative error of our approximation.

[5] In calculations where $k_f = 2.1$.

Electrical characteristics of underwater exploding wires

V. K. Sholom, E. V. Krivitskii, and V. P. Litvinenko

(Submitted August 2, 1973)
Zh. Tekh. Fiz., 44, 2146-2150 (October 1974)

Using the condition of approximate similarity for the electrical characteristics of an underwater explosion of a wire, empirical equations are obtained which make it possible to determine the inductive peak overvoltage, the minimum current value for which an arc is struck, and the maximum current in the arc stage of the discharge as functions of the parameters of the discharge circuit and the wire. The parameters of the maximum discharge are obtained, i.e., discharges corresponding to the boundary of the current break; conditions are defined for producing the maximum rate of energy deposition in the discharge gap.

The underwater electrical explosion of wires is being used increasingly in industry as a source of intense compression waves with amplitudes in the hundreds and thousands of atmospheres. In particular, the possibility of producing a discharge in comparatively small volumes, the formation of a discharge channel of preassigned shape, and the control of energy characteristics by means of the geometric dimensions and material of the wire itself, make it possible to use an underwater exploding wire (UEW) in industry for shaping various materials, for fastening tubing in the tubing sections of heat-exchange devices, for welding, etc.[1-3]

In these procedures it is very important to know (in addition to the energy relations determining the electrical characteristics of the discharge) the magnitude of the overvoltages in order to prevent breakdown of the insulation.

The qualitative picture of the variation of electrical characteristics of the discharge during explosion of a wire in various media is given rather completely by oscilloscope determination of the energy of electrical explosion of wires.[4]

However, the determination of a relation for the current variation in a circuit containing an exploding wire is complicated by the fact that the markedly nonlinear nature of the resistance of the wire during the phase transition makes it difficult to find an analytic expression.

An attempt to relate the current, voltage, and resistance of the exploding wire to each specific parameter of the discharge circuit separately[5] is not useful because the solution for the transition process in the discharge circuit is determined by a combination.

The application of similarity theory to the calculation of certain characteristics of the electrical explosion of wires[6] makes it possible, by determining the magnitude of the first maximum of the current and the time it appears, to reduce all the various factors defining the discharge at that time to two dimensionless combinations:

$$\Pi_1 = \frac{\rho_0 l}{zS}, \quad \Pi_2 = \frac{CU_0^2}{zS^2h^*}, \tag{1}$$

where ρ_0 is the initial specific resistance; l is the length of the wire; $z = \sqrt{L/C}$ is the characteristic impedance; S is the cross section of the wire; U_0 is the voltage of the charge C on the condenser bank; h^* is a constant for the wire material.

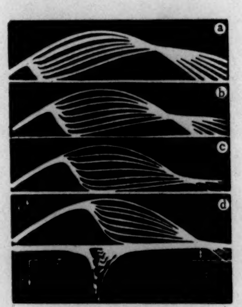

Fig. 1. Oscilloscope traces of discharge current $\bar{i}(\bar{t})$ and voltage $\bar{U}(\bar{t})$ in UEW for various Π_2 and Π_3. Π_2: a) 2.25; b) 0.442; c) 0.19; d) 0.16; $\Pi_3 = (0.0366\text{-}2)\cdot 10^{-2}$.

The fact that the shape and magnitude of the first pulse are determined by processes occurring in the wire itself rather than the nature of the surrounding medium[4] makes it possible to use the defined dimensionless combinations for a description of transition processes during UEW.

As shown below (Fig. 1), however, the two criteria alone are insufficient for the characteristics of the first pulse for a UEW in a mode with no current break.

The criterion Π_1, which defines the current variation during the time for which the wire has a metallic conductivity, has essentially no effect on the nature of the transition process. This is completely justified by the fact that the relation between the current and Π_1 is determined by a power law with an exponent $\alpha \approx 1/12$; for Π_2 = idem, the amplitude of the first pulse of the discharge current remains constant in dimensionless form. However, the trailing edge of the first pulse, which characterizes the depth of the drop, the magnitude of the peak overvoltage produced, and the condition for the onset of the current break remain undetermined.

In the determination of approximate similarity for the characteristics of UEW,[7] it appears possible to represent the system of dimensionless numerical combinations in the form of three criteria: Π_1, Π_2, and Π_3. The values of the criterion Π_2 in refs. 6 and 7 are identical except that the quantity h^* which appears in Π_2 and which is defined as a constant for the EW material with the dimensionality of "specific action," is expressed in ref. 7 in the form of the product

$$h^* \approx \rho_0 \sigma (\lambda + r), \tag{2}$$

where ρ_0 is the density of the wire material, σ is the specific conductivity, λ is the specific heat of fusion, and r is the specific heat of vaporization.

The criterion Π_3 defines the discharge process in the period after breakdown of metallic conductivity and can be determined from the expression[7-9]

$$\Pi_3 = \frac{Al^3}{U_0^2 \pi \sqrt{LC}}, \tag{3}$$

where A is a constant which characterizes state parameters and which is equal to $10^4\ V^2 \cdot sec/m^2$ for UEW.

The basic electrical characteristics are observed by oscillography of the discharge current and voltage. The inductive component of the voltage drop is compensated.[10] The scale factor of the voltage divider is selected so as to ensure recording the peak overvoltage. The parameters of the discharge circuit ($C = 9 \cdot 10^{-6}$ F, $L = 5 \cdot 10^{-6}$ H, $U_0 = 3 \cdot 10^4$ V) correspond to a range within which the conditions for approximate similarity of the UEW are satisfied.[7] The quantities Π_2 and Π_3 are varied by changing the diameter and length of the copper wire.

With Π_2 = idem, six oscilloscope traces of the exploding wire are exposed on each frame of film for various values of Π_3. The range of variation of the third criterion is bounded from above by the limiting case, in which the drop in the discharge current reaches a maximum value, and from below by the case in which there is essentially no current drop. The existence of such traces presents an opportunity to follow the nature of the transition process for all possible values of the criteria in a discharge without a current break.

Figure 1 shows traces of discharge current and voltage when the explosion occurs during the first half-cycle of the discharge current. For comparison, each frame shows the current curve in the short-circuit mode and a voltage curve in the open-circuit mode corresponding to the voltage of the charged condenser bank.

These oscilloscope traces make it clear that for certain definite values of Π_2 and Π_3 the entire energy of the condenser bank is deposited during the first current pulse (Fig. 1). The rise in the current in the first pulse coincides with the rise in the short-circuit mode and can be calculated without any particular error from the equations for R_C, L, and C of the circuit, where R_C = const is the equivalent effective resistance of the elements of the discharge circuit. The peak overvoltage increases (Fig. 2) as the time of explosion approximates the time of discharge and its value can exceed the voltage on the condenser bank by a factor of 4-5. The steepness of the current drop in the first pulse for discharges close to the "maximum" (where the current goes to zero) is practically unchanged when there are changes in Π_2. In absolute magnitude, it is approximately three times greater than U_0/L.

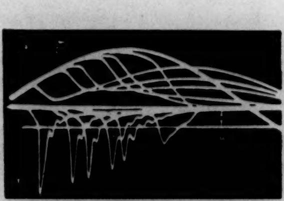

Fig. 2. Variation of peak overvoltage $\bar{U}(\bar{t})$ and of discharge current $\bar{i}(\bar{t})$ for UEW with $\Pi_2 = 2.25$-0.0515 and Π_3 = const.

From other data[4,7,11] one should expect that the transition process in the circuit during explosion of aluminum, silver, and gold wires in water would be similar to the transition process during the explosion of copper wires.

In view of the fact that the properties of the surrounding medium have little effect on the first pulse, the dependence on similarity criteria of the dimensionless current amplitude, $i_m/U_0(\sqrt{L/C})$ and the dimensionless time $\tau_m = t_m/\pi\sqrt{LC}$) for the metals in this group can be described by a power function[6] with the relation

$$\Pi_2 = \frac{1.23P}{\rho_0 \sigma (\lambda + r)} \tag{4}$$

taken into account, where

$$P = \frac{CU_0^2}{2\pi S^2},$$

and S is the cross section of the wire.

The depth of the drop, which is determined by the minimum value of the current i_{min} before the arc stage, and the amplitude of the second pulse i_{max} depend on the criteria Π_2 and Π_3:

$$\left.\begin{aligned} i_{min} &\approx 0.85 \cdot 10^3\, \Pi_2^{-1/4} (\Pi_3 - 0.025)^2, \\ i_{max} &\approx 1 - \Pi_2^{-1/3} \Pi_3^{1/4}. \end{aligned}\right\} \tag{5}$$

The magnitude of the peak inductive overvoltage produced during the explosion of a wire, which is determined by the steepness of the drop in the discharge current, can be found from the approximate expression

$$\frac{U_n}{U_0} = 20 \Pi_2^{1/4} \Pi_3^{1/3}. \tag{6}$$

Verification of Eq. (6), which is obtained from an analysis of the experimental data for the explosion of wires by a condenser bank with a capacity $C = 9 \cdot 10^{-6}$ F charged to a voltage $U_0 = 3 \cdot 10^4$ V and for a discharge circuit inductance $L = 5 \cdot 10^{-6}$ H, is carried out over the range of circuit and wire parameter variations shown in Table 1.

For a discharge without a current break, the deviation of experimental data in the indicated range, and also of other data,[2] from calculated values based on Eq. (6) does not exceed 15%.

As indicated above, the range of variation of conditions and parameters is limited to a discharge without a current break. The limiting case of such a discharge is

TABLE 1

	C, μF	U_0, kV	L, μH	d, mm	l, mm
Lower limit	1	8	1.15	0.07	28
Upper limit	99	40	10	0.9	200

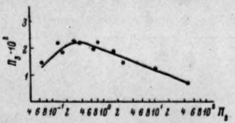

Fig. 3. Region of existence for break-free discharges bounded by the relation $\Pi_3 = f(\Pi_2)$.

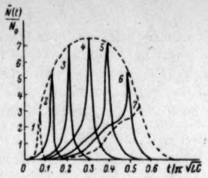

Fig. 4. Family of normalized curves for the electrical power $\tilde{N}$ in discharge modes accompanied by a current drop to zero. Π_2: 1) 9; 2) 2.56; 3) 0.68; 4) 0.228; 5) 0.154; 6) 0.104; 7) 0.065.

a discharge accompanied by a current drop to a value close to zero, with subsequent nearly instantaneous secondary breakdown (secondary initiation).

These discharges (Fig. 1), in terms of the dimensionless similarity criteria, are characterized by a region which is bounded by the curve for the dependence of the maximum value of Π_3 as a function of Π_2 (Fig. 3), above which Eq. (6) cannot be considered to be correct.

Figure 4 gives a family of normalized curves for the electrical power $N(t/\pi\sqrt{LC})/N_0$ for discharge modes accompanied by a current drop to zero in accordance with Fig. 3.

The resultant dependence of the maximum values of Π_3 has a clearly defined maximum, which corresponds to the optimum value of Π_2 from the viewpoint of rate of energy deposition.

Using the expressions for Π_2 and Π_3 as functions of the dimensional constants which characterize the parameters of the discharge circuit and of the wire, one can define conditions which provide a maximum rate of energy deposition in the discharge gap:

$$d_{\text{opt}} = 2\left(\frac{W_0}{z\rho_0\sigma(\lambda + r)}\right)^{1/6}, \tag{7}$$

$$l_{\text{opt}} = 2 \cdot 10^{-3} U_0 \sqrt[4]{LC}, \tag{8}$$

where W_0 is the stored energy. The resultant equations (7) and (8) assume deposition of the energy stored in the condenser bank during the first discharge current pulse.

Thus, the use of an approximate similarity criterion for the underwater explosion of a wire makes it possible to determine the value of the inductive peak overvoltage as a function of wire and discharge-circuit parameters and to determine the conditions corresponding to the maximum rate of energy deposition in the discharge gap.

The expressions obtained here can be used for calculating the electrical stability of special electrode systems and are basic relations determining the hydrodynamics of phenomena in devices based on UEW principles.

Analytic model of the cesium arc

V. P. Pashchenko, V. L. Mironovich, and I. P. Stakhanov

(Submitted November 24, 1973)
Zh. Tekh. Fiz., 44, 2151-2158 (October 1974)

An analytic expression is obtained for the voltage–current characteristic of a cesium discharge with recombination included. The main purpose is to obtain simple, limiting analytic expressions that contain the basic experimental quantities. In this regard the assumptions are more rigorous than those of ref. 1: Coulomb scattering and the electron temperature gradient are neglected. A relationship is established between individual points on the curve and the nature of the volume processes. Agreement between the experimental data and the model is shown.

1. The purpose of the present paper is to establish a relationship between the current J_e and the voltage V of a plane cesium diode with a hot cathode and a cold anode. The parameters of the plasma in the electrode gap and at the boundaries are assumed to satisfy the following relations:

$$\left.\begin{aligned} &\frac{dT_e}{dx}=0;\ \frac{dJ_e}{dx}=0;\ n_1=n_2;\ \Delta\varphi_1>0,\ \Delta\varphi_2<0,\\ &\left(D_a\frac{dn}{dx}\right)_{1,2}\gg\frac{u_i}{u_e}J_e;\quad n_0(T_e)\gg n_m\gg n_1. \end{aligned}\right\} \tag{1}$$

Here, the terms characterizing the electron and ion components are denoted by the subscripts e and i. The subscript 1 denotes quantities at the boundary near the cathode, and 2 those near the anode; the subscript 0 on the plasma density means that this term is obtained from the Saha equation with temperature T_e; n_m is the maximum plasma density in the gap. The symbols for jumps in the electrode potentials $\Delta\varphi_1$ and $\Delta\varphi_2$ are chosen under the assumption that volume ionization prevents loss of the electrons from the plasma gap. The ion production is given by

$$\frac{dJ_i}{dx}=\alpha(T_e,\ p)\,n\left(1-\frac{n^2}{n_0^2(T_e)}\right), \tag{2}$$

where the expression obtained in ref. 2 is used for the ionization coefficient α:

$$\begin{gathered} \alpha=\alpha_0\exp\left\{-\frac{E_*}{T_e}\right\},\\ \alpha_0=1.44\cdot10^{12}\,n_a v_e,\\ E_*=3.21\ \text{eV} \end{gathered} \tag{3}$$

(n_a is the density of the neutral component, and v_e is the thermal velocity of the electrons). Under these assumptions the transport equations and their boundary conditions are

$$\left.\begin{gathered} \frac{d^2n}{dx^2}=-\gamma^2\left(n-\frac{n^3}{n_0^2}\right),\\ \left(\frac{dn}{dx}\right)_{1,2}=\mp\frac{n_1}{\delta L}, \end{gathered}\right\} \tag{4}$$

where $\gamma=\sqrt{\alpha/D_a}$, $\delta=2D_a/v_iL$, and D_a is the ambipolar diffusion coefficient.

From the boundary conditions for the particle and energy fluxes, which are taken in their usual form, and with the symbols selected for the potential jumps near the electrodes, we obtain[1,3]

$$\left.\begin{gathered} \frac{eV}{T_e}-\ln\frac{J_e}{J_R-J_e}=\frac{J_e}{D_e}\int\limits_0^L\frac{dx}{n},\\ \frac{eV}{T_e}-\frac{aJ_R}{J_e}=\frac{n_1v_iE_i}{T_eJ_e}, \end{gathered}\right\} \tag{5}$$

where J_R is the emission current from the cathode; L is the electrode spacing; D_e is the electron diffusion coefficient; $a=2(1-T_1/T_e)$; v_i is the ion thermal velocity; E_i is the effective ionization potential, which is roughly equal to the cesium ionization potential 3.89 eV.

The first relation in (5) is the voltage balance for the internal potential difference. The logarithmic term is equal to the sum of the electrode jumps, and the right side gives the potential drop in the plasma. The second relation is the energy balance equation, from which it follows that Joule heating (J_eV) is expended in heating the electron component (aJ_R) and in the ionization losses represented in the right side. It should be noted that this expression is obtained in the same manner as in the model neglecting recombination[3] since the electrode potential jumps do not prevent the escape of ions from the plasma to the electrodes.

Thus, the development of an expression for the voltage–current characteristic reduces to the calculation of the integral $\int\limits_0^L dx/n$ and to the derivation of an expression for the electron temperature as a function of the density at the boundary n_1. We use Eq. (4) for this purpose. Integrating, we obtain (see ref. 4)

$$\gamma L=2\sqrt{1+k^2}\int\limits_{n_1/n_m}^{1}\frac{dt}{\sqrt{(1-t^2)(1-k^2t^2)}}, \tag{6}$$

where

$$k^2=\frac{\left(\frac{n_m}{n_0}\right)^2}{2-\left(\frac{n_m}{n_0}\right)^2},\quad n_m^2=n_0^2\left(1-\sqrt{1-\left(\frac{\sqrt{2}}{\gamma L\delta}\frac{n_1}{n_0}\right)^2}\right). \tag{7}$$

Equation (6) is used to find the electron temperature. With no recombination ($n_m \ll n_0$), we obtain $\gamma L=\pi(1-2\delta)$ from which the expression for T_e obtained in ref. 3 follows:

$$\frac{1}{T_e^0}=\frac{1}{E_*}\ln\frac{\alpha_0L^2}{\pi^2D_a}. \tag{8}$$

However, for strong recombination, $\pi\delta/\sqrt{2}\ll n_1/n_0\ll1$

$$\gamma L=\frac{n_1\sqrt{2}}{n_0\delta}\frac{1}{\sqrt{1-r_0^2}}, \tag{9}$$

where

$$r_0\approx8\exp\left\{-\frac{n_1}{n_0\delta}\right\} \tag{10}$$

makes a small correction. Neglecting r_0, we write the expression for T_e with recombination taken into account:

$$\frac{1}{T_e}=\frac{1}{T_e^0}-\frac{2}{E_i+E_*}\ln\frac{n_1}{n_{1*}}+\frac{1}{E_i+E_*}\ln\left[\left(\frac{T_e}{T_e^0}\right)^{3/2}\frac{T_1+T_e}{T_1+T_e^0}\right]. \qquad (11)$$

Here, T_1 is the cathode temperature; T_e^0 is given by (8); $n_{1*}=(\pi\delta/\sqrt{2})\cdot n_0(T_e^0)$; $n_0(T_e^0)$ is the Saha electron density corresponding to the temperature T_e^0.

In (11) the last term is small and can be neglected. Then we obtain the Saha equilibrium density for temperature T_e:

$$n_0(T_e)=n_0(T_e^0)\left(\frac{n_1}{n_{1*}}\right)^{\beta}, \quad \beta=\frac{E_i}{E_i+E_*}. \qquad (12)$$

The integral $\int\limits_0^L dx/n$ depends essentially on the small correction to the radical of Eq. (6). After several transformations it can be written $\int\limits_0^{\xi_1} d\xi/(1-\xi^2)$, where $\xi_1 = 1-[(1-k^2)/2]n_1^2/n_m^2$. Then the potential drop in the volume [i.e., the right side of the first equation in (5)] becomes

$$\frac{J_e}{D_e}\int\limits_0^L\frac{dx}{n}=\frac{J_e}{D_e}\frac{2\lambda L}{n_1}\ln\frac{2n_m}{n_1\sqrt{1-k^2}}. \qquad (13)$$

The logarithmic factor in (13) has various limiting values. In the absence of recombination [$n_m \ll n_a$, i.e., $k\approx 0$; see (7)] a valid expression is

$$\ln\frac{2n_m}{n_1\sqrt{1-k^2}}=\ln\frac{2}{\pi\delta},$$

which is the same as the expression obtained in ref. 3. If the recombination is substantial [$n_m \approx n_0$, i.e., $k\approx 1$; see (7)], then this factor increases sharply and its magnitude is determined by the small correction to the radical of Eq. (6). According to (9) and (10), we obtain

$$\ln\frac{2n_m}{n_1\sqrt{1-k^2}}=\ln\frac{2n_m}{n_1}+\frac{1}{2}\ln\frac{1}{r_0}=\ln\frac{n_m}{n_1\sqrt{2}}+\frac{n_1}{2\delta n_0}.$$

The structure of this expression indicates that all the basic changes in the potential drop related to the recombination are determined by the term $n_1/2\delta n_0$, which increases as n_1 increases. Actually, according to (12), $n_0\sim n_1^{\beta}$ and this leads to $n_1/2\delta n_0\sim n_1^{1-\beta}$. In this case $\ln n_m/n_1\sqrt{2}\leq \ln 2/\pi\delta$. Taking the above remarks into account we can approximate the logarithmic factor in (13) by

$$\ln\frac{2n_m}{n_1\sqrt{1-k^2}}=\ln\frac{2}{\pi\delta}\left(1+\frac{n_1}{2n_0\delta\ln\frac{2}{\pi\delta}}\right),$$

which has the correct limiting values for weak and strong recombination.

We introduce the dimensionless parameters

$$\left.\begin{gathered}U=\frac{eV}{T_e},\quad I=\frac{J_e}{J_R},\quad \Lambda=\ln\frac{2}{\pi\delta},\quad \varepsilon=\frac{4E_iD_a\Lambda}{T_eD_e},\\ \nu_1=\frac{n_1v_i}{J_R}\frac{E_i}{\varepsilon T_e},\quad \nu_{1*}=\frac{\pi\delta n_0(T_e^0)v_i}{\sqrt{2}J_R}=\frac{n_{1*}v_i}{J_R}\frac{E_i}{\varepsilon T_e}.\end{gathered}\right\} \qquad (14)$$

In this notation, the expression for the voltage–current characteristic becomes

$$\left.\begin{gathered}U-\frac{a}{I}=\frac{\varepsilon\nu_1}{I},\\ U-\ln\frac{I}{1-I}=\frac{I}{\nu}\left[1+\frac{\pi}{\Lambda\sqrt{8}}\left(\frac{\nu_1}{\nu_{1*}}\right)^{1-\beta}\right],\\ \frac{1}{T_e}=\frac{1}{T_e^0}-\frac{2\beta}{E_i}\ln\frac{\nu_1}{\nu_{1*}},\end{gathered}\right\} \qquad (15)$$

where, as before, $a = 2(1-T_1/T_e)$ and $\beta = E_i/(E_i+E_*)$. In a qualitative analysis we can neglect the variation of T_e with the current in the power and logarithmic functions, setting $a = 2(1-T_1/T_e^0)$ and $n_0(T_e) = n_0(T_e^0)\cdot(n_1/n_{1*})^{\beta}$ [see (12)]. Then the voltage–current characteristic can be written

$$\left(U-\ln\frac{I}{1-I}\right)\left(U-\frac{a}{I}\right)=\varepsilon+\frac{\pi\varepsilon}{\Lambda\sqrt{8}}\left(\frac{\nu_1}{\nu_{1*}}\right)^{1-\beta}, \qquad (16)$$

i.e., as a function of the parameters ε, a, ν_{1*}.

Under typical conditions $\varepsilon \leqslant 0.2$, which means that this parameter has little influence on the shape of the characteristic. The influence of the parameters a and ν_{1*} on the shape of the curve is more substantial. It follows from the structure of (16) that the voltage–current curve is in the region bounded by three intersection curves: the logarithmic asymptote $U_l = \ln I/(1-I)$, the hyperbola $U_h = a/I$, and the power curve $U_p = (\pi\varepsilon/\Lambda\sqrt{8})^{1/(1+\beta)}\cdot(I/\varepsilon\nu_{1*})^{(1-\beta)/(1+\beta)}$. The characteristic points on the curve are the inversion point (U_0, I_0) and the inflection point (U_{in}, I_{in}). A substantial role in the following discussion will be played by the point of intersection of the power-law and hyperbolic asymptotes $(U_1 I_1)$. These properties are shown in Fig. 1.

The introduction of the asymptotic curves allows us to formulate criteria for the influence of recombination. If the power asymptote goes to the left of the point of intersection of the asymptotes U_l and U_h the recombination is weak because the second term in the right side of (16) can be neglected. This term is much larger than ε (i.e., the recombination is substantial) if the point (U_1, I_1) has a much larger abscissa and a much smaller ordinate than the point of intersection of the logarithmic and hyperbolic asymptotes.

Typical families of voltage–current characteristic curves are shown in Fig. 2 for different values of a and $\varepsilon\nu_{1*}$. These curves contain the basic qualitative elements observed experimentally, i.e., they have segments of negative differential resistance, as well as inversions and inflection points that separate the segments of positive and negative curvature. For a certain relationship between the

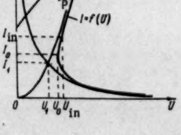

Fig. 1. The voltage–current characteristic and the asymptotic curves.

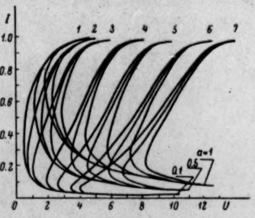

Fig. 2. Families of voltage–current characteristics with different degrees of recombination. 1) $(\varepsilon\nu_{*})^{-1} = 0$; 2) 250; 3) $2.6\cdot10^3$; 4) $3.3\cdot10^4$; 5) $1.2\cdot10^5$; 6) $3.6\cdot10^5$; 7) $6.6\cdot10^5$.

parameters a and ν_{1*}, for example $a = 0.1$ and $(\varepsilon\nu_{1*})^{-1} = 2.6\cdot10^3$ the voltage–current characteristic has a large linear segment (Fig. 2).

2. The complex, two-parameter family of curves (16) can be simplified by introducing new variables:

$$\left.\begin{aligned} &x=\frac{U}{U_1},\quad y=\frac{I}{I_1},\\ &U_1=\sqrt{\frac{\pi\varepsilon}{\Lambda\sqrt{8}}\left(\frac{a}{\varepsilon\nu_{1*}}\right)^{1-\beta}},\quad I_1=\sqrt{\frac{\Lambda\sqrt{8}}{\pi\varepsilon}a^{1+\beta}(\varepsilon\nu_{1*})^{1-\beta}}.\end{aligned}\right\}\qquad(17)$$

Then, in the coordinates x and y, Eq. (16) is written

$$(xy-1)\left[\frac{x}{y}-\frac{1}{U_1y}\ln\frac{y}{\frac{U_1}{a}-y}-\frac{\varepsilon}{U_1^2(xy-1)}-(xy-1)^{-\beta}\right]=0.\qquad(18)$$

This expression consists of two factors. Equating the first to zero, we obtain the hyperbolic asymptote, which approximates the falling branch of the voltage–current curve, i.e., that part below the inversion point (Fig. 1). Equating the second factor to zero, we obtain an approximation of the branch of the curve above the inversion point. We consider this case in more detail.

If the two terms of the second factor in (18) are negligible compared to the first two, we obtain an approximation for the characteristic in the saturation region – a logarithmic asymptote. If the relationship between the latter two terms satisfies $\varepsilon/U_1 \gg (xy-1)^{1-\beta}$ we obtain an expression for the characteristic in the absence of recombination. When $\varepsilon/U_1 \ll (xy-1)^{1-\beta}$, we have the characteristic of a process in which recombination is dominant:

$$(xy-1)\left[\frac{x}{y}-(xy-1)^{-\beta}-\frac{1}{U_1y}\ln\frac{y}{\frac{U_1}{a}-y}\right]=0.\qquad(19)$$

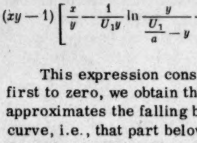

Fig. 3. Envelope (1) and families of voltage–current curves in the absence (2) and presence (3) of recombination for $a = 0.4$, $U_1 = 0.8, 2, 4, 8, 20$.

Equation (19) with parameters a and U_1 describes the family of curves with envelope

$$F(x,\ y)=x(xy-1)^{-\beta}-y=0,\qquad(20)$$

which consists of a falling branch ($y = 1/x$) and a segment with a positive derivative – a power asymptote [$y = x^{(1+\beta)(1-\beta)}$]. The inversion point $(x_0, y_0)|_{dx/dy=0}$ and the inflection point $(x_{\mathrm{in}}, y_{\mathrm{in}})|_{d^2y/dx^2=0}$ lie on the envelope. Any of the characteristic curves of a family with predominant recombination are to the right of the curve (20), lying closest to its middle section and on the falling branch. All nonrecombination characteristics in the middle section and on the falling branch are to the left of the envelope. Only in the saturation region can they enter the half-plane to the right of the envelope. Thus, the curve $F(x, y) = 0$ is a unique boundary for the recombination characteristics (Fig. 3).

We now analyze the envelope. The appropriate calculation gives the expressions

$$x_0=\beta^{-\beta/2}(1-\beta)^{\frac{\beta-1}{2}}=1.410,$$
$$y_0=\beta^{\beta/2}(1-\beta)^{-\frac{1+\beta}{2}}=1.568$$

for the coordinates of the inversion point. Calculating the inflection point, we obtain its coordinates

$$x_{\mathrm{in}}=\sqrt{\frac{2+\sqrt{1+3\beta^2}}{(1-\beta^2)\left(\frac{2+\sqrt{1+3\beta^2}}{1-\beta^2}-1\right)^{\beta}}}=1.521,$$

$$y_{\mathrm{in}}=\sqrt{\frac{2+\sqrt{1+3\beta^2}}{1-\beta^2}\left(\frac{2+\sqrt{1+3\beta^2}}{1-\beta^2}-1\right)^{\beta}}=3.174.$$

We now expand about the inversion point:

$$y=3.17+11.43(x-1.52),\qquad(21)$$

to obtain an approximate voltage–current characteristic from the inversion point to the point with coordinates $x = 2$, $y = 10$ to within 5%. The derivative $(dy/dx)|_{x_{\mathrm{in}},y_{\mathrm{in}}} = 11.43$ is the minimum value of the slope of all points of the characteristic above the inversion point.

We now consider the effect of the Richardson current on the voltage–current characteristic. On the falling branch ($y \approx a/x$) and in the saturation region [$y = U_1/a$, see (19)], the current is proportional to I_R by virtue of (17). According to these same equations and (21), in the neighborhood of the inflection point I_R has a weaker effect on the current across the converter. Here, $I \sim I_R^{(1+\beta)/2} \approx I_R^{0.77}$. Near the power asymptote ($y = x^{(1+\beta)/(1-\beta)}$) the current is independent of I_R. In this case the dimensional value of the current is

$$J=\left(\frac{\Lambda\sqrt{8}}{\pi\varepsilon}\right)^{\frac{\beta}{1-\beta}}D_e\frac{n_0(T_e^0)}{L},\qquad(22)$$

where Λ, $n_0(T_e^0)$, and ε are determined by (12) and (14). Equation (22) is satisfied when

$$\frac{JU}{a}\gg J_R\gg3\left(\frac{\Lambda\sqrt{8}}{\pi\varepsilon}\right)^{\frac{\beta}{1-\beta}}a^{\frac{1+\beta}{1-\beta}}D_e\frac{n_0(T_e^0)}{L},\qquad(23)$$

which, for experimentally reasonable values $\Lambda \approx 2$, $a \approx 0.1$ and $U \approx 10$ becomes

$$J \cdot 10^2 \gg J_R \gg 2 \cdot 10^{-2} D_e \frac{n_0(T_e^0)}{L}.$$

Consequently, (23) is self-consistent even for fairly large values of $D_e n_0(T_e^0)/I$, i.e., the parameters entering can be chosen so that the current across the converter is independent of I_R.

3. In ref. 5, the characteristic without recombination is compared to the experimental data and satisfactory agreement is noted for those experiments in which the voltage–current curves have a current saturation segment. In regard to the internal plasma parameters (n, T_e), it is found that in the middle of the electrode gap the density distribution is almost sinusoidal, and the electron temperature agrees to within 20% with the conditions for an ion discharge $\gamma L \approx \pi$. The characteristic does not agree with the experimental data in the quasisaturation region, where the Schottky effect is important.[5]

The above analysis indicates that the characteristic with recombination (19) contains all the elements usually observed for a family: a segment of negative differential resistance, a saturation region, and segments for the power and linear dependence of current on voltage (Fig. 2). This provides a basis for more detailed comparisons. As a start, we restrict the comparison to the relative values of the principal parameters: the density at the maximum and the electron temperature.

For a characteristic without recombination, T_e is independent of the current. The density at the maximum n_m is proportional to the density at the boundary. The variation with the current is expressed on the falling branch of the characteristic by

$$\frac{n_m}{n_m^*} = \left(\frac{J}{J^*}\right)^2 \tag{24}$$

and by

$$\frac{n_m}{n_m^*} = \frac{J}{J^*} \tag{25}$$

for the region near the inversion point (see ref. 5). (Throughout, n^*_m, T^*_e, and J^* are certain values of the density at the maximum, the electron temperature, and the current across the converter that are assumed for the curve of the family under analysis).

For characteristics with recombination we obtain from (15)

$$\frac{n_m}{n_m^*} = \left(\frac{J}{J^*}\right)^{\frac{2\beta}{1+\beta}}, \tag{26}$$

$$\frac{1}{T_e^*} - \frac{1}{T_e} = \frac{4\beta}{(1+\beta) E_i} \ln \frac{J}{J^*}. \tag{27}$$

Figures 4 and 5 give these functions and the experimental data published in refs. 6–8. The temperature is taken in the linear segment of the characteristic in the middle of the electrode gap. Evidently (27) correctly describes the current dependence, although the slope for this relation (Fig. 4) is lower than in experiment.

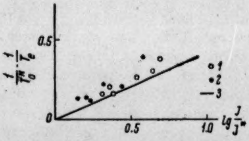

Fig. 4. Electron temperature as a function of current. 1) Data from ref. 6: p = 2-4 torr, T_1 = 1790-1900°K; 2) data from ref. 7: p = 1 torr, T_1 = 1065°K; 3) Eq. (27).

In the absence of recombination the density at the maximum has a quadratic or linear dependence on the current [see (24) and (25)]. When recombination predominates, n_m depends on the current according to a power law with an exponent $2\beta/(1+\beta) \approx 0.71$. Then, if the exponent is known for the dependence $n_m = f(J)$, one can determine whether or not the recombination affects the voltage–current characteristic. For example, the experimental data in ref. 5 do not correspond to the model given in ref. 5 but they give a much better fit with the recombination model of system (15).

For the observed families with curves having inversion points it is convenient to introduce coordinates similar to (17):

$$\left.\begin{aligned} x' &= \frac{x}{x_0} = \frac{U}{U_0} = \frac{V - \Delta\varphi_k}{V_0 - \Delta\varphi_k}, \\ y' &= \frac{y}{y_0} = \frac{I}{I_0} = \frac{J}{J_0}. \end{aligned}\right\} \tag{28}$$

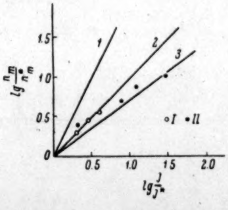

Fig. 5. Maximum density as a function of current. 1,2) Segment of the declining branch and the neighborhood of the reversal point without recombination; 3) theory with recombination included; I) data of ref. 7; II) data of ref. 8.

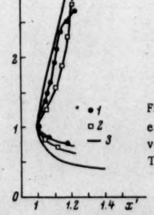

Fig. 6. Comparative behavior of the envelope (3) and the experimental voltage–current curves. p = 1.45 torr, T_1 (°K): 1) 1755; 2) 1805.

The advantage of these coordinates is that the electron temperature and Richardson current need not be known to analyze the voltage–current characteristic. Characteristics plotted in these coordinates have a common inversion point ($x' = 1$, $y' = 1$) and the relative slope in the region $y' > 1$ can be used to estimate the effect of recombination on the process. In Fig. 6, the experimental data of ref. 9 are compared with the envelope in x', y' coordinates. The experimental points for $y' > 1$ are fairly close to the envelope; for $y' < 1$ the agreement is not good. Evidently, the discrepancy between theory and experiment for regions below the inversion point is due to surface ionization, which is not taken into account in this model. This picture is even more convincing when one recalls that the ratio of the current at the inversion point to the diffusion saturation current is roughly 1.5.

In conclusion, the authors thank E. E. Sibir for compiling the experimental data.

Thermionic emission properties of zirconium, hafnium, and titanium nitrides in cesium vapor

M. A. Eremeev, V. S. Neshpor, A. B. Novikov, E. M. Stefanovskaya, and V. P. Fedorinov

M. I. Kalinin Leningrad Polytechnical Institute

(Submitted July 2, 1973)
Zh. Tekh. Fiz., 44, 2159-2167 (October 1974)

The thermionic emission of zirconium, hafnium, and titanium nitrides in vacuum and in cesium vapor is studied when the flux density of cesium atoms varies from $4 \cdot 10^{14}$ to 10^{18} cm^{-2} · sec^{-1}. The emitters acquire new stable thermionic emission properties as a result of a long exposure in cesium vapor. The work function of these materials in the high-temperature region is reduced considerably as compared with the values obtained before exposure to cesium vapor. There are reasons to believe that cesium incorporated into the volume of the nitride exists there in a chemically combined state.

The emission properties of the nitrides of the transition metals have not been studied to any great extent. There are only a few publications[1-3] in which values of the work functions of the nitrides of Ti, Zr, V, Nb, and Ta are given; there are no experimental data for the thermionic emission parameters of hafnium nitride.

There appear to be no data on the thermionic emission properties of nitride compounds in an atmosphere of alkali metal vapor.

Because of the particular characteristics of the crystal and electronic structure of nitrides it is likely that the thermionic emission of these materials in alkali metal vapor will be uncharacteristic of the alloys and the usual intermetallic compounds. We have therefore carried out an experimental investigation of the thermionic emission parameters of zirconium, hafnium, and titanium nitrides in vacuum and in cesium vapor.

It should be noted that the thermionic emission parameters of compounds of this type can depend on the method of fabricating the specimens, their purity, their thermal dissociation during the measurement, the presence of residual gases in the system, and also on the time they are heated before the measurements are made. These features are therefore given particular attention.

EXPERIMENTAL PROCEDURE

The thermionic emission properties are investigated in sealed-off glass tubes, the construction of which is shown in Fig. 1. All the emitters are placed simultaneously in a vacuum device, which enables us to compare their emission properties under identical vacuum conditions and under identical conditions for the deposition of cesium atoms on their surfaces.

To obtain a flow of cesium atoms over the surface of the specimens the whole device is placed in a large thermostat, and the extension with a small amount of cesium metal is placed in a small thermostat. The pressure of the cesium vapor in the tube, and consequently, the intensity of the flow of cesium atoms over the surface of the emitter, is governed by the temperature of the extension. The flux density of the cesium atoms can also be determined from the surface ionization current from a tungsten filament which is placed in the tube and serves as a control emitter.

The emitters are made in the form of wires approximately 400 μ thick. In order to obtain the purest and densest emitting surfaces chemical deposition in the gas phase[4,5] is used. A tungsten alloy wire (with 20% Re) 200 μ thick is used as the core of the cathodes. This alloy, unlike tungsten, molybdenum, and tantalum cores, preserves its plasticity when the nitride emitters are deposited, which considerably facilitates further processing.

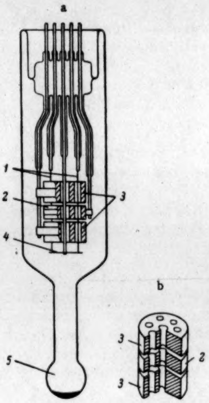

Fig. 1. Experimental device (a) and system of collectors (b). 1) Emitters; 2) measuring collector; 3) guard collectors; 4) flat tantalum spring; 5) reservoir for cesium.

The nitrides are deposited from a gas–vapor mixture containing the tetrachloride of the metal, nitrogen, hydrogen, and helium as inert diluents.

The nitride was deposited by a dissociation and exchange reaction of the gas–vapor mixture on the surface of the core in accordance with the overall equation of the reaction

$$\mathrm{MeCl_4} + 2\mathrm{H_2} + \frac{1}{2}\mathrm{N_2} = \mathrm{MeN} + 4\mathrm{HCl},$$

where Me = Ti, Zr, or Hf.

The thickness of the nitride coating is 70-100 μ. Data on the characteristics of the deposited nitride compounds are given in Table 1.

On the basis of data obtained under similar conditions[6] for more massive specimens we assume that the specimens investigated here have compositions that are approximately stoichiometric $(\mathrm{Me}_{1.0-0.97})$. This assumption is confirmed by data on the lattice periods of the nitride emitters in the initial state before their contact with cesium vapor. Analysis of x-ray powder interference patterns of the emitters shows that they contain a certain growth orientation with a predominance of the (h00) crys-

TABLE 1. Characteristics of the Nitride Emitting Layer on the Surface of a Core of W/20% Re Alloy

	before carrying out the experiments	after carrying out the experiments	before carrying out the experiments	after carrying out the experiments
TiN	4.213	4.245	1970±120	1890±110
ZrN	4.575	4.624	1220±106	1130±50
HfN	4.532	4.566	—	2190±250

tallographic planes in the emitter surface.

A chemical analysis of massive pyrolitic specimens of the nitrides, obtained under the same conditions, shows that they do not contain noticeable quantities of carbon and oxygen impurities (the overall content of these is less than 0.1%); the overall content of metal impurities does not exceed 0.12%. The zirconium nitrides contain up to 1.1% of hafnium impurity, while the hafnium nitrides contain up to 2.2% of zirconium impurity.

Before assembling the apparatus the surface of the emitter is polished with fine abrasive paper and subjected to electrolytic etching to obtain a smooth surface. No changes are observed in the lattice period and in the relative intensities of the x-ray lines of the specimens after this process.

The temperature of the operating part of the cathode is found by means of an LMP-066 optical micropyrometer taking account of the correction for the emission factor of the material.[7] We thus establish the relation between the temperature of the operating part and the heating current I_H for each emitter. To determine the temperature in the region below 1150°K the calibration curve $T = f(I_H)$ is extended by extrapolation into the region of lower values of I_H. During the measurements we also take account of the effect of the temperature of the large thermostat on the emitter temperature.

Unlike pure metals, the materials investigated are complex substances. Their surfaces, generally speaking, can be very nonuniform as far as work function is concerned; it is possible for the state to vary, depending on the duration and temperature of the heating which precedes the measurements, so that the thermionic emission constants can also vary. Hence, the emission properties of the compounds are first measured under vacuum conditions before they are measured in an atmosphere of alkali metal vapor.

During the measurements the pressure of the residual gases in the tube is less than 10^{-8} mm Hg. After determining the thermionic emission constants under thermionic vacuum conditions cesium is introduced into the

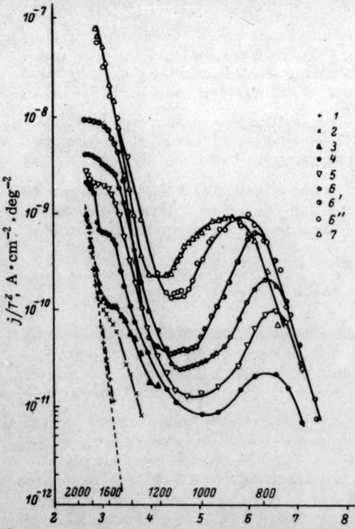

Fig. 2. Temperature dependence of thermionic emission of zirconium nitride for different flux densities of cesium atoms. The flux intensities of the cesium atoms $n \cdot 10^{17}$ (cm^{-2} · sec^{-1}) are: 1) 0.055; 2) 0.23; 3) 0.45; 4) 0.8; 5) 1.5; 6, 6', 6'') 2.5; 7) 10; the dashed curve is without cesium.

W	4.63±0.05	160	4.40±0.05	$-3 \cdot 10^{-5}$	1900—2400

tube without disturbing the vacuum.

To obtain data on the effect of cesium atoms on the emission of nitride cathodes, for each given value of the flux of the cesium atoms we plot a family of voltage–current characteristics for different emitter temperatures. The rectilinear parts of the voltage–current characteristics are extrapolated to zero field, and in this way we determine the values of the saturation current densities at a given temperature. The values obtained for the saturation current densities enable us to represent the data on the temperature dependence of the emission current in the form of the functions $\log (j/T^2) = f(5040/T)$ (so-called S curves). From these we calculate the work function by the total-current method, and determine its temperature dependence.

All the measurements are performed for each case.

RESULTS AND DISCUSSION

The results obtained for the emission properties of the nitride cathodes in vacuum are shown in Figs. 2-5; these confirm the stability of the thermionic emission of these materials and are independent of the annealing process.

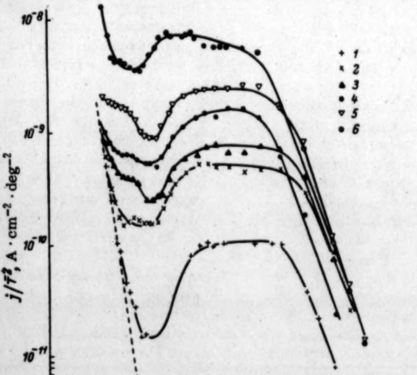

Fig. 4. Temperature dependence of the thermionic emission of titanium nitride for different flux densities of cesium atoms. The values of the flux intensities of the cesium atoms $n \cdot 10^{17}$ (cm^{-2} · sec^{-1}) are: 1) 0.055; 2) 0.23; 3) 0.45; 4) 0.8; 5) 1.5; 6) 2.5.

The values of the work function determined by Richardson's method and the total-current method are shown in Table 2. For comparison the table also gives data for a polycrystalline tungsten emitter. Figures 2-5 also show the results obtained in an atmosphere of cesium vapor.

The S curves obtained with a tungsten filament are found to be in good agreement with the data given in the literature,[8] and are not presented here. Unlike the curves for tungsten and other pure metals the S curves for zirconium, hafnium, and titanium nitrides do not exhibit a straight Richardson section corresponding to vacuum conditions. Beginning at a certain flux density of cesium atoms the curves show a kink, which becomes a "shelf" at high densities. The rectilinear parts of the curves in the high-temperature region change their slope as the flux density is increased, and shift towards lower temperatures. In the region of the maxima the curves do not have a common tangent, defining an optimum degree of coating. In addition, the S curves for the different emitters differ in the position of the extrema and the value of the current density for the same temperature and flux density.

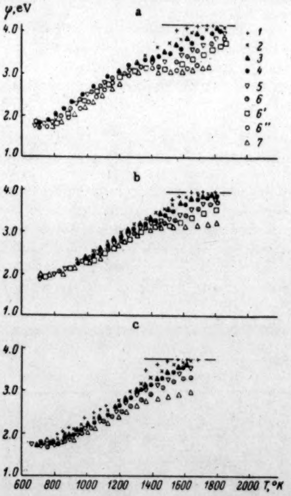

Fig. 5. Temperature dependence of the work function for different flux densities of cesium atoms. a) For zirconium nitride; b) for hafnium nitride; c) for titanium nitride. The values of the flux intensities of cesium atoms $n \cdot 10^{17}$ (cm^{-2} · sec^{-1}) are: 1) 0.055; 2) 0.23; 3) 0.45; 4) 0.8; 5) 1.5, 6, 6', 6") 2.5; 7) 10; the continuous curve is without cesium.

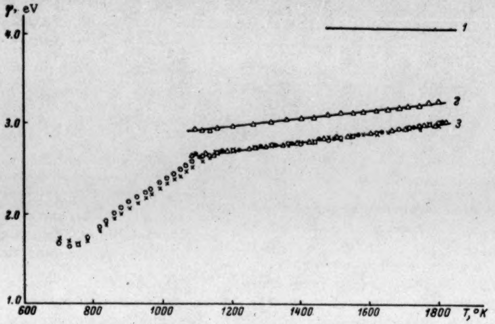

Fig. 6. Temperature dependence of the work function for zirconium nitride. 1) Without cesium; 2) in the intermediate stage of the experiment with $n = 4 \cdot 10^{14}$ $cm^{-2} \cdot sec^{-1}$; 3) at the end of the experiment with $n = 4 \cdot 10^{14}$ $cm^{-2} \cdot sec^{-1}$; 4) with $n = 4 \cdot 10^{14}$ $cm^{-2} \cdot sec^{-1}$ after emitting an ion current for three hours at T = 1860°K, and simultaneously freezing out cesium vapor with dry carbon dioxide; 5) $n = 10^{16}$; 6) $n = 10^{17}$ $cm^{-2} \cdot sec^{-1}$.

These features of the S curves of the nitride can be clearly seen from the curves of the temperature dependence of the work function shown in Fig. 5. As follows from Fig. 5, for each flux density of cesium atoms the work function increases as the emitter temperature is increased. However, the highest value of the work function for each emitter is not the same for all the curves of the family; as the flux density increases the maximum value of the work function falls.

It should be noted that the chronological sequence in which the curves are plotted is the same as the increase in flux density. Hence, the time for which the emitter remains in the atmosphere of cesium vapor increases as the flux increases.

The unusual form of the curves in Figs. 2-5 suggests that a change occurs in the material of the emitter itself while the measurements are being made. In order to check this possibility we again plot the S curves for the same flux densities of the cesium atoms. Figure 2 shows several S curves obtained for an emitter of ZrN for a flux density of $2.5 \cdot 10^{17}$ $cm^{-2} \cdot sec^{-1}$ ($T_{Cs} = 393$°K). In accordance with the sequence in which they were plotted, these curves indicate a reduction in the work function of the emitter with time.

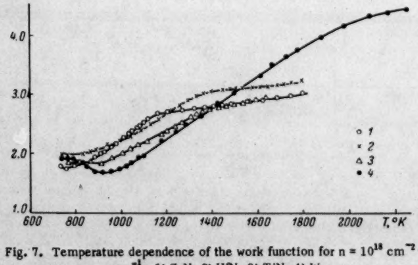

Fig. 7. Temperature dependence of the work function for $n = 10^{18}$ $cm^{-2} \cdot sec^{-1}$. 1) ZrN; 2) HfN; 3) TiN; 4) W.

The temperature dependence of the work function, obtained at different times for a flux density of the cesium atoms of $4 \cdot 10^{14}$ cm^{-2}/sec^{-1} ($T_{Cs} = 303$°K), also indicates a change in the emitter material due to exposure in an atmosphere of cesium. At the beginning of the measurements in cesium the work function of ZrN is the same as the work function obtained under vacuum conditions, and for an emitter temperature below 1500°K there is no appreciable thermionic emission current up to a vapor pressure corresponding to a flux density of cesium atoms of $2.5 \cdot 10^{16}$ $cm^{-2} \cdot sec^{-1}$; at an intermediate stage significant thermionic emission currents are observed even at a temperature of approximately 1100°K and a flux of $4 \cdot 10^{14}$ $cm^{-2} \cdot sec^{-1}$ ($T_{Cs} = 303$°K) (curve 2, Fig. 6). At the end of the measurements under these conditions curve 3 is obtained. It can be clearly seen from Fig. 6 that during the measurements the work function of zirconium nitride falls. Since the changes in the work function of the emitter are due to exposure to cesium vapor, it is natural to assume that when the electron current is emitted from it diffusion of cesium into the volume occurs. When a current of ions is emitted, diffusion to the surface must occur. Hence to answer the question of whether the change in the emitter is reversible, the specimens are annealed at a temperature T = 1860°K with the emission of a current of ions for three hours, with simultaneous freezing out of the cesium vapor with dry carbon dioxide. Curve 4, obtained with this treatment, is the same as the curve obtained previously. The agreement between these curves obviously indicates that there is no diffusion of cesium from the volume, or that the effect of this factor is negligible. In addition, the agreement between these curves indicates that the process by which the emitter changes at the end of the experiments is either completed or is close to completion. This is also confirmed by the thermionic emission data of ZrN, obtained at other vapor pressures of cesium, after the above-mentioned emitter changes had been completed. In the temperature range from 1200 to 1800°K they all lay on a single curve (Fig.

6). Hence, there can be no doubt that the change in the thermionic emission properties of zirconium nitride is due to its exposure to cesium vapor. A similar picture is also obtained for HfN and TiN, but is seen most clearly for ZrN. Thus, the final reduction in the work function for ZrN is 1 eV, for HfN it is 0.8 eV, and for TiN it is 0.7 eV.

Prolonged heating of these cathodes with the emission of an ion current and simultaneous freezing out of the cesium does not return them to their initial states, and there is no change in the thermionic emission properties obtained, which indicates the irreversible nature of the changes and their stability.

Figure 7 shows the temperature dependence of the work function for a flux density of cesium atoms of 10^{18} $cm^{-2} \cdot sec^{-1}$ ($T_{Cs} = 419°K$), for all nitrides after they had acquired stable thermionic emission properties. As follows from Fig. 7, the minimum values of the work function of zirconium and hafnium nitrides lie in the temperature range 700-750°K, i.e., almost 200°K lower than tungsten. Whereas the surface of a tungsten emitter can only be freed from cesium at a temperature of approximately 2100°K (the work function reaches values of 4.4 eV), titanium and hafnium nitrides are practically pure at a temperature of 1300°K, and zirconium nitride is practically pure even at 1100°K. The slight increase in the work function above these temperatures is most probably due to the positive temperature coefficient of the work function.

Hence, the temperature range over which a sharp change in the work function occurs due to desorption of cesium is extended by 300°K (from 800 to 1100°K) in zirconium nitride, and in tungsten this range is greater than 1000°K.

The very small temperature range over which almost complete desorption of cesium from the surface of the nitride occurs indicates the fairly low heat of evaporation of cesium from the material.

Hence, the changes which occur in the emitters during the measurements are due to their long exposure in an atmosphere of cesium vapor, and to the absence of any appreciable diffusion from the volume when the ion current is drawn off. Comparison of these factors leads to the conclusion that, obviously, sorption of cesium has a volume character, and the cesium is retained in the emitter by chemical bonding.

The changes in the emitters due to exposure to cesium vapor are also confirmed by qualitative spectral emission analysis after tests in cesium vapor, which showed that cesium is present in all the emitters in amounts greater than 1%. Specimens for analysis are made by chemical solutions of a layer of the emitter, in a mixture of fluoric and nitric acid. The solution is stopped, and the specimens are extracted from the solution as soon as the surface of the core is uncovered. Hence, the results obtained pertain only to the nitride layer.

We find no changes in the microstructure or external form of the emitters even after they have been exposed for a long time in air (for two months). This indicates that cesium impurity is present in the specimens in a chemically combined state. In favor of this idea is the increase in the lattice period of nitride emitters after they have been operating in cesium vapor, which is outside the limits of the accuracy of the measurements (Table 1), which may be due to implantation of the larger ions of cesium in the lattice of the nitride. As can be seen from Table 1, the greatest implantation of cesium occurs in an emitter of zirconium nitride.

A determination of the lattice periods of nitride emitters immediately after their removal from the apparatus and after long exposure in air does not reveal any changes.

Bearing in mind the results obtained in ref. 9 in a study of the properties of a number of carbide emitters in cesium vapor, we conclude that the implantation of cesium is probably peculiar to the majority of refractory compounds with an NaCl-type structure.

In conclusion we wish to thank V. V. Sokolov, who helped to fabricate the emitters.

Electron energy spectrum in high-energy nanosecond accelerators

V. V. Kremnev, G. A. Mesyats, and V. P. Reznikov

Atmospheric Optics Institute, Siberian Branch,
Academy of Sciences of the USSR, Tomsk

(Submitted July 13, 1973; resubmitted February 13, 1974)
Zh. Tekh. Fiz., 44, 2168-2173 (October 1974)

The effects of matching the storage line to the diode, the switching time, and circuit inductance on the electron energy spectrum of an accelerator beam are considered. The spectrum is analyzed for a linear load, a diode with a field emission cathode, a diode with a thermionic cathode (three-halves law) and a diode with explosive electron emission. Relationships are obtained for the spectrum amplitude and half-width and for the maximum electron energy in the beam. Equations are derived for estimating the effects on the energy spectrum of the electron beam of movement of the plasma front in a diode with explosive emission and of retardation in a foil at the diode output.

INTRODUCTION

Powerful nanosecond electron beams are usually obtained by discharging a storage line through a switch and vacuum diode.[1] If it is assumed that the switch is perfect, i.e., that it switches instantaneously from the nonconducting to the conducting state, that the resistance of the diode is exactly equal to the characteristic impedance of the line and that there is no inductance in the circuit, then the electrons which arrive at the anode must be strictly monoenergetic. It is not possible to achieve these conditions in real accelerators. The energy characteristics of the beam then depend on the discharge circuit, the switch, the emission mode, and processes in the diode; they also depend on the way the electron beam is extracted into the drift space. Since the switching time t_s and the time constant L/R (L is the inherent inductance of the circuit and R is the characteristic impedance of the line) are comparable with the lifetime of the nanosecond beams, the electron energy spectrum is usually very wide, several tens of per cent. The greater the electron current and the smaller the beam lifetime the wider the spectrum; this is the case because the switching time increases with the current, as does the value of L/R (owing to the reduction in R).

In this paper we analyze the effect of these factors on the spectral characteristics of the beam.

1. PRINCIPAL RELATIONSHIPS

The spectral characteristic of the beam gives the number of electrons Δn in the energy range from W to $W+\Delta W$, i.e, $\Delta n=(dn/dW)\Delta W$, where n is the total number of electrons. We assume in what follows that the beam electrons at the diode output are monochromatic and that the electron energy is defined by the potential difference applied to the diode. These conditions are satisfied when the electron thermal velocity is much smaller than the velocity at the anode and if no collective processes arise in the diode, leading to acceleration or retardation. The energy distribution function for the electrons can then be written

$$\frac{dn}{dW}=\frac{I(t)}{e}\frac{dt}{dW}, \tag{1}$$

where $W = eU(t)$, $U(t)$ is the potential across the diode at some fixed instant of time t, $I(t)$ is the electron current in the diode and e is the electron charge.

Thus, if we know the diode voltage and current, we can calculate the energy spectrum of a beam of electrons arriving at the anode of an accelerator diode.

Calculations have been carried out for the following voltage–current characteristics:

a diode with a linear characteristic

$$R_L=\frac{U(t)}{I(t)}=\text{const}, \tag{2}$$

a diode subject to the three-halves law

$$R_L=4.3\cdot 10^5\frac{d^2}{S}U(t)^{-0.5}, \tag{3}$$

and a diode with a field-emission cathode[2]

$$R_L=\frac{6.4\cdot 10^5\varphi d^2}{[U(t)\mu^2 S]}\exp\left[\frac{6.85\cdot 10^{-7}\varphi^{3/2}}{U(t)\mu}\Theta\left(\frac{1.32\cdot 10^{-7}U(t)\mu}{\varphi^2 d}\right)\right], \tag{4}$$

where Θ is the Nordheim function, which we have approximated (with an error of less than 1%) by the equation

$$\Theta(y)=1-0.5(y+y^{3/4}),$$

φ is the work function (eV), d is the length of the vacuum gap in the diode (cm), S is the emission area of the cathode (cm²), μ is the magnification of the field at a cathode whisker. The number of whiskers $n_0 \approx S/S'$, where S' is the effective emission area of a single whisker. Calculations using (4) have been performed for a tungsten cathode with an electric field $E_0 = U_0\mu/d = (9.3, 16, 22)\cdot 10^7$ V/cm. The principal relationships for the three-halves diode and the field-emission cathode diode are obtained by numerical solution. The movement of the cathode plasma in a diode with explosive emission is taken into account in Sec. 4.

2. EFFECT ON THE SPECTRUM OF MISMATCH BETWEEN STORAGE LINE AND DIODE

If $R_L > R$, $L = 0$, $t_s = 0$ (perfect switch), then with a linear load a series of voltage pulses is applied to the diode and we get a line spectrum (Fig. 1b). The final magnitude of these lines can be found by normalizing them to the amplitude of the spectral line at $R_L = R$ and $L = 0$, $t_s \to 0$, i.e., by $(dn/dW)_c$. Then for a linear load

$$\frac{\left(\frac{dn}{dW}\right)}{\left(\frac{dn}{dW}\right)_c}=2b\sum_{i=1}^{\infty}a_0^{i-1}\varphi(x-x_i), \tag{5}$$

where i is the number of the spectral line,

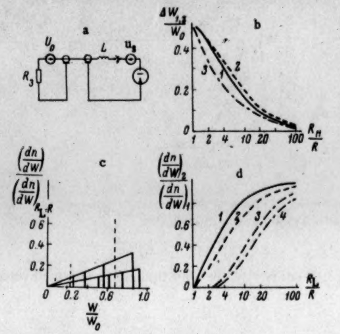

Fig. 1. a) Circuit for forming electron beam; b) typical spectral characteristics $R_L > R$ (dashed lines $R_L/R = 2$, continuous lines $R_L/R = 5$ and 10); c) Curves of $\Delta W_{1,2}/W_0$; d) curves of $(dn/dW)_2/(dn/dW)_1$. 1) Diode with linear load; 2) diode with 3/2 law; 3 and 4) field-emission diode with $E_0 = (16$ and $9.3)\cdot 10^7$ V/cm, respectively.

$$x_i = \frac{\frac{R_L}{R}}{1+\frac{R_L}{R}} a_0^{i-1}, \quad a_0 = \frac{\frac{R_L}{R}-1}{\frac{R_L}{R}+1},$$

$$b = \frac{1}{1+\frac{R_L}{R}},$$

$$\varphi(x-x_i) = \begin{cases} 0 & \text{for} \quad x \neq x_i, \\ 1 & \text{for} \quad x = x_i. \end{cases}$$

A line spectrum is also obtained for the other diode. The diode resistance during the time interval $0 < t < 2T$, where T is the electrical length of the line, is used as the criterion in these cases.

For a slight mismatch, with $R_L/R \approx 1$, the spectrum consists of a small number of lines very different in amplitude and energy level; for a severe mismatch, with $R_L/R \gg 1$, the spectrum can be characterized by the width of the envelope drawn through the 0.5 amplitude points of the line.$^{1)}$ For cases (2) and (3), the width of this envelope, referred to the maximum spectrum energy $\Delta W/W_M$, is independent of R_L/R. Thus for a linear load $\Delta W/W_M = 0.5$ and for a three-halves diode $\Delta W/W_M = 0.37$. For a diode with a field emission cathode the parameter varies weakly with R_L/R and is approximately equal to $\Delta W/W_M \approx 0.075$ and 0.1 for fields of $E_0 = (9.3$ and $16)\cdot 10^7$ V/cm, respectively. With a slight mismatch ($R_L/R \approx 1$) it is more convenient to use the relation

$$\frac{W_M - W_2}{W_0} = \frac{\Delta W_{1,2}}{W_0},$$

where W_2 is the energy of the second line in the spectrum. These relations are given for the various diodes in Fig. 1c. It is of interest to determine the ratio of the amplitudes of two neighboring lines $(dn/dW)_2/(dn/dW)_1$. This ratio is shown in Fig. 1d and for a diode with a linear load is

$$\frac{\left(\frac{dn}{dW}\right)_2}{\left(\frac{dn}{dW}\right)_1} = \frac{\frac{R_L}{R}-1}{\frac{R_L}{R}+1}.$$

It can be seen from Fig. 1d that nonlinearity of the diode characteristics brings about a decrease in the height of the following spectral line. The advantage of the field-emission cathode is indicated by the physics of the electron field-emission process, for which a small reduction in the field E at time $t \geq 2T$ causes a significant decrease in the current and, hence, in the amplitude of the second spectral line. However, if the field E_0 is increased, the field-emission electron emission from the whiskers approaches saturation and a change in E at $t \geq 2T$ has little effect on the current. The second spectral line therefore approaches the first in amplitude.

3. EFFECT OF THE SWITCHING TIME AND CIRCUIT INDUCTANCE ON THE SPECTRUM

The effect of the switching process on the electron spectrum is allowed for by assuming[1] that the voltage across the switch is given approximately by the function $U_s = U_0 e^{-at}$, where $a = 2.2/t_s$ and t_s is the switching time during which the voltage falls from $0.9\,U_0$ to $0.1\,U_0$. In the calculations we take $L = 0$, $R_s = R$ for $t \to \infty$. Only the time interval $0 < t < t_I$ is considered, where $t_I = 2T$.

The energy spectrum is characterized by the amplitude $(dn/dW)_M$, the maximum electron energy W_M and the width of the spectrum at $0.5\,(dn/dW)_M$, equal to ΔW. Figure 2, a, b, and c shows these characteristics as a function of the parameter t_I/t_s. It can be seen from Fig. 2c that ΔW depends strongly on the switching time and this is most marked for a linear load and least noticeable for a field-emission cathode diode. When $t_I/t_s > 2$, the spectral width is less than 1% of the maximum value W_M.

The effect of the inductance L on the electron spectrum is calculated for the case of an ideal switch ($t_s = 0$)

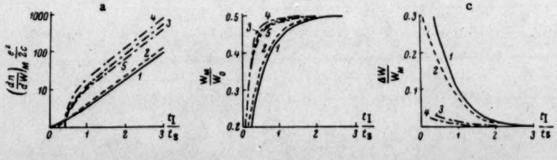

Fig. 2. Curves of $(dn/dW)e^2/2C$ (a), W_M/W_0 (b), and $\Delta W/W_M$ (c) for different diodes vs the parameter t_I/t_s. The notation for curves 1-4 is the same as in Fig. 1; 5) diode with field-emission cathode and $E_0 = 2.2\cdot 10^8$ V/cm. C is the capacity of the storage line.

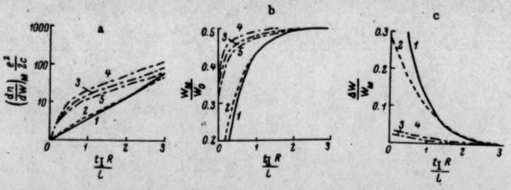

Fig. 3. Curves of $(dn/dW)_M e^2/2C$ (a), W_M/W_0 (b), and $\Delta W/W_M$ (c) for various types of diode against the parameter $t_I R/L$. The notation for curves 1-5 is the same as in Figs. 1 and 2.

in the time interval $0 < t < t_I$ with $R_L = R$. The results are shown in the curves of Fig. 3, a, b, and c. It follows from these curves that when $(R/L)t_I > 2.5$, the width of the spectrum is not more than 2% of the maximum energy. The width decreases rapidly with increasing $(R/L)t_I$ and, as in the case of a nonideal switch, the width decreases with an increase in the nonlinearity of the voltage–current curves.

4. EFFECT OF OTHER PROCESSES ON THE ELECTRON SPECTRUM

According to ref. 3, the voltage–current relationship for a diode in which the electron emission results from the explosion of whiskers on the cathode follows a 3/2 law. It must be remembered, however, that the emission boundary in such a diode moves from the cathode to the anode at a velocity $v = 2 \cdot 10^6$ cm/sec. This can be allowed for by changing from d^2 to $(d - vt)^2$ in (3). If the diode is matched to the storage line at $t = 0$, it will become mismatched at times as a result of the decrease in resistance caused by the reduction in the interelectrode gap. This leads to a broadening of the spectral lines for an ideal accelerator ($t_s = 0$, $L = 0$) when $0 < t < t_I$ and $vt/d \gg 1$:

$$\frac{\Delta W}{W_0} \approx \frac{vt}{d}. \tag{6}$$

When the line is mismatched with an explosive emission diode, the electron current pulses which arise as a result of the reflected voltage pulses cannot be calculated in the same way as for other diodes. During the interval between voltage pulses the diode becomes filled with the plasma formed by the explosion of the whiskers. This leads to a reduction in the effect of the electron space charge on the diode current and to an increase in this current.[1]

Since the electron beam is usually extracted from the diode through a metal foil at the anode, the spectrum undergoes an additional broadening. According to ref. 4, the half-width of the spectrum for a monoenergetic electron beam with energy W_0 exiting through a foil of thickness δ(cm) is given by

$$\frac{\Delta W}{W_0} \approx \frac{4\xi}{W_0}, \tag{7}$$

where $\xi = 0.154\, Z\rho\,\delta/A\beta^2$ (MeV), Z and A are the atomic number and weight of the foil element, ρ is the density of the foil (g/cm³), $\beta = v_0/c$, c is the velocity of light and v_0 is the velocity of an electron with energy W_0. Equation (7) was obtained for $\xi \gg I^*$ and $\xi \ll W_0/2$, where I^* is the average ionization energy of the atoms in the substance, $I^* \approx 13.5\, Z \cdot 10^{-6}$ MeV. The most probable energy (i.e., the energy for which the electron distribution function is a maximum) is given by

$$\frac{W_M}{W_0} = 1 - \left(\frac{\xi}{W_0}\right)\left[\ln\left(\frac{\xi}{y}\right) + 0.373\right], \tag{8}$$

where

$$\ln y = \ln\left(\frac{1-\beta^2}{2\beta^2}\,\frac{I^{*2}}{mc^2}\right) + \beta^2,$$

m is the rest mass of the electron. It follows from (7) and (8) that when $\xi W_0 < 0.01$, it is possible to neglect the effect of the foil on the electron spectrum. With an aluminum foil, for example, of thickness 20 μ and an electron beam of 1 MeV, we have $\rho = 2.7$ g/cm³, $Z = 13$, $A = 27$, $\beta \approx 1$, $\xi = 4 \cdot 10^{-4}$ MeV, $\Delta W/W_0 \approx 1.6 \cdot 10^{-3}$, $W_M/W_0 \approx 0.996$. Thus the effect of the foil is small in this case.

---

1) It should be noted that the case $R_L/R \gg 1$ is not typical of accelerators and is included here only for completeness.

Electronics

Shot noise in a thermionic cathode

A. F. Golubentsev and A. S. Shapovalov

N. G. Chernyshevskii Saratovsk State University

(Submitted October 22, 1973; resubmitted March 18, 1974)
Zh. Fiz., 44, 2174-2177 (October 1974)

One of the causes of shot noise in thermionic cathodes is investigated. The spectral density of the current fluctuations from a cathode whose emission undergoes random changes in time is calculated. The noise level of such a cathode exceeds the value given by Schottky's equation by an order of magnitude. The results can be used to calculate the spectral density of the current fluctuations for any distribution of the time intervals between the emission of successive electrons. Numerical results are given for the case in which the distribution is given by the sum of two exponentials with appropriate weighting factors.

Experimental investigations of efficient thermionic cathodes, in particular oxide cathodes, show that in a number of cases the shot noise level can exceed the value given by the Schottky equation[1-3] by a significant amount. In this paper we analyze one of the possible reasons for the anomalous shot effect.

Schottky's equation is derived on the assumption that the distribution density of the time interval τ between emission of two successive electrons is described by an exponential:[4,5]

$$f(\tau)=\lambda e^{-\lambda\tau}. \tag{1}$$

The parameter λ in this distribution represents the intensity of the electron emission process and is equal to the average number of particles emitted per unit time. Analysis of the physical–chemical processes taking place at the surface and in the bulk of the emitter shows that the "equilibrium" is not static, but dynamic in character.[6-8] Consequently, the intensity of the electron emission process λ is subject to random variations with time, and the cathode passes successively through a large number of "emission states." For this reason the distribution density of the interval τ for a practical cathode cannot always be described by the distribution (1). Hence, in this paper we calculate the spectral density of the cathode emission current fluctuations for an arbitrary distribution for the interval τ. The numerical results are presented for the case in which the distribution density of τ is described by the sum of two exponential laws with appropriate weighting factors.

The emission current observed in the plane of the emitter is represented by a random pulse process of the form

$$i(t)=\sum_{\nu=-\infty}^{\infty} e\delta(t-t_\nu),$$

where e is the electron charge, $\delta(t)$ is the delta function, and t_ν is the time an electron is emitted with index number ν. The spectral density of the current fluctuations $S_i(\omega)$ is given by[3]

$$S_i(\omega)=\lim_{T\to\infty}\frac{1}{2\pi T}M\{|i_T(\omega)|^2\}.$$

Here $i_T(\omega)=\int_{-\infty}^{+\infty} i_T(t)e^{-j\omega t}dt$ is the Fourier transform of the truncated current sample $i_T(t)$,

$$i_T(t)=\begin{cases} i(t) & \text{for } |t|\leqslant\frac{T}{2},\\ 0 & \text{for } |t|>\frac{T}{2},\end{cases}$$

and M is the mathematical expectation.

Suppose that in the time interval $(-T/2, +T/2)$ there are 2N+1 current pulses, i.e., $T\simeq(2N+1)\bar{\tau}$, where $\bar{\tau}$ is the mathematical expectation for the time interval between emission of two successive electrons. (We choose the origin of the time axis to be the time an electron is emitted with index number $\nu=0$.) Then

$$i_T(t)=\sum_{\nu=-N}^{N} e\delta(t-t_\nu),$$

$$i_T(\omega)=i_N(\omega)=\sum_{\nu=-N}^{N} ee^{-j\omega t_\nu},$$

$$S_i(\omega)=\lim_{N\to\infty}\frac{1}{2\pi(2N+1)\bar{\tau}}M\{|i_N(\omega)|^2\}.$$

Writing $|i_N(\omega)|^2$ in the form of a double sum

$$|i_N(\omega)|^2=\sum_{\nu=-N}^{N}\sum_{\mu=-N}^{N} e^2e^{-j\omega t_\nu}e^{j\omega t_\mu}$$

and carrying out simple calculations, we obtain

$$S_i(\omega)\doteq\frac{1}{2\pi\bar{\tau}}\left\{e^2+\sum_{p=1}[h_p(\omega)+h_p(-\omega)]\right\}, \tag{2}$$

where

$$h_p(\omega)=e^2M\{e^{-j\omega(t_\nu-t_\mu)}\},\quad p=\nu-\mu.$$

Since the intervals $\tau_i=t_{i+1}-t_i$ are independent and obey the same distribution we have

$$h_p(-\omega)=e^2[\varphi(\omega)]^p,\quad h_p(\omega)=e^2[\varphi^*(\omega)]^p, \tag{3}$$

where

$$\varphi(\omega)=M\{e^{j\omega\tau}\},\quad \varphi^*(\omega)=M\{e^{-j\omega\tau}\}.$$

Substituting Eq. (3) into Eq. (2), we obtain the final expression for the spectral density of the emission current fluctuations:

$$S_i(\omega)=\frac{eI_0}{2\pi}\left[1+2\,\mathrm{Re}\,\frac{\varphi(\omega)}{1-\varphi(\omega)}\right], \qquad (4)$$

where $I_0 = e/\bar{\tau}$ is the mean value of the current.

It is easy to show that for an exponential distribution of the interval τ the second term in Eq. (4) is zero, and the expression obtained is the same as Schottky's equation. In the general case this term is not zero.

For the frequencies used in electronics (including microwave frequencies) and practical currents I_0, the inequality $\omega\bar{\tau} \ll 1$ is satisfied. Expanding $M\{e^{j\omega t}\}$ in a power series and confining ourselves to terms of second order we find that for $\omega \ll 1/\bar{\tau}$ the quantity $S_i(\omega)$ is independent of frequency, being given by

$$S_i(\omega)=\frac{eI_0}{2\pi}v^2,$$

where $v = \sigma_\tau/\bar{\tau}$ is the variance of the interval, and σ_τ^2 is the dispersion of the interval.

To obtain numerical results we must make certain assumptions regarding the form of the distribution density of τ. We assume that the i-th emission state of the cathode is represented by a constant value of the intensity λ_i, the conditional distribution density of τ within a single state is described by the exponential law (1) with $\lambda = \lambda_i$, and the change of emission states is a Markov process. Then the unconditional distribution density of the interval will be given by a sum of exponentials with weighting factors which have a meaning of the probability p_i of the corresponding emission state. For simplicity we will assume that the cathode can operate under two conditions which are represented by $\lambda = \lambda_1$ and $\lambda = \lambda_2$ $(\lambda_1 > \lambda_2)$. For this mode of cathode operation the distribution density of the interval can be written

$$f(\tau)=p_1\lambda_1 e^{-\lambda_1\tau}+p_2\lambda_2 e^{-\lambda_2\tau}. \qquad (5)$$

Using Eq. (5) and assuming that $p_1 + p_2 = 1$, we find the initial times of the interval

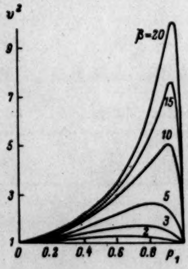

Fig. 1. The square of the variance of the interval v^2 as a function of the probability p_1 for different β.

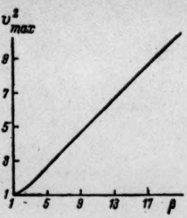

Fig. 2. The maximum value of the square of the variance of the interval $v^2_{\max}$ as a function of β.

$$\bar{\tau}=\frac{p_1}{\lambda_1}+\frac{1-p_1}{\lambda_2}, \quad \bar{\tau^2}=2\left(\frac{p_1}{\lambda_1^2}+\frac{1-p_1}{\lambda_2^2}\right)$$

and the square of the variance

$$v^2=1+2(\beta-1)^2\frac{p_1(1-p_1)}{[(1-p_1)\beta+p_1]^2}, \qquad (6)$$

where $\beta = \lambda_1/\lambda_2$ is a coefficient which represents the drop in the emissive power of the cathode when its modes of operation change.

Curves of v^2 as a function of p_1 for different β are shown in Fig. 1. For p = 0 and $p_1 = 1$ or $\beta = 1$ the functions (1) and (5) are the same and $v^2 = 1$. Consideration of the remaining cases shows that the shot noise level of a cathode with this emission mechanism can exceed several-fold the value given by the Schottky equation. The value of v^2 increases as the parameter β increases, and for $\beta = 20$ and $p_1 = 0.95$ reaches a value of 10. For each value of β a certain probability $p_1 = p_{1\max}$ exists for which the square of the variation coefficient is a maximum: $v^2 = v^2_{\max}$. These values of the parameters are given by the following expressions, which are obtained from an analysis of Eq. (6):

$$p_{1\max}=\frac{\beta}{1+\beta}, \quad v^2_{\max}=1+\frac{(1-\beta)^2}{2\beta}.$$

A curve of $v^2_{\max}$ as a function of β is given in Fig. 2. The numerical results shown in Figs. 1 and 2, and a direct analysis of (4) and (6) show that a cathode operating mechanism similar to that considered may be one of the reasons for the considerable increase in the shot noise level of emitters.

Use of a field-emission microscope to measure the pressure of pump oil

V. Ya. Pliskovskii, M. S. Sukonnik, and V. A. Shishkin

(Submitted May 28, 1973)
Zh. Tekh. Fiz., 44, 2178-2185 (October 1974)

We describe a method for measuring the background pressure of pump oil in vacuum systems by means of a field-emission microscope. The oil molecules accumulate on a cold tungsten field-emission cathode for controlled times and undergo thermal decomposition when the cathode is heated to T = 1400°K. The emission images corresponding to the chemisorption of pyrolytic carbon on the tungsten surface are analyzed. The functional relationship between the oil vapor pressure and the time over which the surface coverage of oil is built up (required to calibrate the emission images of the pyrolytic carbon) is determined by adsorption, on the cathode, of oil evaporated from a Knudsen molecular source. As the emitter is heated the probability that the tungsten surface will capture carbon from the adsorbed oil film depends on the ratio of the flux of the oil vapor and the residual gas during the period over which the oil accumulates on the surface. This method can be used to measure oil-vapor fluxes in the range $1 \cdot 10^{9}$-$1 \cdot 10^{13}$ $cm^{-2} \cdot sec^{-1}$; the maximum measurement error is ± 50%.

INTRODUCTION

In many problems of experimental and applied physics it is necessary to have a quantitative knowledge of the backstreaming of vacuum-oil vapor into the system from the pumping system. Vacuum oils are large-molecule fluids, usually complex hydrocarbons. Since the behavior of such compounds is quite different from that of permanent gases,[1] and since serious technical difficulties arise,[2] mass-spectrometer analysis of these compounds is not very useful. Because of their high heat of adsorption, molecules of vacuum oils can accumulate on the walls of the tubing and leak into the evacuated apparatus by surface migration, while their concentration in the gas phase remains below the sensitivity of the mass spectrometer. It is thus advisable to determine the amount of oil vapor by measuring the surface concentration of the oil molecules. Most of the methods based on this principle are either technically elaborate or relatively insensitive.[3-8] Field microscopy is one of the simplest and most sensitive of such methods; the ability of a field-emission microscope to detect hydrocarbon molecules in vacuum was demonstrated long ago[9,10] and has been exploited for qualitative purposes.[11,12] It can also be used for quantitative measurements.[13] One possible procedure is to allow the oil molecules to accumulate on the surface of a cold tungsten field-emission cathode and then thermally decompose these molecules to carbon; the carbon, by becoming chemisorbed on the emitter surface, produces characteristic field-emission images with a sharp concentration gradation ("calibration emission images"). The concentration of chemisorbed carbon is proportional to the surface concentration of oil molecules which, in turn, is proportional to the flux incident on the emitter surface from the volume. With the appropriate calibration a quantitative relationship can be established between the surface concentration of carbon and the flux of oil vapor.

Below we describe the basic aspects of the method of calibration emission images, the actual procedure followed, and the results of calibrations carried out for types VM-5 and 5F4É oils under various vacuum conditions.

1. EXPERIMENTAL PROCEDURE

a) Experimental apparatus. The glass apparatus shown schematically in Fig. 1, consists of the field-emission microscope and a Knudsen molecular source, sealed to the microscope.[14] The limiter of the source is covered by a ground seal 1 by means of a magnet. In a side arm of the source, connected to the evacuation system, is an ampoule 2 containing oil which has been outgassed in vacuum. At the desired time this ampoule is broken against the wall by another magnet, and the oil spills into the source, held at a constant temperature by the vapor of a boiling coolant.

Figure 2 shows the shape of the source limiter. Its area is measured by optical projection with a magnification of 20 ×. The functional dependence of the vapor pressure on the temperature is determined beforehand with an absolute pendulum gauge[15] within ± 3% for the lots of type VM-5 vaseline oil and 5F4É polyphenyl ester chosen for the experiments.

Two versions of the apparatus, differing in the area of the source limiter, are evacuated by an oil-free apparatus with a limiting residual pressure of $1 \cdot 10^{-9}$ torr. The residual gas pressure is determined by an IM-12 gauge in the immediate vicinity of the instruments.

b) Experimental procedure. After the limiting residual pressure is reached in the apparatus the ampoule is broken, and the oil flows into the source. To achieve an equilibrium oil vapor pressure in the source ($1 \cdot 10^{-4}$-$1 \cdot 10^{-5}$ torr, varying with the type of oil), we heat the source for a long time with the vapor of a boiling

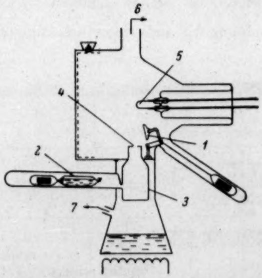

Fig. 1. Experimental apparatus. 1) Seal; 2) ampoule containing oil; 3) source; 4) limiter of source; 5) tungsten tip (the field-emission cathode); 6) pump; 7) reverse refrigerator.

coolant (water or metaxylene) with the limiter covered.

Immediately before an experiment the cleanliness of the emitter surface is checked from its emission image; if necessary, contaminants are removed by briefly heating the emitter to ~2600°K ("flashes"). After the emitter cools to room temperature the source is opened for the desired time. The adsorbed oil decomposes as the emitter is heated to ~1400°K for 20 sec; then the cathode is recooled to room temperature, a high voltage is supplied to the screen of the field-emission microscope, and the emission image is photographed.

After the emitter has been cleansed of carbon by repeated flashes and the emission image corresponding to the clean tungsten surface has been restored the entire procedure is repeated with a longer exposure. These cycles are continued until the tungsten surface becomes saturated with carbon, at which point the decomposition of more adsorbed oil does not cause any further change in the emission image.

In experiments on the effect of the residual-gas flux on the experimental results the pressure in the microscope is varied by varying the pumping rate.

c) A few necessary equations. The surface concentration of the oil on the emitter and the corresponding flux of oil vapor can be calculated with the help of Fig. 2. The flux Q of a vapor whose molecular weight is M, whose vapor pressure is p, and which is flowing through a limiter of diameter S from a source at temperature T is, under molecular-flow conditions,

$$Q = 3.51 \cdot 10^{22} \frac{pS}{\sqrt{MT}} \text{ sec}^{-1}, \tag{1}$$

where S is in square centimeters, p is in torr, and T is in Kelvin degrees.

The flux incident on a small plane area a distance r from the source is[14]

$$\nu_1 = \frac{Q}{\pi} \frac{\cos\theta \cos\varphi}{r^2}, \tag{2}$$

where θ is the angle between the normal to the small area and the flux direction, and φ is the angle between the normal to the source and the flux direction.

In calculating the surface concentration of oil on the tungsten field-emission cathode we take the following circumstances into consideration:

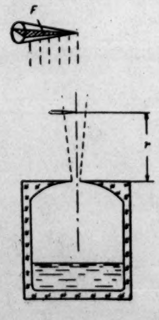

Fig. 2. Diagram used to calculate the surface concentration of oil on the emitter.

1. The literature reveals no information on the heats of adsorption q for vacuum oils on metals. However, it gives[16] q = 102 kcal/mole for ethylene on tungsten, so we can assume the heat of adsorption of an oil on a clean tungsten surface to be higher than this value. Even in the case of physical adsorption in the second layer the value of q should be no lower than the heat of vaporization, some 27-30 kcal/mole for vacuum oils.[17] The sticking probability for a substance with $M > 400$ and $q \geq 30$ kcal/mole can be set equal to unity.

2. For these values of q the lifetime of the molecules in the adsorbed state (~10^8 sec, according to the equation given by Frenkel') is much longer than the experimental time over which the oil film is deposited on the emitter (< 10^4 sec). We can thus neglect desorption of the oil.

3. At T = 300°K the rate of surface migration of adsorbed oil molecules is a few microns per second;[18] a simple geometric calculation shows that the concentration equalizes over the entire surface of the cone before the emitter is heated.

4. The emitting surface of the field-emission cathode (which is, in a first approximation, hemispherical) is several orders of magnitude smaller than a conical surface area. Accordingly, the oil concentration in this region and the oil concentration on the cone after migration is completed can be assumed to be equal.

On the basis of these arguments we can calculate the hypothetical oil concentration on the plane of an axial cros. section of the cone, N_1 (plane F in Fig. 2), and then redistribute this value over the lateral surface of the cone. The linear dimensions of plane F are much smaller than the distance r (in the actual apparatus, r is ~70 mm, while the cone of the field-emission cathode is ~1 mm long), so we can treat it as negligibly small. Since this plane makes a right angle with the axis of the limiter we have $\cos\theta = \cos\varphi = 1$; thus

$$\nu_1 = \frac{Q}{\pi r^2}, \tag{3}$$

and

$$N_1 = \nu_1 t = \frac{Q}{\pi r^2} t, \tag{4}$$

where t is the time over which the adsorption occurs.

The lateral surface of the cone is larger than surface F by a factor $\pi/\cos\alpha$, where α is the vertex half-angle of the cone. However, since the value of α for the emitters usually used in field-emission microscopes is less than 5°, we can treat the $\cos\alpha$ as unity. Then the oil concentration on the cone at the completion of migration is

$$N = \frac{N_1}{\pi} = \frac{\nu_1}{\pi} t = \nu t. \tag{5}$$

The coefficient $\nu_1/\pi = \nu$ gives the flux density uniformly distributed over the cone surface. Accordingly, the adsorption of oil molecules from the beam onto the "illuminated" side of the cone and the subsequent migration to the "shadowed" side, involving an equalization of the concentration over the entire cone surface, are equivalent to the adsorption of these molecules from a random distribution in the volume around the emitter, at a flux density at the surface smaller by a factor of π.

Finally we can write the equations for the surface concentration of the oil and the corresponding flux density:

$$N = 3.56 \cdot 10^{21} \frac{pSt}{r^2\sqrt{MT}} \text{ cm}^{-2}, \qquad (6)$$

$$\nu = \frac{N}{t} \text{ cm}^{-2} \cdot \text{sec}^{-1}. \qquad (7)$$

The experimental error involved in a determination of N from Eq. (6) is ± 10%.

2. EXPERIMENTAL RESULTS AND DISCUSSION

a) Calibration emission images. As we heat the tungsten tip to 1400°K, with various coverages of the tip by oil molecules, we find more than 10 distinct emission images. Four of the most typical images (A, B, C, and D in Fig. 3) are used as calibration images; these are formed in times in the ratios 1 : 2 : 3 : 4 (at constant ν). A distinctive feature of image A is the presence of bright lobes on two sides of the {011} faces along bands of [100], [010] and [001] zones and bright bands between {011} and {121} faces along bands of $[1\bar{1}1]$ and $[11\bar{1}]$ zones. Under the conditions corresponding to image B the lobes become broad rings around {011} faces. We also see bands of [100], [010], and [001] zones as narrow dark bands intersecting at the "poles" of {001} faces. However, the most characteristic feature of this image is the appearance of dark {334} faces. In image C the circular {334} faces are broadened and deformed into irregular hexagons, and the rings around the {011} faces join with bright formations around {121} faces. Finally, at the coverage corresponding to image D, the (001) and (010) faces are ringed with halos, within which there are dark "Maltese crosses." The {334} faces vanish, and broad bands form from the center of the {111} faces to the {011} faces. A further accumulation of pyrolytic carbon on the surface does not affect the topography of the emission image (bright spots due to carbon conglomerates appear in random positions in image D), implying the formation of a saturated film.

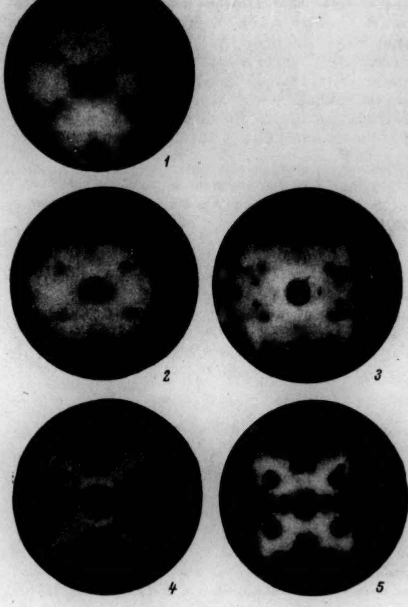

Fig. 3. "Calibration emission images." 1) Clean tungsten surface; 2) calibration image A; 3) B; 4) C; 5) D.

These emission images are obtained at cathode temperatures between 1200 and 1800°K. However, different surface concentrations of the oil correspond to the images, depending on the temperature. For example, to obtain image B at 1800°K requires roughly the same oil concentration as that required to obtain image C at 1500°K. This result, which is evidence of carbon diffusion into the surface layers of the metal, governs our choice of the oil decomposition temperature (1400°K); over the range 1200–1500°K the correlation between the surface concentration of the oil and the nature of the emission image of the carbon is not broken.

Destruction of the saturated carbon film (image D) begins at ~2300°K; at 2600°K only a few "flashes" are required to completely clean the carbon from the tungsten surface.

b) Calibration results. Calibration of the ap-

*Preliminary coverage of the emitter with a residual-gas monolayer.

paratus consists of a determination of the time over which the oil vapor must be adsorbed from a molecular flow of known flux density in order to produce one or several calibration emission images. At high residual gas pressures the accuracy of images A and D becomes smaller because of the adsorption of these gases on the emitter. In these cases the readings are based on images B and C, which have the best contrast. The time required for the formation of the saturated film is calculated from the proportion given above.

The time required to reach the carbon surface concentration corresponding to a given calibration image, c_c, is obviously given by

$$t_c = \frac{c_c}{\nu z \beta}, \tag{8}$$

where z is the number of carbon atoms in a molecule of the oil, and β is the probability that carbon is captured by the surface in the decomposition of the adsorbed oil. Since $\nu t_c = N_c$ we can write

$$c_c = N_c z \beta, \tag{9}$$

where N_c is the surface concentration of oil required to obtain the given calibration concentration of carbon.

If we record the same calibration concentration of carbon c_c, we see from Eq. (9) that $N_c z$ = const for any type of vacuum oil under the condition β = const. However, preliminary experiments show that this product does not remain constant but increases as the vacuum is degraded, and this result can mean only that the value of β decreases. It is not possible to determine the absolute values of the coefficient β by our method, but it is possible to follow the relative changes1) in β, setting $\beta_0 = 1$ for the adsorption of oil on a clean surface.

Table 1 shows the calibration results; for simplicity, the values of t_c and N_c are shown only for image D. The coefficient K gives the ratio of the oil flux density calculated from Eq (7) and the flux density of the residual gas, calculated from the indications of the IM-12 gauge.

Analysis of this table reveals the following:

1. The value of $N_c z$ in the case of the adsorption of type 5F4É oil directly on a clean tungsten surface (K = 50) is $(3.12 \pm 0.32) \cdot 10^{15}$ cm^{-2}. Then, according to our assumption $\beta_0 = 1$ this value can be treated as the concentration of carbon atoms in the saturated film. It is then a simple matter to calculate the values of c_c for the other calibration images.

2. The value of β falls off as the surface becomes contaminated with residual gas. Over the range 50 ≥ K ≥ 1.6 this decrease is small (~20%). Comparison of the dimensions of the oil and residual-gas molecules shows that in this range of K a large part of the "landing field" for the oil molecule is free of adsorbed gas. Nevertheless, as the emitter is heated, fragments of the oil molecules on top of adsorbed gas can desorb as radicals, carrying off part of the carbon. Over the range K = 1.6–0.3 the value of β falls another 30%. A further reduction of K, all the way to zero (the adsorption of oil on top of a residual-gas monolayer is equivalent to K = 0), does not cause any significant change in β. The different values of β obtained for this range of K reflect an experimental scatter, since the error in the indications of the calibration images in a vacuum worse than $5 \cdot 10^{-8}$ torr is ~20%.

Accordingly, we distinguish between two ranges of K, in which the average values of the coefficient β are 0.9 and 0.5, respectively:

$$\text{a)}\quad 50 \geqslant K \geqslant 1.6; \quad \nu = \frac{c_c}{t_c z \cdot 0.9}\ \text{cm}^{-2} \cdot \text{sec}^{-1} \tag{10}$$

(for this range of K the error in the determination of ν is ~± 25%);

$$\text{b)}\quad 0.3 \geqslant K \geqslant 0; \quad \nu = \frac{c_c}{t_c z \cdot 0.5}\ \text{cm}^{-2} \cdot \text{sec}^{-1} \tag{11}$$

(in this case the error in the determination of ν does not exceed ± 35%). If K cannot be evaluated, the assumption $\beta = 0.7$ should be adopted; then the error in the determination of ν is degraded to ± 50%.

To estimate the minimum value $\nu_{\min}$ detectable by this method we consider the conditions prevailing during the accumulation of oil molecules on a tungsten surface contaminated by residual gas (K < 0.3). We assume that the minimum concentration of pyrolytic carbon which can be determined from an emission image corresponds to calibration image B [$(1.56 \pm 0.16) \cdot 10^{15}$ cm^{-2}]. Then Eq. (9) shows that the surface concentration of the accumulated oil must be $1 \cdot 10^{14}$ cm^{-2}, or roughly a monolayer.[11] During the buildup of this concentration the desorption rate increases continuously, in accordance with

$$\frac{dN}{dt} = \frac{N}{\tau_0} \exp\left(-\frac{E}{RT}\right), \tag{12}$$

where $\tau_0 \simeq 10^{13}$ sec, N is the surface concentration of the oil, and E is the activation energy for the desorption. Since at equilibrium the adsorption rate is equal to the desorption rate, we can use Eq. (12) to determine the value of dN/dt at which the necessary surface concentration of oil (in this case, $1 \cdot 10^{14}$ cm^{-2}) is the equilibrium concentration. At T = 300°K and with $E \simeq q$ = 30 kcal/mole, we would have $dN/dt \simeq 1 \cdot 10^{6}$ cm$^{-2}\cdot$sec^{-1}. This value is evidently $\nu_{\min}$. At $\nu < \nu_{\min}$ the necessary oil concentration is not attained; at $\nu > \nu_{\min}$ condensation occurs immediately after the formation of a monolayer of oil.

Accordingly, Eq. (11) can be used to determine ν at T = 300°K and with $q \simeq 30$ kcal/mole only under two conditions:

1. The detected values of ν must be above $1 \cdot 10^{7}$ cm$^{-2} \cdot$ sec^{-1}; at smaller values the additional error due to oil desorption exceeds 10%.

2. The surface concentration of the accumulated oil must not exceed $\sim 1.5 \cdot 10^{14}$ cm^{-2}, since, according to Eq. (9), the tungsten surface becomes completely saturated with carbon as $N \simeq 2 \cdot 10^{14}$ cm^{-2} is approached. Accordingly, over a certain range $N > 2 \cdot 10^{14}$ cm^{-2}, regardless of the value of N, calibration image D would be obtained; with a further increase in N we would find the emission image of a nucleated carbide phase. In both cases an estimate of ν becomes problematical.

After an analogous examination of the conditions governing the applicability of Eq. (10) we conclude that N must not exceed $\sim 0.75 \cdot 10^{14}$ cm^{-2}. Under the conditions prevailing during the adsorption of the oil on the clean tungsten surface we can expect $q \gg 30$ kcal/mole and thus $\nu_{\min} \ll 10^{6}$ cm$^{-2} \cdot$ sec^{-1}.

In practice, however, it is inconvenient to determine such small values of ν, since the time required for the buildup of the required surface concentrations of oil becomes impractical ($> 10^{7}$ sec). If we restrict this time to 10^{5} sec, we can recommend this method for determining the flux density of any vacuum oil having a molecular weight of M = 400-500 and containing 30-40 carbon atoms per molecule in the range $1 \cdot 10^{9}$-$1 \cdot 10^{13}$ cm$^{-2} \cdot$ sec^{-1} (the upper limit is set by the rapid formation of a saturated carbon film). For the type VM-5 and 5F4É oils this range corresponds to $3 \cdot 10^{-6}$-$3 \cdot 10^{-2}$ mg/(cm$^{2} \cdot$ h). The oil can be accumulated on the cathode over a broad pressure range, from 10^{-2} to 10^{-11} torr, but the emission images can be observed only at a vacuum no worse than $1 \cdot 10^{-7}$ torr. For most vacuum systems the condition $K < 0.3$ holds, so it is advisable to use Eq. (11) to calculate ν.

The authors thank A. I. Ermakov and R. A Potapovich for assistance in this work, and M. L. Alashkevich and V. I. Mirimanova for furnishing data on the vapor pressures of the VM-5 and 5F4É oils.

---

1) The literature reveals no information about the mechanism for the decomposition of high-molecular hydrocarbons on hot metal surfaces, but it is shown in refs. 19 and 20 that when tungsten is heated to T > 800°K the light hydrocarbons (acetylene, ethane, ethylene, propane) adsorbed on it are completely dehydrogenated. The hydrogen desorbs into the gas phase, while the carbon skeleton of the molecules becomes tightly bound to the surface. We believe that this mechanism also holds for complex hydrocarbons.

Emission parameters of a field-emission cathode

G. N. Freiberg

Moscow Polytechnical Institute

(Submitted September 6, 1973; resubmitted February 13, 1974)
Zh. Tekh. Fiz., 44, 2186-2191 (October 1974)

It is shown theoretically that absolute determinations of the work functions, current density, and electric field at a field-emission cathode, the effective emission area, and the form factor are possible through the use of a particular parameter: the ratio of the maximum current density at the cathode to its average value over a period of the alternating electric field at the cathode. Computer calculations indicate the feasibility of such determinations. Graphical relations for finding these properties are given. A simple procedure is proposed for determining the field-emission current density at the cathode.

Current problems in the use of field-emission cathodes in vacuum-tube devices require studies of the physical processes associated with field emission. To approach this problem correctly we need to know such physical properties as the emission current density, the electric field near the cathode surface, the effective work function, the emitting surface area, and the form factor. This information is also necessary in choosing operating conditions for field-emission cathodes and for monitoring their operation.

The methods available for determining these parameters[1-3] are basically relative methods, requiring prior knowledge of one of these parameters from some other experiments. The methods by which these parameters are found through analysis of the voltage–current characteristics and the functional dependence of the field-emission current on the temperature[4,5] or of the energy distribution of the field-emission electrons[6,7] suffer from the complexity of the corresponding experiments. Furthermore, they are based on the assumption of a simplified equation for the field emission, and their results are not available during the experiment, since they require laborious calculations. Solution of the system of equations on the basis of three points on the voltage–current characteristic of the field-emission device[8] can in principle yield the values of all the parameters, if the current and voltage are measured within four or five significant figures, but a computer is required to obtain the results.

Below we propose another absolute method[9] for determining the parameters of a field-emission cathode, a method which yields results during an experiment. The time saving results from the introducing of dimensionless functions whose values can be measured during tests of the devices.

THEORY BEHIND THE METHOD

We consider the Fowler–Nordheim equation in the form

$$j=\frac{AE^{2}\exp\left[-B\varphi^{3/2}\frac{\theta(y)}{E}\right]}{\varphi v^{2}(y)^{2}},\qquad(1)$$

which is an analytic relation for the physical quantities E, j, and φ. Here, j is the field-emission current density, E is the electric field at the cathode surface, φ is the work function, $\Theta(y)$ is the tabulated Nordheim function, and $y = d\sqrt{E/\varphi}$, v(y) is defined by

$$v(y)=\Theta(y)-\frac{2}{3}y\frac{d\Theta}{dy},$$

where A, B, and D are constants.

We assume that E is specified as a function of the time:

$$E(t)=E_{m}f(\omega t),\qquad(2)$$

where E_m is the peak field, $f(\omega t)$ is an arbitrary smooth function having a period of 2π and a peak value of unity [$1 \geq |f(\omega t)| \equiv$ const; the plot of $f(\omega t)$ is rectangular], t is the time, and ω is the frequency.

We then find the current density at any time,

$$j(t)=\frac{AE_{m}^{2}f^{2}(\omega t)\exp\left\{-\frac{B\varphi^{3/2}\theta(y)}{[E_{m}f(\omega t)]}\right\}}{\varphi v^{2}(y)},\qquad(3)$$

and the maximum current density,

$$j_{m}=\frac{AE_{m}^{2}\exp\left[-\frac{B\varphi^{3/2}\theta(y_{m})}{E_{m}}\right]}{\varphi v^{2}(y_{m})},\qquad(4)$$

and the time-averaged current density,

$$j_{\text{av}}=\left[\frac{AE_{m}^{2}}{(2\pi\varphi)}\right]\int_{0}^{2\pi}\left[\frac{f^{2}(x)}{v^{2}(y)}\right]\exp\left\{-\frac{B\varphi^{3/2}\theta(y)}{[E_{m}f(x)]}\right\}dx,\qquad(5)$$

where $x = \omega t$, $y_m = D\sqrt{E_m}/\varphi$, $y = D\sqrt{E_m f(x)}/\varphi$.

We construct the new function

$$K=\frac{j_{m}}{j_{\text{av}}}.\qquad(6)$$

This function can be a function of either E_m and φ or j_m and φ [see Eqs. (4) and (5)]. We construct the family of curves $K_L(j_m, \varphi_L)$ where L = 1, 2, . . . , n (Fig. 1). In Fig. 1a we draw two straight lines through ordinates K_1

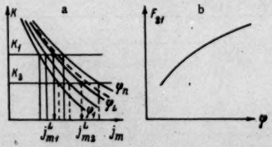

Fig. 1. a) Qualitative functional dependences of the ratio of the peak current density to the time-averaged current density on the peak current density for various work functions φ_L; b) the quantity $F_{21} = j_{m2}/j_{m1}$ as a function of φ.

and K_2 and parallel to the j_m axis. These lines intersect the family of curves $K_L(j_m, \varphi_L)$ at points with abscissas j_{m1}^L and j_{m2}^L. We also construct the function

$$F_{21} = \frac{j_{m2}^L}{j_{m1}^L} \tag{7}$$

for each work function φ_L, and plot a curve from the given points (Fig. 1b). This function, for given K_1 and K_2, is a function of the work function φ alone, i.e., $F_{21} = F_{21}(\varphi)$.

Accordingly, knowing the ratio of the peak current densities under two different sets of operating conditions of the cathode, with $j_m/j_{av} = K_1$ and $j_m/j_{av} = K_2$, we can find the work function φ for the given cathode by varying the electric field E at the cathode according to some law (2).

In practice, we deal with the total current I and the anode–cathode potential difference U. For an idealized cathode we can write

$$I = Sj, \tag{8}$$

$$E = \beta U, \tag{9}$$

where S is the area of the emitting surface and β is the form factor. By "idealized" here we mean a cathode for which φ and β are uniform along the entire surface and for which φ, β, and S are independent of the emission current density. Conditions approximating these can be achieved experimentally by recording voltage–current characteristics with probes from small regions of individual faces of single-crystal cathodes.

The quantities S and β in (8) and (9) are usually unknown, but by using (8) we can write

$$K_1 = \frac{I_{m1}}{I_{av1}}, \tag{10}$$

$$K_2 = \frac{I_{m2}}{I_{av2}}, \tag{11}$$

$$F_{21} = \frac{I_{m2}}{I_{m1}}; \tag{12}$$

i.e., dividing the peak currents I_{m2} for $K = K_2$ by I_{m1} for $K = K_1$, we find the experimental value of F_{21}, and from a plot of $F_{21}(\varphi)$ we find the unknown work function φ for the particular cathode. Then from the family of $K_L(E_m, \varphi_L)$ and $K_L(j_m, \varphi_L)$ curves constructed from the data on K_2, K_1 and φ, we find the corresponding values of E_m and j_m; knowing the corresponding values of j and U, we find from Eqs. (8) and (9) the area of the emitting surface, S, and the form factor β.

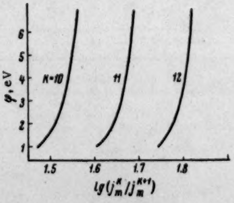

Fig. 2. Diagram used to determine the work function φ from the known value of $\log(j_m^K/j_m^{K+1})$.

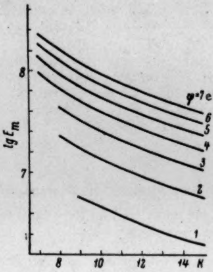

Fig. 3. Diagram used to find the field E_m from the known values of K and φ.

This solves the problem of finding the parameters of the field-emission cathode. This method is based on the Fowler–Nordheim equation alone and is absolute, so that it furnishes yet another method for testing the validity of the theory of field emission of metals for particular cathodes. We also note that this method is not rendered more complicated by the specification of some functional dependence other than that in (1), even if the functional dependence is specified implicitly.

RESULTS OF COMPUTER SOLUTIONS

We use a computer to solve the problem for the case of a sinusoidal time dependence of the electric field:

$$f(\omega t) = \sin(\omega t). \tag{13}$$

Figures 2 and 3 show the calculated results as $\varphi[\log(j_m^K/j_m^{K+1})$ and $\log E_m(K, \varphi_L)$ curves. Analysis of these curves demonstrates the feasibility of this method for determining the necessary information about the field-emission cathode.

To determine the work function φ within ± 1% it is necessary to measure the ratios of currents at their peak values, I_m, within 0.2-0.1% – which is feasible. For the other parameters the accuracy is better by a factor of 5 to 10 under the same measurement conditions.

In solving this problem we analyze the relationship between the numerical values of the width of the current pulses (we use the width at half-height, $\tau_{1/2}$; Fig. 4) and the quantity K. We find that the relative pulse width $\bar{\tau}_{1/2} = \tau_{1/2}/T$, where T is the period, is independent of the work function, being a function of K alone. Figure 5 shows the relative pulse width as a function of the ratio of the peak current to the average current over a period.

We can thus work with the relative width $\bar{\tau}_{1/2}$ instead of K, converting all the K_L curves into $\bar{\tau}_{1/2}^L$ curves; in this

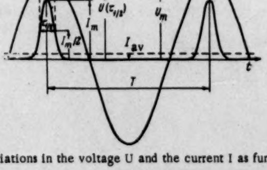

Fig. 4. Variations in the voltage U and the current I as functions of the time t.

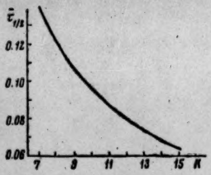

Fig. 5. Relationship between the relative width of the current pulse, $\bar{\tau}_{1/2}$, and the ratio of the peak current to the average current.

way we avoid measuring I_m, I_{av}, and their ratios and thus avoid much labor. We simply measure I_m and the relative pulse width, e.g., at half-height, by rf methods.

The computer solution of this problem reveals another important result: Over a certain range of work functions φ the emission current density can be a function of the relative width of the current pulse alone (or of the ratio $K = I_m/I_{av}$), in a first approximation. Hence we can determine the emission current density and the effective emitting area from a single value of $\bar{\tau}_{1/2}$. This capability simplifies the choice of a safe region for testing field-emission devices and studying their operation.

Figure 6 shows that for K = 10 (or $\bar{\tau}_{1/2} = 0.096$) the current density remains essentially constant as the work function is changed from 2.0 to 7.0 eV (the deviation from the average value is ≤ ± 10%).

Figure 4 also shows that to each value of $\tau_{1/2}$ there corresponds a definite relative anode voltage, since we have

$$\frac{U(\tau_{1/2})}{U_m} = \cos\left(\frac{\omega}{2}\tau_{1/2}\right). \tag{14}$$

It follows that $\bar{\tau}_{1/2}$ is a function of the relative anode voltage $\bar{U}_{1/2} = U(\bar{\tau}_{1/2})/U_m$ or, equivalently,

$$\bar{U}_{1/2} = \frac{U\left(\frac{I}{2}\right)}{U(I)}. \tag{15}$$

This result leads to the possibility of determining all the parameters at a constant voltage, i.e., at a voltage independent of the time, by using the results of the solution for the case of a sinusoidal voltage across the field-emission diode. We thus always have

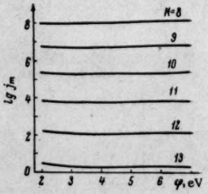

Fig. 6. The quantity $\lg j_m$ as a function of φ for various values of K.

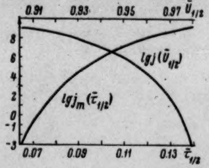

Fig. 7. Diagram used to determine the current density for known values of $\bar{\tau}_{1/2}$ or $\bar{U}_{1/2}$.

$$\tau_{1/2} = \frac{1}{\pi} \arccos \bar{U}_{1/2}. \tag{16}$$

Figure 7 shows the logarithm of the field-emission current density (error ≤ ± 10%) as a function of $\bar{\tau}_{1/2}$ and $\bar{U}_{1/2}$ for a field-emission cathode whose work function is unknown.

We thus have three methods for determing the parameters of a field-emission cathode: 1) the method based on the ratio of the peak current to the average current (the "K method"); 2) the method based on measurement of the width of the current pulse at some height (the "τ method"); 3) the method based on the ratio of the anode voltages at different currents, e.g., for currents differing by a factor of 2 (the "U method").

The U method is technically the simplest; in its essential form it requires no new instruments. In terms of the convenience and efficiency with which results are obtained, the τ method is the best.

Both methods have been tested in the laboratory in determinations of the field-emission current density; the results show that the two methods are fully consistent with each other and with the method based on the ratio of the slope of the Fowler–Nordheim line to the anode voltage.[10] We note, however, that the calculation burden associated with the method of ref. 10 is about 10 times that of our U method, for equivalent results in terms of the current density. Furthermore, because of the simplicity of the dimensionless functions we introduce here, their values can be determined during the experiment. It would be a simple matter to construct a system to automatically maintain a specified current density in the face of any changes at the cathode. Such a system could be useful, e.g., in studying the behavior of the emitting surface.

Characteristics of the spatial distribution of the fluxes of sodium chloride dimers and monomers from effusion cells of various designs are reported. The conditions under which the effusion characteristics of the monomers and dimers are very different or slightly different have been determined experimentally. In particular, a study has been made of the effect of a temperature gradient in the effusion cell on the shape of the characteristics. These results make it possible to carry out experiments which show that under certain conditions the degree of dissociation of dimers incident on a tantalum target is lower than the thermodynamic equilibrium value.

These experiments are part of an effort to determine how the composition of a molecular flux incident on a target affects the composition of the flux leaving the surface. The flux leaving a tantalum target is studied in refs. 1-4 for the case of a constant incident flux of sodium chloride dimers and monomers. Different functional dependences on the target temperature are found for the flux of dimers leaving the target: There is a constant region or plateau in the dimer flux at high temperatures in refs. 1 and 2 but not in refs. 3 and 4. The difference is found to be attributable to the use of different sources for the incident flux.

We have carried out two series of experiments: 1) We have studied the fluxes from effusion chambers, like those used as the sources of the incident flux in refs. 1-4; 2) we have measured the changes in the composition and intensity of the flux leaving the surface as a function of the incident flux.

1. In the first series of experiments we study the characteristics of the spatial distribution of the monomers (NaCl) and of the dimers (Na_2Cl_2) from evaporators of various designs (Fig. 1). The evaporator in Fig. 1a, heated by radiation from a coil, is isothermal; evaporators of this kind are used in refs. 1 and 2. That in Fig. 1b is a tube of 10 μ tantalum foil, heated by a current flowing through the tube itself. In evaporators of this type there is a temperature drop ΔT between the center and edges of the evaporator which can be measured with thermocouples, as shown in Fig. 1b. The value of ΔT is varied by changing the rate at which heat is removed from the edges and by changing the pattern of the foil from which the tube is welded; it also changes as the salt is expended. An evaporator of this kind is used in refs. 3 and 4 as the source of the incident molecules.

In the present experiments an MS-1303 mass spectrometer is used, and the test evaporator is rotated around an axis passing through the effusion aperture (point 0 in Fig. 1 is the intersection of this axis with the plane of the figure). Between the evaporator and the ionization chamber of the ion source is a shield which protects the electrodes of the ion source from being sprayed with the salt. The measurable molecular beam fills an angle much smaller than 1°. Figure 2 shows effusion characteristics obtained with the evaporator of Fig. 1a. The characteristics are normalized to the maximum values of the I^{58}

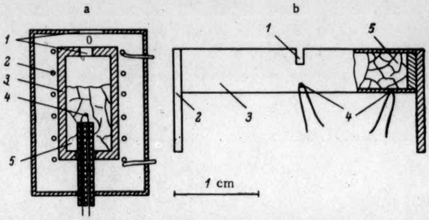

Fig. 1. Construction of the evaporators. a: 1) Effusion aperture; 2) coil; 3) stainless steel crucible; 4) thermocouple; 5) salt; 0) intersection of the rotation axis with the plane of the figure (this axis is perpendicular to this plane). b: 1) Effusion aperture; 2) current leads; 3) tantalum-foil tube; 4) thermocouples; 5) salt; 0) intersection of the rotation axis with the plane of the figure.

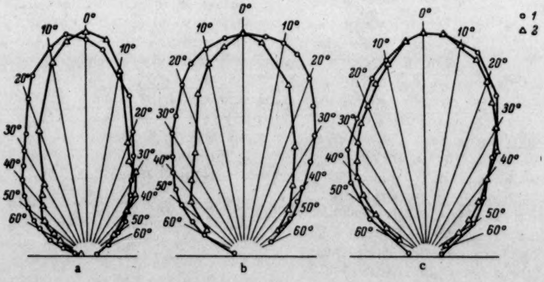

Fig. 2. Effusion characteristics of the evaporator in Fig. 1a. 1) I^{58}; 2) I^{81}; T, °C: a) 525; b) 566; c) 625.

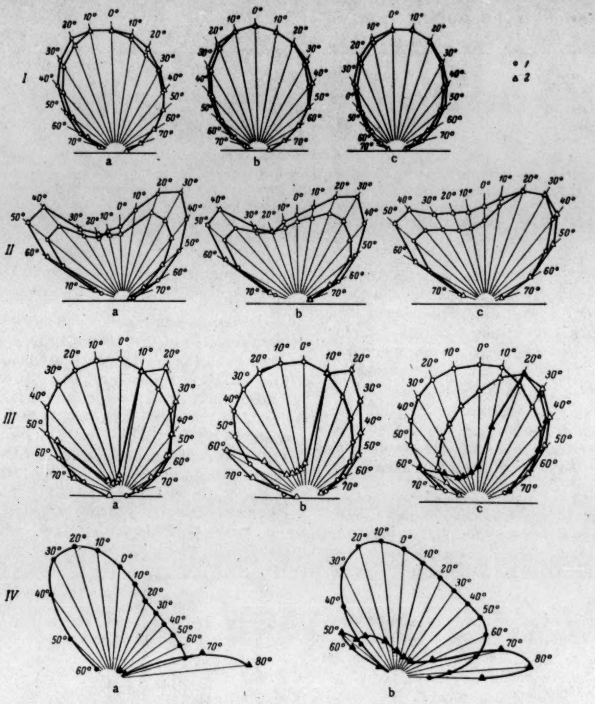

Fig. 3. Effusion characteristics of the evaporator in Fig. 1b. Here ΔT is the difference between the thermocouple readings (Fig. 1b, item 4), i.e., the evaporator temperature minus the reading of the central thermocouple. 1,2) The same as in Fig. 2. I: Evaporator full of salt, $\Delta T = 20°$ at 700°C. T, °C: a) 560; b) 630; c) 700. II: Roughly half the salt has been expended, $\Delta T = 30°$ at 700°C. T, °C: a) 560; b) 630; c) 700. III: Evaporator not full. T, °C: a) 790; b) 845; c) 890. IV: Salt at only one end of the evaporator, $\Delta T = 200°$ at 700°C. T, °C: a) 765; b) 800.

and I^{81} ion currents, which are proportional to the fluxes of the NaCl monomer (the $NaCl^+$ ion) and the Na_2Cl_2 dimer (the Na_2Cl^+ ion), respectively. The dimer contribution to the total I^{58} current (due to dissociative ionization) is neglected. With this evaporator we have $I^{58}_{max}/I^{81}_{max} = 2\text{-}3$. It is evident from Fig. 2 that at relatively low temperatures there is a greater difference between the effusion characteristics for the monomers and dimers; as the temperature is raised this difference is reduced and the characteristics become less sharp. Figure 3 shows characteristics for the second evaporator; the value of ΔT along the length of the evaporator increases from top to bottom. For the evaporator of Fig. 1b the difference between the effusion characteristics of the monomers and dimers is more pronounced than for the evaporator of Fig. 1a. There is also an increase in the difference between the characteristics with increasing ΔT in the evaporator. In contrast with the characteristics obtained with the evaporator of Fig. 1a, the shape of the characteristics obtained with the evaporator of Fig. 1b changes markedly as the charge diminishes (Fig. 3, I and II). There is also a change in the composition of the molecular flux: $I^{58}_{max}/I^{81}_{max} = 1\text{-}1.5$ for Fig. 3, I, and $I^{58}_{max}/I^{81}_{max} = 2\text{-}3$ for Fig. 3, II A change in the thermal conditions in the evaporator can also change the shape of the I^{81} characteristic (Figs. 3, III c). The open triangles show the characteristic 3 min after a change in the current through the evaporator while the solid triangles show the situation 20 min after this change. We find $I^{58}_{max}/I^{81}_{max} = 8\text{-}10$ for Fig. 3, III and $I^{58}_{max}/I^{81}_{max} = 18\text{-}25$ for Fig. 3, IV. The temperature drop ΔT is not measured for the characteristic in Fig. 3, III but on the basis of visual observation of the distribution of the brightness we conclude that this drop should lie between those corresponding to the characteristics in Fig. 3, II and Fig. 3, IV.

A difference between the partial effusion characteristics of monomers and dimers was first predicted by Voronin.[5] We have observed a substantial intensification of this effect under the influence of a temperature drop in the evaporator. The characteristics are discussed below.

The changes in the monomer and dimer fluxes with

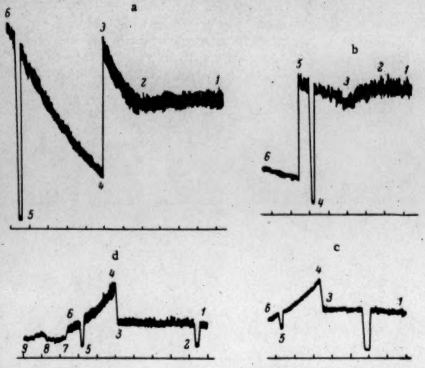

Fig. 4. Changes in the monomer (a, b) and dimer (c, d) fluxes as a function of current through the evaporator in Fig. 1b. Time elapses from right to left. a: Incident I^{58} flux. 1,2) Constant current through the evaporator; 2-6) increase in the signal with a sharp increase in the current through the evaporator; 3,4) scale is switched; 5) the incident-flux shutter is closed. b: Desired I^{58} flux; 1,2) constant current through the evaporator; 2) time at which the current decreases; 3) time at which the current increases; 3-6) gradual increase in the signal; 4) incident-flux shutter closed; 5) scale is switched. c: Incident I^{81} flux. 1-3) Constant current through the evaporator; 2) beam shutter is closed; 3) time at which the current decreases; 3-6) gradual change in signal; 5) successive increase and decrease in the current. d: Desorbed I^{81} flux. 1-3) Constant current through the evaporator; 2,5) incident-flux shutter operates; 3) current through the evaporator is decreased; 6) time at which the current increases; 8) time at which the current decreases.*

changing temperature are also different for the evaporators in Figs. 1a and 1b. That in Fig. 1a produces parallel changes in I^{58} and I^{81} as the temperature is changed, while there is a difference between the I^{58} behavior and the I^{81} behavior when the evaporator in Fig. 1b is used, with its central region free of salt (Figs. 4a and 4c). As the current through the evaporator is increased the I^{58} flux increases smoothly; as the current is reduced, the I^{58} flux decreases. As the current through the evaporator is reduced the I^{81} flux at first increases rapidly, but then decreases smoothly. A current increase causes the opposite behavior. This effect is more pronounced, the larger the temperature drop ΔT over the length of the evaporator. We can thus cause instantaneous changes in the dimer concentration in the incident flux while holding the total flux essentially constant (the monomers are predominant in the flux).

To study the effect of the composition of the incident flux on the flux leaving the target we use the evaporator in Fig. 1a, whose characteristics are shown in Fig. 3III.

2. In the second series of experiments the molecular flux is incident on a tantalum target and the composition of the flux leaving the surface is analyzed for changes in the target temperature. The experimental apparatus is the same as in refs. 1-4. The flux incident on the target spans the interval from −5° to + 5° (Figs. 2 and 3). Figure 5 shows the temperature dependences of the dimer flux (I^{81}) leaving the target. Curve a is obtained with the evaporator of Fig. 1a, while curve b is obtained with the evaporator in Fig. 1b. We see that the magnitude of the dimer flux leaving the target in the high-temperature part of the curve is much higher with the evaporator of Fig. 1a, in which case there are more dimers in the incident flux (Figs. 2 and 3, III).

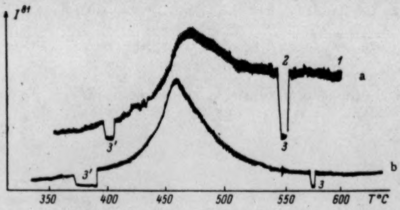

Fig. 5. Desorbed dimer flux as a function of the substrate temperature. The incident flux is from: a) the evaporator in Fig. 1a; b) that in Fig. 1b having the characteristic in Fig. 3, III. 1,2) Plateau; 3) incident-flux shutter is closed; 3') exciting-flux shutter is closed.

The data in Figs. 4, a and b, correspond to comparatively rapid changes in the temperature in the central part of the evaporator, free of salt, and comparatively slow changes in the temperature at the ends of the evaporator, which are filled with salt. We note that the temperature is always lower at the ends than at the center of these evaporators. The effect illustrated in Figs. 4, a and b, is observed in the evaporator of Fig. 1b, and in the flux leaving the target as well. Figure 4 shows the changes in I^{58} (b) and I^{81} (d) in the flux leaving the target upon a change in the current through the evaporator, with a target temperature which is constant and in the plateau region. These results imply that the dimer flux leaving the target in the plateau region is proportional to the dimer flux in the incident beam and not to the total incident flux. This result contradicts the assumption (used in ref. 5) that the desorbed fluxes are functions of the incident flux and the adsorbent temperature alone and independent of the dimer−monomer composition of the incident flux.

These experimental results (Figs. 2 and 3) can be explained by arguing that the total flux of molecules leaving the evaporator is governed primarily by the temperature of the evaporating salt. On the other hand, the composition of this flux is a function of 1) the temperature of that part of the surface which irradiates the detector, 2) whether there is a condensed phase present, and 3) the intensity and composition of the flux incident on this region (Fig. 5). Accordingly, when the detector is irradiated by the part of the evaporator filled with salt the beam has a higher dimer content than when the detector is irradiated by the hotter part of the evaporator.

These results furnish additional evidence that some of the dimers incident on a tantalum target at temperatures in the plateau region (Fig. 5) are characterized by a degree of dissociation lower than the thermodynamic equilibrium value. Further study by other experimental methods is necessary to determine the nature of the reflection of the fraction of dimers which do not participate in a dissociation reaction ($Na_2Cl_2 \rightarrow 2NaCl$) on the substrate.

The authors thank the participants of a seminar of **É. Ya. Zandberg** and **N. I. Ionov** for discussion.

Publisher's note: Point 7 in Figure 4 is not defined in the Russian original.

Radial distribution of density and potential in a glow discharge in CO_2 and water

A. I. Maksimov and V. F. Sokolov
Ivanov Chemicotechnological Institute

(Submitted August 7, 1973; resubmitted November 5, 1973)
Zh. Tekh. Fiz., 44, 2198-2202 (October 1974)

Expressions are obtained for the radial charge distribution when the particle currents are equal. Experimental measurements carried out in the pressure range 0.5 to 2 torr for currents of 1 mA to 5 mA show good agreement with the calculations. The experimental data are used to estimate the relative density of the negative ions $\alpha = n_-/n_e$.

The nature of the joint diffusion of electrons, positive ions, and negative ions and the charge balance with negative ions present have been considered by a number of workers.[1–5] In these papers expressions are obtained for the effective diffusion coefficients in a plasma with negative ions, and the relation between the space-charge field and the relative density of the negative ions is obtained. There are also available, certain measurements of the radial potential distribution and the radial charge density distribution in an electronegative plasma.[6]

The purpose of the present investigation is to analyze the relation between the spatial distribution of the space-charge field and the charged particle density in the column of a glow discharge in a gas capable of forming negative ions by dissociative electron trapping.

1. FUNDAMENTAL RELATIONS

The space-charge field is found from the condition that the positive and negative currents be equal:

$$\left.\begin{aligned}\Gamma_+ &= -D_+\nabla n_+ + \mu_+ n_+ E,\\ \Gamma_- &= -D_-\nabla n_- - \mu_- n_- E,\\ \Gamma_e &= -D_e\nabla n_- - \mu_e n_e E,\\ \Gamma_+ &= \Gamma_- + \Gamma_e.\end{aligned}\right\} \qquad (1)$$

Here, Γ is the current density, D is the diffusion coefficient, μ is the mobility, and n is the density. The subscripts "+", "-", and "e" refer to the positive ions, negative ions, and electrons, respectively.

From (1) we obtain the space-charge field

$$E = \frac{D_+\nabla n_+ - D_-\nabla n_- - D_e\nabla n_e}{\mu_+ n_+ + \mu_- n_- + \mu_e n_e}. \qquad (2)$$

Invoking neutrality and putting $n_-/n_e = \alpha$, we can convert Eq. (2) to the form

$$\frac{dU}{dr} = -\nabla n_+\left(D_+ - \frac{\alpha}{1+\alpha}D_- - \frac{1}{1+\alpha}D_e\right) - \nabla\alpha\left[\frac{n_+D_-}{(1+\alpha)^2} - \frac{n_+D_e}{(1+\alpha)^2}\right]. \qquad (3)$$

When $\nabla\alpha = 0$ Eq. (3) gives the ion density distribution, which has the Boltzmann form

$$n_+ = n_+^0 \exp\left(-\frac{\Delta U}{G}\right). \qquad (4)$$

Here, n_+^0 is the axial ion density, ΔU is the potential difference between the given point and the axis, and

$$G = \frac{D_+ - \frac{\alpha}{1+\alpha}D_- - \frac{1}{1+\alpha}D_e}{\mu_+ + \mu_-\frac{\alpha}{1+\alpha} + \mu_e\frac{1}{1+\alpha}}. \qquad (5)$$

When $\alpha = 0$ the quantity G is determined in practice solely by the mean electron energy, and Eq. (4) becomes the usual expression for the ambipolar diffusion condition without negative ions.[7] Note that the condition $\nabla\alpha = 0$ is equivalent to the relation (for $\alpha \gg 1$)

$$\frac{\nabla n_-}{\nabla n_e} \approx \frac{\nabla n_+}{\nabla n_e} \approx \frac{\nabla n_i}{\nabla n_e} \approx \alpha. \qquad (6)$$

This relation, which is fairly obvious qualitatively, indicates a plane radial distribution of the electron density with heavy negative ions.

An expression of the form (4) can be obtained from Eq. (3) in certain cases when $\nabla\alpha \neq 0$. When $\alpha \gg 1$, assuming that $D_e \gg D_-$, $D_e \gg D_+$, $\mu_i = \mu_- \approx \mu_+$, from Eq. (3) we have

$$\frac{dU}{dr} = -\frac{\nabla n_+\frac{D_e}{\alpha} + \nabla\alpha\frac{n_+}{\alpha^2}D_e}{n_+\left(2\mu_i + \frac{\mu_e}{\alpha}\right)} = \frac{\nabla n_+}{n_+}\frac{D_e}{2\alpha\mu_i + \mu_e} - \frac{\nabla\alpha}{\alpha}\frac{D}{2\alpha\mu_i + \mu_e}. \qquad (7)$$

Finally, if the value of α has an upper limit determined by the condition $2\alpha\mu_i + \mu_e$, or if the dependence of the sum $2\alpha\mu_i + \mu_e$ on α is small, the relation $D_e/(2\alpha\mu_i + \mu_e) = G_1$ can be assumed to be independent of radius, and Eq. (7) becomes

$$\left.\begin{aligned}\frac{n_+}{\alpha} &= \left(\frac{n_+}{\alpha}\right)_0 \exp\left(-\frac{\Delta U}{G_1}\right),\\ \ln\left(\frac{n_+}{n_+^0}\right) &= \ln\left(\frac{\alpha}{\alpha_0}\right) - \frac{\Delta U}{G_1}.\end{aligned}\right\} \qquad (8)$$

With the above assumptions this is equivalent to a Boltzmann distribution of the electron density in the space-charge field with a value G_1 which plays the role of the average electron energy.

Expression (8) only holds in the range of variation of α from 10 to 100.

2. EXPERIMENTAL INVESTIGATIONS

We measure the radial distribution of the positive ion density and the potential in the column of a glow discharge in CO_2, and in water vapor using a single probe. The construction of the discharge tube with a probe movable in the radial direction is shown in Fig. 1. The probe is made from tungsten wire 0.065 mm in diameter and the uninsulated part is 2 mm long. The gas pressure is 0.5-2 torr, the discharge current is 1-5 mA, and the tube radius is 1.4 cm.

The radial distributions of the floating potential and space potential are found experimentally. The latter is found from the point of inflection of single-probe characteristics, plotted on a semilogarithmic scale. (The point of inflection of the curve can be measured with an accuracy better than ± 2 V).

The positive ion density is calculated from the ion branches of the probe characteristics. In calculating the radius of the collecting sheath we use the experimental values of the floating potential of the probe with respect to the plasma potential. It is also assumed that the potential of the boundary layer is determined by the mean ion energy (this holds[6] for $\alpha > 3$). The ion temperature is assumed to be equal to the temperature of the gas in the discharge; this temperature is measured using a miniature (scaled in glass) thermocouple located at the axis of the discharge.

An example of the experimentally obtained radial distribution of the positive ion density and the plasma potential in the column of the glow discharge in CO_2 and H_2O is shown in Fig. 2. The ion distribution is the usual one for diffusion decay, and the space potential exhibits a fairly flat axial part.

It follows from (8) that where $\alpha/\alpha_0 \approx$ const a linear relationship should be observed between $\ln n_+/n_+^0$ and ΔU. Plotting the experimental data in these coordinates shows that this linear relation does in fact exist (Fig. 3). From the slope of the linear part of the relation $\ln n_+/n_+^0 = f(\Delta U)$ we can estimate the values of G_1, and use it to find the radial distribution of the ratio α/α_0. The results of the calculation are shown in Fig. 4; as one moves along the radius α changes by less than a factor of 2. However, near the axis one cannot neglect $\Delta\alpha$ since the variation of α is essentially the same as the variation of n_+ for small r. This result indicates that the electron density obtained directly from Eq. (8) for the region with a flat potential distribution, is constant.

Since the presence of negative ions changes the space-charge field, it is best to compare the experimental potential distribution with that predicted by diffusion theory, which ignores the negative ions. For $\alpha = 0$, $n_+ = n_e$, and $\Delta n_+ = \Delta n_e$, it follows from Eq. (2) that

$$E \approx -\frac{\nabla n_e}{n_e}\frac{kT_e}{e} = \frac{kT_e}{e}\frac{J_1\left(\frac{2.4}{R}r\right)}{J_0\left(\frac{2.4}{R}r\right)}. \tag{9}$$

Hence, we obtain for the potential difference ΔU between the axis and the given point

$$-\frac{\Delta U e}{kT_e} = 2.4\int_0^{r/R}\frac{J_1\left(\frac{2.4}{R}r\right)}{J_0\left(\frac{2.4}{R}r\right)}\,d\left(\frac{r}{R}\right). \tag{10}$$

The curve described by Eq. (10) is shown in Fig. 5. The same figure also shows the experimental distribution of the dimensionless potential of the plasma $\Delta U/G_1$. The large difference between the theoretical and experimental curves may be due to the presence of negative ions.

Tompson[5] gives the ratio of the space-charge fields with and without negative ions in the form

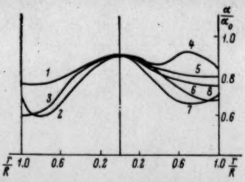

Fig. 4. Radial distribution of the relative negative ion density. CO_2, p(Torr), I_p (mA): 1) 1.9, 1.5; 2) 0.6, 3.0; 3) 0.6; 4.5, 4) 1.2, 4.5; 5) 1.2, 1.5; 6) 1.2, 3.0; H_2O: 7) 1.8, 1.5; 8) 1.8, 3.0.

$$\frac{E(\alpha)}{E(0)}=\frac{1-\frac{D_+}{D_+^{\alpha}}}{1+\alpha}\left(\frac{1+\gamma}{\gamma}\right). \qquad (11)$$

Here γ is the ratio of the mean energies of the electrons and ions, and D_+^{α} is the effective diffusion coefficient of the positive ions, which depends on α. Analysis of Eq. (11), using the expression for D_+^{α} given by Tompson, for $\gamma \gg 1$ and $\alpha \leq 100$ leads to

$$\frac{E(\alpha)}{E(0)}=\frac{1}{1+2\alpha}. \qquad (12)$$

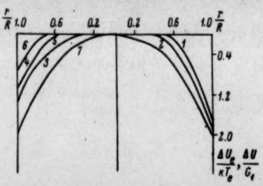

Fig. 5. Radial variation of the ratio of the space-charge field. H_2O, p(torr), I_p(mA): 1) 1.8, 1.5; 2) 1.8, 3.0; CO_2: 3) 1.2, 1.5; 4) 1.2, 3.0; 5) 0.6, 3.0; 6) 0.6, 4.5; 7) the curve given by Eq. (10).

This relation enables one to estimate the order of magnitude of α, by comparing the theoretical and experimental curves in Fig. 5. For small r, estimates give $\alpha \approx 10$.

Zh. Tekh. Fiz., 44, 2203-2210 (October 1974)

A beam of atomic particles with an energy of $\sim 10^4$ eV modulated at a frequency $\sim 10^6$ Hz is used to probe dense plasmas (nL $\sim 10^4$-10^{15} cm^{-2}) characterized by high ultraviolet emission. A data-taking system has been developed and tested which provides measurements with high time resolution ($\tau \sim 10^{-6}$ sec) against a high-level background. The signal-to-noise ratio is 10^4. Comparison of the results of plasma density measurements (nL < 10^{15} cm^{-2}) using modulated probe beams with data obtained by other means yield good agreement. Certain conclusions regarding the potential usefulness of particle corpuscular diagnostics using modulated beams are presented.

INTRODUCTION

Wider application of active particle diagnostic techniques to the study of hot, dense plasmas is made difficult by the presence of intense fluxes of corpuscular and electromagnetic radiation from the plasma volume.

The basic problems which must be solved in order to use probe beams are those of separating the effects of interactions of probing particles with plasma particles from the background due to the intense emission from the plasma itself.[1-3]

Since monoenergetic and uniform beams of particles are used to probe plasmas, the most widely used methods of separating probe particles are based on 1) the use of electrostatic energy analyzers, 2) the use of mass-monochromators as momentum analyzers, or 3) combinations of these two methods.[4]

Detectors using energy or momentum selection have, along with their obvious advantages, a number of intrinsic shortcomings, which appear to be fundamental. In high-density plasmas scattering and energy loss play a significant role when probe-beam particles interact with the plasma.

Scattering shows up in changes in the transverse dimensions of probe beams. Energy losses and the associated smearing of the energy spectrum also lead to additional broadening of the beam in analyzing fields.

The use of neutral-particle beams for plasma diagnostics usually implies the presence of targets intended to transform neutrals into charged particles. This introduces additional scattering of probe beams. The influence of all these effects on the results of the measurements can be reduced, increasing the detector aperture; however, this is not always technically feasible. It should be noted that when particles of the same nature as those in the plasma are used for diagnostics, effective separation of probe particles from the particle emission background of the plasma is possible only when the energy of the probe beam lies outside the energy spectrum of the emitted plasma particles.

There is still another method, based on a different principle, for separating the useful signal from a high noise level. This method is based on the use of intensity modulated beams of atomic particles for plasma diagnostics. It is then possible to isolate the signal due to probe particles at the output of a detector by electronic means.

The necessity of studying rapid processes in plasmas demands high temporal resolution. This leads to a requirement for wide-band data-collecting systems for the modulated beams, such that

$$\Delta f \sim \frac{1}{\tau}, \qquad (1)$$

where τ is the required time resolution of the system and Δf is the frequency width of the recording channel.

Effective suppression of noise signals is possible if the noise signal level in the frequency band, Δf, at the chosen modulation frequency, f_M, is substantially smaller than the signal caused by changes in intensity of the probe beam. This condition can be written in the form

$$\left|\int\limits_{\Delta f} \varphi(f) e^{i2\pi f t} df\right| \ll \omega I R_{eq}, \qquad (2)$$

where $\varphi(f) = \int\limits_0^\infty \varphi(t) e^{-i2\pi f t} dt$ is the noise spectral density; $\varphi(t)$ is the signal at the load (on the beam particle detector) due to plasma particles; ΔI is the change in intensity of the equivalent probe beam current; R_{eq} is the equivalent resistance of the detector load at the modulation frequency, f_M.

It follows from Eq. (2) that to reduce noise it is necessary to reduce the passband, Δf; on the other hand, good time resolution is possible only with a wide passband [Eq. (1)].

In the majority of cases the signal at the detector output due to the plasma particles has a frequency bandwidth of several tens of hundreds of kilohertz; hence the contradictory conditions (1) and (2) can be satisfied if high-frequency modulation is used for the probe beam ($f_M > 10^6$ Hz).

Papers on the use of modulated beams for plasma diagnostics can be found in the literature. Among them is a study of a high-frequency discharge by means of beams He^0 and Ar^0 modulated[5] at 10 kHz and measurements of plasma parameters in a stellarator using beams of hydrogen atoms modulated[3] at 100 kHz.

In ref. 3 the recording channel has a bandwidth of 10 kHz, which permits a resolution time of $\tau \sim 100$ μsec. This technique of modulating the probe beam is used along with momentum analysis of the particles. The frequency response of the recording channel in ref. 5 is not stated, but it apparently does not provide a resolution time of

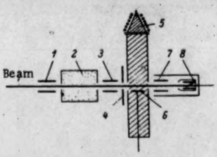

Fig. 1. Experimental arrangement

better than 10^{-3} sec and the noise is reduced basically by reducing the passband.

The present paper examines the possibility of using high-frequency ($f > 10^6$ Hz) modulation of beams of atomic particles as a diagnostic for a dense plasma.

EXPERIMENTAL ARRANGEMENT

The experiments are performed on the system shown schematically in Fig. 1.

Modulation of a monoenergetic beam of H_1^+ ions with energy $\sim 10^4$ eV is accomplished using a system, referred to below as the modulator, consisting of a plane electrostatic condenser 1, with a drift space S, and an output diaphragm 4.

The length of S is 57 cm, and the length of the condenser plates is 5 cm. The output diaphragm is 1.5 mm in diameter. A high-frequency modulated voltage from a standard sine wave generator (type GZ-41) is applied to the condenser plates. A constant bias voltage is also applied to the plates.

In order to obtain beams of neutral H_1^0 a gaseous charge exchange target 2 is located in the drift space. The protons which do not undergo charge exchange are removed from the beam by the electrostatic field of another plane condenser 3. From the modulator the beam enters a chamber into which plasma bursts are injected[6] by a conical injector 5. A metal barrier 6 can be placed in the path of the plasma flow directly adjacent to the intersection of the probe beam with the plasma.

The beam coming from the plasma is analyzed by a detection apparatus consisting of a condenser 7, which divides the complex beam according to charge, and a particle detector 8. This detector works with modulated beams of charged or uncharged particles. The construction is shown schematically in Fig. 2.

The secondary electrons from the plate 1 are collected by a cylindrical collector 2. An electric field applied between the plate and the collector ensures complete collection of the electrons by the collector. A guard cylinder 3 at negative potential with respect to the collector prevents escape of electrons from the detector volume. Shielding from external electric fields is accomplished by a copper shield 4. Insulators 5 are located between the measuring electrodes 1 and 2. The diameter of the input opening of the detector is 10 mm, which ensures an aperture of 1°. The internal capacitance of the particle detector is 27 pF, which results in an input impedance of $R_{eq} = 1.5$ kΩ at 3 MHz.

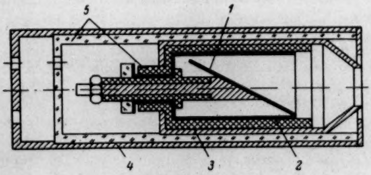

Fig. 2. Particle detector.

EXPERIMENTAL TECHNIQUES AND RESULTS

By using the above described modulator it is possible to obtain beams of charged and neutral particles modulated at frequencies of from 10^5 to $2 \cdot 10^7$ Hz, with the same modulation efficiency at all frequencies.

The choice of a detection system for modulated beams used as a plasma diagnostic is determined by the following conditions. The particle detector must have a wide dynamic range for incoming signals. It is impossible to use a system with ion-optical conversion[7] or open secondary electron multipliers as a particle detector if the signal is not preselected. The basic loading is determined by the level of plasma emission, which in most cases exceeds the signal connected with changes in intensity of the probe beams by several orders of magnitude. The basic advantages of these detectors are better time resolution, low intrinsic noise level, and high sensitivity; the last feature implies operations in a single-particle counting mode.

However, in plasma diagnostics the necessary beam intensity and, thus, sensitivity of the detectors, are determined by the allowable statistical fluctuations. The mean-square fluctuation intensity is given by

$$\frac{\overline{\Delta I^2}}{I^2}=\frac{1}{N}=\frac{e}{I\tau}.$$

where I is the beam intensity; N is the number of particles entering the detector in time τ, and e is the unit charge.

If we take the resolution time to be $\tau \sim 10^{-6}$ sec and require measurement of intensity changes in the probe beam of $\Delta I/I \approx 10^{-3}$, then the equivalent current of the beam used must be $I \geq 10^{-7}$ A.

Beams of charged and neutral particles with equivalent currents of 10^{-8}-10^{-6} A are used in these experiments. The particle detector used here has a wide dynamic range; however, it does not have sufficient gain to drive the oscilloscopes.

Preamplification is obtained by means of a bandpass amplifier developed especially for this purpose; it has a passband $2.1 < f < 3.1$ MHz, for which the gain is ~ 83 dB.

The required gain can be determined from the average intensity of the probe beam, $I \sim 10^{-7}$ A, and the output impedance of the particle detector, $R_{eq} \sim 1.5$ kΩ.

The amplifier passband, which contains the modulation frequency f_M, is chosen to be compatible with (1) and (2). To obtain the best time resolution for the given passband, $\Delta f = 1$ MHz, the modulation frequency is chosen to be $f_M = 3.1$ MHz. Since this frequency lies on the upper cutoff of the frequency characteristic, the detector circuit

Fig. 3

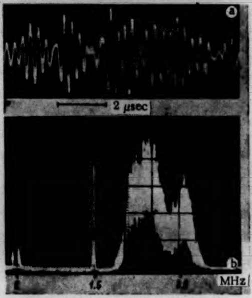

Fig. 4. a) Oscilloscope trace of the intrinsic noise voltage at the amplifier output; b) frequency spectrum of the amplifier noise.

only passes one sideband (lower) of the useful signal. The oscilloscope trace of Fig. 3 illustrates the frequency properties of the recording circuit. In this case the charged particle beam, modulated at 3.1 MHz, is deflected from the initial trajectory by a rectangular voltage pulse of 2 μsec long. The deflection voltage pulse is applied to the plates of condenser 3 (Fig. 1). A signal corresponding to weakening of the modulated beam is recorded at the detector. From the figure it follows that the circuit used provides a time resolution of $\sim 10^{-6}$ sec.

The lower limit of measured beam current is 10^{-8} A. This limit is determined by the intrinsic noise level of the amplifier. An oscilloscope trace of the intrinsic noise voltage at the output of the amplifier is shown in Fig. 4a. The maximum noise level, extrapolated to the amplifier input, is 10 μV. The frequency spectrum of the amplifier noise, taken by means of a type S4-8 spectrum analyzer, is shown in Fig. 4b. The markers on the abscissa correspond to 1.5 MHz. It follows from this figure that the spectrum of the intrinsic amplifier noise lies within its passband.

A further increase in system sensitivity will require a reduction in the intrinsic noise of the amplifier.

The modulation technique and recording system for modulated beams developed here are used to study plasma flows produced by a conical injector and to measure the densities of charged and neutral particles in the boundary layer formed when this plasma hits a metal barrier. Insertion of this barrier into the plasma flow sharply increases the level of ultraviolet emission from the plasma volume.

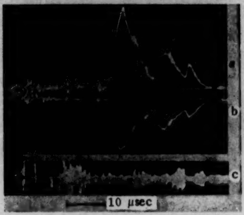

Fig. 5. Oscilloscope traces of: a) the ion saturation current in a double probe; b) the ultraviolet plasma radiation signal at the detector output; c) the signal after passing through the recording circuit.

Figure 5 shows oscilloscope traces of a) the ion saturation current in a double probe placed in the plasma, b) the signal produced at the particle detector output by ultraviolet emission from the plasma, and c) the same signal after passing through the selective circuits of a passband amplifier with a gain of $1.5 \cdot 10^4$. The maximum amplitude of the UV signal (Fig. 5b) is 0.4-0.6 V and its frequency spectrum lies within 30-200 kHz. The sensitivity of the oscilloscope is the same in Figs. 5a and b. The useful signal (due to changes in intensity of the probing beam) for a current $I = 10^{-7}$ A is less than $1.5 \cdot 10^{-4}$ V.

After passing through the bandpass amplifier the useful signal level is 2.25 V. The oscilloscope trace of Fig. 5c corresponds to conditions for which the probe beam does not enter the detector. In this figure only the intrinsic noise of the amplifier can be observed; the UV signal here is lower than the intrinsic noise level. The density of the plasma being studied in this case is $n^+L = 10^{15}$ cm^2 (n^+ is the density of charged particles per cubic centimeter and L is the path length of the probing beam in the plasma).

Thus, the selectivity of the recording circuit ensures that the intensity of modulated probe beams can be measured for a ratio

$$\frac{\text{useful signal}}{\text{noise}} \geqslant 10^{-4}.$$

at the output of the particle detector.

The density of charged and neutral particles in plasma flows are measured using the technique described above.

Oscilloscope traces of the signals due to the change in charge composition of modulated beams passing through a plasma are shown in Fig. 6. The modulation frequency f_M = 3.1 MHz.

Figure 6d shows the appearance of hydrogen atoms, H_1^0, in a proton beam due to charge exchange between probe particles and plasma neutrals. After deflection of charged particles by the field of the plane condenser, the detector only records neutrals in the probe beam. The maximum signal amplitude corresponds to transformation of about 20% of the initial H_1^+ beam intensity into H_1^0.

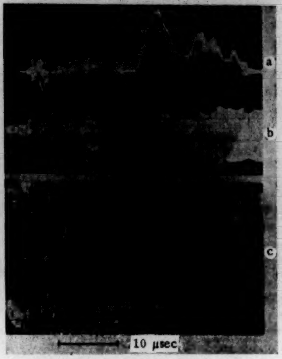

Fig. 6. Oscilloscope traces of: a) the ion saturation current in a double probe; b) the signal due to formation of H_1^0 particles in a probe beam of H_1^+; c) the signal due to attenuation of a probe beam of H_1^0.

The oscilloscope trace of Fig. 6c corresponds to attenuation of the initial intensity of an H_1^0 atom beam due to electron loss in the plasma. The relative magnitude of the attenuation can be estimated directly from the figure.

The line densities of charged (n^+L) and neutral (n^0L) particles in the plasma are determined from the change in charge composition[8,9] of probe beams H_1^0 and H_1^+. The results of measurements of these parameters obtained by means of modulated probe beams agree with the values obtained from a system without modulation.[8] Satisfactory agreement is obtained up to values of $n^+L + n^0L = 3.5 \cdot 10^{14}$ cm^{-2}.

Scattering processes begin to play an important role in thicker plasma targets. Their significance in changing the intensity of probe beams is difficult to take into account under the previous analysis and detection schemes.

With the detector used in this work it is possible to determine directly the change in beam intensity due to scattering of probe particles in the plasma at angles greater than those corresponding to the input aperture of the detector.

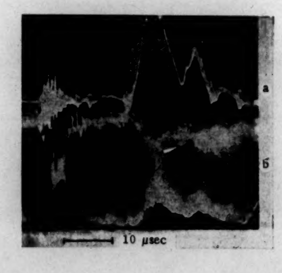

Fig. 7. Oscilloscope traces of: a) the ion saturation current in a double probe; b) the change (reduction) in intensity of a probe beam of H_1^+ due to scattering.

It is also possible to use scattering of probe particles in the plasma in order to determine the plasma density when $nL > 10^{15}$ cm^{-2}. For plasma targets with these parameters the probe particles will undergo multiple collisions in the plasma; hence, the charge composition of the passing beam does not depend on the density of the medium.

To determine the plasma density n^+L in this case it is assumed that the scattering of the proton beam in the plasma is Coulomb scattering by charged particles.

The mean square of the transverse component of momentum, $p^2_\perp$, acquired by the probe particles due to collisions is[10]

$$\overline{p_\perp^2} = \frac{16\pi e^4 \ln \lambda n^+ L}{v^2},$$

where v is the velocity of the probe particles, ln λ is the Coulomb logarithm, and e is the charge on a particle. This expression is correct if the velocity of the beam particles exceeds the speed of the particles in the plasma. The corresponding mean-square angle at which the particles initially parallel to the beam are scattered is given by

$$\theta_1^2 = \frac{\overline{p_\perp^2}}{p^2} = \frac{16\pi e^4 \ln \lambda n^+ L}{m^2 v^4} = \frac{4\pi e^4 \ln \lambda n^+ L}{E^2}, \qquad (3)$$

where $E = mv^2/2$ is the kinetic energy of the probe particles.

Since this scattering is a random process the intensity of the passing beam as a function of angle will have a normal distribution with an angular dispersion θ_1 given by

$$I(\theta) = I_0 \frac{\sqrt{2}}{\theta_1 \sqrt{\pi}} \exp\left(-\frac{\theta}{\sqrt{2}\theta_1}\right)^2.$$

Here, θ is the angle at which the particles have been scattered and I_0 is the initial beam intensity.

The equivalent beam current at the particle detector is

$$I(\varphi) = \int_0^\varphi I(\theta)\, d\theta = I_0 \Phi\left(\frac{\varphi}{\sqrt{2}\theta_1}\right),$$

where φ is the angular aperture of the receiver, and $\Phi(x) = (2/\sqrt{\pi}) \int_0^x e^{-t^2} dt$ is the probability integral. By measuring the ratio $I(\varphi)/I_0$ experimentally it is possible to calculate the angle θ_1, and thus to determine n^+L from Eq. (3).

An oscilloscope trace of the change in intensity of an H_1^+ (proton) probe beam after passing through a plasma is shown in Fig. 7b.

In this case both charged particles and neutral particles which appear in the beam are recorded simultaneously; thus, the change in total intensity of the diagnostic beam is due only to scattering of particles at angles greater than those corresponding to the input aperture of the detector. As can be seen from comparison of this oscilloscope trace with a probe signal (Fig. 7a) a correlation can be observed in this case between the intensity of the probe beam and the density of charged particles in the plasma.

The calculated line density of the plasma corresponding to the maximum amount of scattering on the oscilloscope trace of Fig. 7b is $n^+L = 3.5 \cdot 10^{15}\ \mathrm{cm}^{-2}$. Taking the finite degree of ionization of the plasma into account changes this quantity by an insignificant amount if $n^+L/n^0L \geqslant 0.5$.

The advantage of using scattering processes in active particle diagnostics of dense plasmas is that by changing the energy of the probe beam and the aperture of the particle detector it is possible to determine the particle density of the plasma over a wide range.

The development of techniques for high-frequency modulation of atomic beams and the possibility of using wide aperture detectors without initial selection of the particles opens up wide opportunities for active particle plasma diagnostics.

Doppler profile of an atomic line to the differential excitation cross section

É. S. Parilis and V. Kh. Ferleger

(Submitted August 6, 1973; resubmitted April 8, 1974)
Zh. Tekh. Fiz., 44, 2211-2216 (October 1974)

The spectral characteristics of Doppler line profiles for excitation and ionization by inelastic collisions are related to the differential excitation cross sections. The shape and location of the maximum and the wings of the spectrum can be used to find the differential cross section and threshold angle.

When heavy particles with velocities of 10^6-10^8 cm/sec collide, many inelastic processes are possible, including excitation and ionization of inner shells. Since the time for optical transitions (10^{-8} sec) is much greater than the collision time, while the time for radiationless transitions (10^{-13}-10^{-15} sec) is of the same order as the collision time, in many cases relaxation takes place in the system after the particles have separated.

Thus, electromagnetic radiation and characteristic electrons (for example, Auger electrons) are emitted by a rapidly moving atom whose velocity is determined by the scattering kinetics. The spectral line then shows a significant Doppler shift and broadening as do the Auger electron peaks. This feature must be taken into account in treating optical and electron spectra.[1-3]

The form of the spectral lines contains information on collision kinematics and the differential cross section for atomic excitation. If the Doppler distortion of the spectral line can be separated from the background consisting of the natural and Stark broadening, it is possible to establish a direct relationship between the line shape and the differential excitation cross section.

Using simple assumptions as to the form of the excitation function, we relate this function to line shape in this paper; a simple method is also proposed to solve the inverse problem of recovering the differential excitation cross section from the Doppler profile.

EXCITATION OF OPTICAL LINES

It is convenient to examine this case since the line shape in optical excitation is really determined by the Doppler distortion.[4]

The Doppler shift corresponding to emission at wavelength λ_0 is

$$\Delta\lambda = \lambda_0 - \lambda = \lambda_0 \frac{v(\theta)}{c} \cos\alpha. \tag{1}$$

If we ignore the changes in the kinematics due to inelastic losses, then the velocity of the scattered atom is

$$v(\theta) = v_1 \frac{\cos\theta + \sqrt{\mu^2 - \sin^2\theta}}{\mu + 1}. \tag{2}$$

Here, v_1 and θ are the velocity and scattering angle of the incident particle in the laboratory system; c is the speed of light; $\mu = m_2/m_1$ is the mass ratio of the incident, m_1, and target, m_2, atoms; and, α is the angle between the scattering direction (θ, φ) and the detector $(\theta_0, \varphi_0 = 0)$.

In the scattered atom velocity space Eq. (1) defines a surface of constant wavelength,

$$d(\lambda) = [\cos\theta + \sqrt{\mu^2 - \sin^2\theta}][\sin\theta \cos\varphi \sin\theta_0 + \cos\theta \cos\theta_0], \tag{3}$$

where

$$d(\lambda) = \frac{\Delta\lambda (1 + \mu) c}{\lambda_0 v_1}. \tag{4}$$

The intensity of emission at wavelength λ in direction θ_0 is proportional to the total number of particles whose velocity vectors form the surface described by Eq. (3) and is given by

$$J(\lambda, \theta_0) \sim \int \sigma_i(\theta) \frac{d\varphi}{d\lambda} \sin\theta d\theta, \tag{5}$$

where $\sigma_i(\theta) = (d\sigma(\theta)/d\Omega) P_i(\theta)$ is the differential cross section for excitation of the i-th spectral line, $P_i(\theta)$ is the excitation probability, and $d\sigma(\theta)/d\Omega$ is the differential cross section for scattering at angle θ. In Eq. (5) it is convenient to transform to the scattering angle, χ, in the center of mass system, where

$$\chi = \theta + \arcsin\left(\frac{\sin\theta}{\mu}\right). \tag{6}$$

Then

$$J(\lambda, \theta_0) \sim \int_{\chi_1}^{\chi_2} \frac{\sigma_i(\chi) \sin\chi d\chi}{\sqrt{\mu^2 \sin^2\chi \sin^2\theta_0 - [d(\lambda) - \mu\cos\chi\cos\theta_0 - \cos\theta_0]^2}}. \tag{7}$$

The limits of integration are

$$\left.\begin{aligned} \chi_1 &= \left|\theta_0 - \arccos\frac{d(\lambda) - \cos\theta_0}{\mu}\right|, \\ \chi_2 &= \left|2\pi n - \theta_0 - \arccos\frac{d(\lambda) - \cos\theta_0}{\mu}\right|, \end{aligned}\right\} \tag{8}$$

where

$$n = \begin{cases} 0, & \text{if} \quad \arccos\frac{d(\lambda) - \cos\theta_0}{\mu} \leqslant \pi - \theta_0, \\ 1, & \text{if} \quad \arccos\frac{d(\lambda) - \cos\theta_0}{\mu} > \pi - \theta_0. \end{cases}$$

To calculate the line profile, neglecting natural broadening, according to Eq. (7) it is necessary to know the value of $\sigma(\chi)$. If it is possible to use Firsov's formula[5] for the scattering cross section, $d\sigma(\chi)/d\Omega$, over the interval considered, then there is no general method for calculating $P_i(\chi)$. For the simplest systems, in the limit of large velocities, $P_i(\chi)$ can be obtained in the Born approximation.[6] The authors of ref. 7 calculated $P_i(\chi)$ using the molecular orbital model for a rotational $\sigma-\pi$ transition in the K shell of Ne, and in ref. 8 a function analogous to $P_i(\chi)$ is approximated by a simple dependence with a parameter whose value is chosen by comparing the theoretical curve of $J(\lambda, \theta_0)$ with experiment.

We note that several properties of the curve $J(\lambda, \theta_0)$ can be obtained by examination of Eqs. (8) without calculating the integral (7) by making some simple assumptions about the properties of $P_i(\chi)$.

1. Let $P_i(\chi)$ be defined for all angles $0 \leq \chi \leq \pi$ and increase from zero no more rapidly than $d\sigma/d\Omega$ falls off. Then:

the maximum of $J(\lambda, \theta_0)$ is reached for

$$\lambda_m = \lambda_0\left(1 - \frac{v_1}{c}\cos\theta_0\right), \tag{9}$$

the long wavelength boundary of the spectrum is

$$\lambda_l = \lambda_0\left(1 + \frac{v_1}{c}\frac{\mu - \cos\theta_0}{1+\mu}\right), \tag{10}$$

the short wavelength boundary of the spectrum is

$$\lambda_s = \lambda_0\left(1 - \frac{v_1}{c}\frac{\mu + \cos\theta_0}{1+\mu}\right), \tag{11}$$

and the full linewidth is

$$\lambda_l - \lambda_s = \lambda_0\frac{2\mu v_1}{(1+\mu)c}. \tag{12}$$

In general the distribution is asymmetric with:

a long wavelength region of width

$$\Delta\lambda_l = \lambda_l - \lambda_m = \lambda_0\frac{v_1}{c}\frac{\mu(1+\cos\theta_0)}{(1+\mu)}, \tag{13}$$

and a short wavelength region of width

$$\Delta\lambda_s = \lambda_m - \lambda_s = \lambda_0 v_1\frac{\mu(1-\cos\theta_0)}{c(1+\mu)}.$$

Only for $\theta_0 = 90°$

$$\Delta\lambda_l = \Delta\lambda_s = \lambda_0\frac{v_1\mu}{c(1+\mu)} \tag{14}$$

is the curve symmetric, in agreement with the results of refs. 4 and 8.

2. If there exists an excitation threshold in the scattering angle, that is $P_i(\chi) = 0$ for $\chi < \chi_0$, and then P grows no more rapidly than $d\sigma/d\Omega$ falls for $\chi > \chi_0$, then the position of the maximum changes compared with Eqs. (9)-(14). For $\chi_0 < \theta_0$,

$$\lambda_m = \lambda_0\left[1 - \frac{v_1}{c}\frac{\mu\cos(\theta_0 - \chi_0) + \cos\theta_0}{1+\mu}\right]$$

and for $\chi_0 > \theta_0$

$$\lambda_m = \lambda_0\left[1 - \frac{v_2}{c}\frac{\mu\cos(\theta_0 + \chi_0) + \cos\theta_0}{1+\mu}\right],$$

but the boundaries of the spectrum remain the same.

3. If $P_i(\chi) = 0$, for all $\chi > \chi_1$, then the location of the boundaries of the spectrum changes. For example, let $\chi(\lambda_e) > \chi(\lambda_s) > \chi_1$. Then the long wavelength boundary is

$$\lambda_l = \lambda_0\left[1 - \frac{v_1}{c}\frac{\mu\cos(\theta_0 + \chi_1) + \cos\theta_0}{1+\mu}\right],$$

the short wavelength boundary is

$$\lambda_s = \lambda_0\left[1 - \frac{v_1}{c}\frac{\mu\cos(\theta_0 - \chi_1) + \cos\theta_0}{1+\mu}\right],$$

and the full width is

$$\lambda_l - \lambda_s = \frac{2\lambda_0 v_1\mu\sin\theta_0\sin\chi_1}{c(1+\mu)}.$$

These relations allow us to determine χ_0 and χ_1, the threshold angles for excitation, when λ_m, λ_d, and λ_s are precisely measured spectroscopically. Furthermore, in order to be able to vary the form of $P_i(\chi)$ and to trace its effect on the Doppler distortion of a spectral line we write $P_i(\chi)$ in the form

$$P_i(\chi) = \operatorname{th} q^{-b},$$

where $q = \pi - \chi/\sqrt{\chi(2\pi - \chi)}$ is a dimensionless collision parameter for the potential of ref. 5, and b is an arbitrary parameter. The form of the function $P_i(\chi)$ for b = 0, 1, and 3 is shown in Fig. 1 (curves 1-3). Plots of $J(\lambda, \theta_0)/J_m$ for the Ar II λ_0 = 4879Å line excited by collisions with Kr, for θ_0 = 60° and E_0 = 15 keV are shown in Fig. 2. $J_m \equiv J(\lambda_m)$ is the maximum intensity. The form and half-width of the curves depend significantly on the parameter b.

Thus, the line profile is fairly sensitive to small

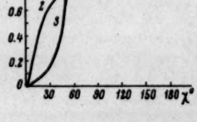

Fig. 1. The excitation probability, P(χ), as a function of scattering angle and the parameter b.

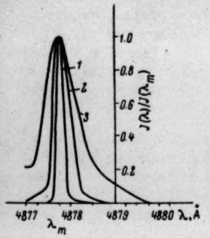

Fig. 2. Doppler profiles of the relative intensity of the Ar II λ_0 = 4879 Å line excited by collisions with Kr, for θ_0 = 60° and E_0 = 15 keV. 1) b = 0, 2) 1, 3) 3.

changes in $P_i(\chi)$, expecially at small scattering angles.

RECOVERY OF THE EXCITATION CROSS SECTION FOR OPTICAL LINES

Eq. (7) can be construed as an integral equation with respect to an unknown function $\sigma_i(\chi)$. We write $J(\lambda, \theta_0)$ in the form

$$J(\lambda, \theta_0) = \int\limits_{\chi_1(\lambda, \theta_0)}^{\chi_2(\lambda, \theta_0)} \frac{\sigma_i(\chi) \sin\chi \, d\chi}{\sqrt{(\cos\chi_1 - \cos\chi)(\cos\chi - \cos\chi_2)}}. \qquad (15)$$

Transforming to the variable $x = \cos\chi$ and writing

$$\sigma_i(\arccos\psi) = \Phi(x),$$

we obtain

$$J(\lambda, \theta_0) \equiv J(x_1, x_2) = -\int\limits_{x_1}^{x_2} \frac{\Phi(x)\, dx}{\sqrt{(x_1 - x)(x - x_2)}}, \qquad (16)$$

where $x_1 = \cos\chi_1$ and $x_2 = \cos\chi_2$. Equation (16) can be solved by setting

$$x_1(\lambda, \theta_0) = a = \mathrm{const}, \qquad (17)$$

Equation (17) gives the relationship between the observation angle, θ_0, and the measured wavelength, λ. In practice this means that for every observation angle, θ_0, the emission must be measured at the wavelength, λ, given by Eq. (17). Thus, with $a = 1$ we obtain the simple relation

$$\lambda = \lambda_0\left(1 - \frac{v_1}{c}\cos\theta_0\right). \qquad (18)$$

Evidently, for transitions associated with small energy transfers, Eq. (18) gives the location of the intensity maxima, while $J[\lambda(\theta_0), \theta_0] = I(\theta_0)$ will be the envelope of this kind of maxima obtained by continuous variation of θ_0. In the case under consideration Eq. (16) is an Abel integral equation. Using transformations analogous to those used in ref. 9 and for the boundary conditions $\sigma_i(0) = 0$, the solution may be written in the form

$$\sigma_i(\chi) = \frac{\sqrt{2}}{\pi} \frac{\sin\chi}{2} \int\limits_0^{\chi/2} \frac{\frac{dI}{d\theta_0}\, d\theta_0}{\sqrt{\cos 2\theta_0 - \cos\chi}}. \qquad (19)$$

We now consider the question of reconstructing the cross section from the entire spectrum taken at a fixed observation angle.

It is convenient to set $\theta_0 = 90°$. In this case, the result is the sum of the excitation cross sections at supplementary angles:

$$\sigma_i(\chi) + \sigma_i(\pi - \chi) = \frac{2}{\pi}\cos\chi \int\limits_{d(\lambda) = -\mu\sin\chi}^{d(\lambda) = \mu\sin\chi} \frac{\frac{dJ}{d\lambda}\, d\lambda}{\sqrt{\frac{d^2(\lambda) - \sin^2\chi}{\mu^2}}}. \qquad (20)$$

It is necessary to have an experimentally measured profile of the whole line, $J(\lambda)$, for $\theta_0 = 90°$. This method can be used to reconstruct $\sigma_i(\chi)$ for sufficiently small χ, when $\sigma_i(\pi - \chi)$ can be neglected compared with $\sigma_i(\chi)$ because of the small cross section for scattering at large angles. If the scattering cross section is known, Eqs. (19) and (20) determine $P_i(\chi)$.

Thus, two methods for reconstructing the differential cross section from the experimentally measured Doppler line profile have been proposed. The first method requires measurement of the intensities $J[\lambda(\theta_0), \theta_0]$ with continuous variation of θ_0 and that the curve $I(\theta_0)$ be obtained from them. This method is analogous to the method for measuring differential cross sections for atomic collisions. In a typical case of excitation without a threshold, $\lambda = \lambda_m$ and $I(\theta_0)$ is the envelope of the principal maxima of the spectral curves. The second method requires measurement of the entire profile $J(\lambda)$ at the fixed value $\theta_0 = 90°$ for all values of λ.

SPECTRA OF AUGER ELECTRONS AND HARD X RAYS

The emission of Auger electrons and x-ray photons in atomic collisions is connected with excitation of inner shells and is accompanied by strong scattering whose kinematics has a significant effect on the spectrum.

In calculating the discrete part of the energy spectra of electrons and the characteristic x radiation, inclusion of Doppler distortion is important.[3,10] The distinctive features of these processes as opposed to optical excitation are the significantly larger excitation thresholds with respect to scattering angle and energy[1,11] and the existence of a nonzero $P_i(\chi)$ over a rather wide range of scattering angles. This latter fact leads to an increase in the relative width of the Doppler profiles compared to the analogous profiles under optical excitation. In addition, because of the small lifetime (10^{-13}-10^{-15} sec) of the corresponding excited states, it is necessary to take the natural linewidth into account in calculating the resulting profile.

The above methods of recovering the differential excitation cross section may be applied to an isolated peak in the electron or x-ray spectrum in those cases where the Doppler distortion and broadening are predominant over other broadening mechanisms.

SPECTRA DUE TO REFLECTION OF ATOMS FROM A SOLID SURFACE

In the kinematic portion of this problem the effect of the surface reduces to a cutting off of the contribution to $J(\lambda)$ of particles whose velocity vectors are directed toward the interior of the substance. It has been noted by one of the authors[12] that atoms which have undergone multiple scattering on the surface also contribute to $J(\lambda)$. In accordance with the theory of multiple scattering spectra,[13] the energy distribution of the scattered particles shows up in $J(\lambda)$ in this case. It is also necessary to take account of the influence of the surface on changes in excitation state of the particles. Here, two groups of competing processes are the basic contributing factors. Thus, Auger relaxation with energy transfer to a target electron and resonance ionization leads to a reduction in the flux of excited particles compared to that from collisions in a gas. From the theory of atomic surface interactions the probability of conserving the excitation can be estimated from the expression

$$W=\exp\left(-\frac{A}{av_{\perp}}\right), \tag{21}$$

where $v_{\perp}$ is the component of particle velocity perpendicular to the surface; A and a are parameters whose magnitudes depend on the atom-surface pair and level being considered. On the other hand, a portion of the particles are ionized and as they move along the surface, Auger and resonance neutralization at the given level increase the flux of excited particles.

Thus, for collisions with a solid the function $P_i(\varkappa)$ (the probability for an atom to leave the surface in a given excitation state) is more complicated than the corresponding function for a gas. If the target is a monocrystal then $P_i(\chi)$ also depends on φ (the azimuthal scattering angle) since there is preferential neutralization in the directions of close packing.[14] This effect must appear in a corresponding dependence of the $J(\lambda)$ profiles on φ_0 (the azimuthal angle of rotation of the spectrometer with respect to the crystal axes).

It is obvious that the procedure discussed above for recovering the differential excitation cross section can also be applied to the case of atomic collisions with the surface of a solid. If the scattering cross section is known, the function $P_i(\chi)$ can be recovered.

General

Distortion of single-turn solenoids in ultrahigh magnetic fields

G. A. Shneerson

M. I. Kalinin Leningrad Polytechnic Institute

(Submitted October 1, 1973; resubmitted December 28, 1973)
Zh. Tekh Fiz., 44, 2217-2228 (October 1974)

Equations are derived and solved for the distortion of special solenoids which act to reduce the field below its calculated value. Hydrodynamic flow is assumed within the framework of spherically symmetric motion of an ideal incompressible fluid under the action of the magnetic pressure; the skin effect, the "slow" explosion of the skin layer, and a composite model are discussed. The distortion of solenoids has been investigated experimentally in fields up to 190 Wb/m². The measured values of the induction and the effective radius confirm the calculations and behave qualitatively as predicted by dimensional analysis. In particular the experimental data are compatible with the expected asymptotic dependence of the induction $B_m = \sqrt{J'}$, where J' is the initial growth rate of the current.

Three main processes determine the rate of distortion of a single-turn solenoid in an extremely high field: hydrodynamic flow, the skin effect, and the electrical explosion of the conductor.[1-9] All these processes lead to an increase in the effective inside radius of the solenoid and to a decrease in the induction below its calculated value.[3-6,9] Our calculations and experiments involve "biconical" solenoids (Fig. 1), in which the length l is proportional to the inside radius R, $l = \xi_0 R$, where $\xi_0 = 2\cot\varphi_0$. For a perfect conductor the induction at the center of such a solenoid is inversely proportional to R:

$$B(0,\ 0)=\frac{\mu_0 a_0 i}{R}, \tag{1}$$

where i is the current, a_0 is the dimensionless coefficient, equal to 0.19 for our solenoids, and $\xi_0 = 1.5$ ($\varphi_0 = 53°$). A relation of the form (1) for the induction at the center is established by measurements in a weak field produced by a 200 kHz alternating current in copper solenoids of various radii, including those deformed by the discharge. For deformations up to twice the initial radius the ratio of the length of the solenoid to the diameter of the opening varies slightly. It can thus be assumed that the flow in a biconical solenoid is nearly spherical and that the simple relation (1) for the induction can be used in the calculations and in the interpretation of the experiments. The dependence of the induction on the peak value and growth rate of the current can be traced as this dependence becomes asymptotic.

1. THE HYDRODYNAMIC MODEL AND "SLOW EXPLOSION"

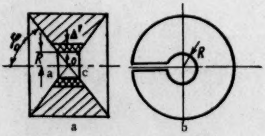

Fig. 1. Biconical solenoid.

Let us first consider hydrodynamic flow by assuming a perfect conductor, i.e., neglecting the diffusion of the field and electrical explosion. In short, solenoid effects due to compressibility and shock wave formation do not play a significant role,[7-9] and plastic flow is the principal process. This process can be likened to the motion of an ideal incompressible fluid if $B_e^2/2\mu_0 \gg \sigma_s$, where B_e is the field at the edge of the opening of the solenoid and σ_s is the dynamic yield stress.[4-10] In addition the following simplifying assumptions are made: The motion is assumed to be spherically symmetric, i.e., the displacement of the fluid through the free conical surfaces is neglected; the difference between the cylindrical surface (the part ac on Fig. 1a) and the surface of a sphere is neglected, which is admissible if $\varphi_0 \gtrsim 50°$; $B_e \approx B(0, 0)$. Under these assumptions the motion in the flow zone, where the pressure $p > \sigma_s$, becomes the same as the expansion of a sphere in an incompressible fluid.[10] Assuming that the pressure at the flow zone boundary[1)] is equal to σ_s, and neglecting elastic deformation, we obtain the following equation[10] for the magnetic pressure and the inside radius R:

$$R\,\frac{d^2R}{dt^2}+\frac{3}{2}\left(\frac{dR}{dt}\right)^2=\frac{1}{\gamma_0}\left(\frac{B_e^2}{2\mu_0}-\sigma_s\right), \tag{2}$$

where γ_0 is the density. By solving this equation together with (1) and assuming that $R = R_0$ and $dR/dt = 0$ for $B_e \leq \sqrt{2\mu_0\sigma_s}$ we find the field for a given current. This calculational model takes only very crude account of strength effects, but does reflect the threshold character of the deformation. It will be seen later that strength effects are small in an extremely high field

In the special case of a sinusoidal current of amplitude J_m and initial growth rate J' system (1) and (2) can be written in the dimensionless form

$$y\,\frac{d^2y}{dx^2}+\frac{3}{2}\left(\frac{dy}{dx}\right)^2=\frac{1}{y}\,\frac{\sin^2 k_0x}{k_0^2}-\theta_1, \tag{3}$$

$$\frac{B_e}{B_\infty}=\begin{cases}\left(\frac{2}{3}\right)^{1/4}\frac{1}{k_0}\sin k_0x & \text{for}\quad \sin k_0x\leqslant k_0\sqrt{\theta_1},\\ \left(\frac{2}{3}\right)^{1/4}\frac{1}{4k_0}\sin k_0x & \text{for}\quad \sin k_0x> k_0\sqrt{\theta_1},\end{cases} \tag{4}$$

where $x = t/t_r$, $t_r = R_0(2\gamma_0/\mu_0)^{1/4}(a_0J')^{-1/2}$; $k_0 = \omega t_r = J't_r/J_m$; $y = R/R_0$; $\theta_1 = \sigma_s(2/\mu_0\gamma_0)^{1/2}/a_0J'$; and $B_\infty = \mu_0^{3/4}(3\gamma_0)^{1/4}(a_0J')^{1/2}$. The numerical solution of Eqs. (3) and (4) shows that the maximum induction is reached before the current maximum, and that the relative change in the radius at maximum induction t_m is small. At large values of the parameter $1/k_0$ (strong fields) the maximum field is reached at the front of the sinusoid ($i = J't$). The

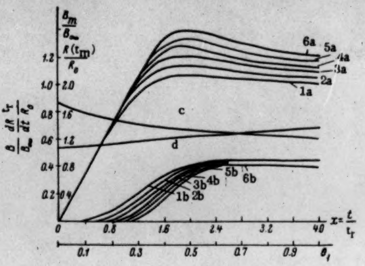

Fig. 2. Calculated time dependence of the field in a biconical solenoid for a linearly increasing current (hydrodynamic model). a) $B/B_\infty = f(x)$; b) $(dR/dt)t_r/R_0 = f(x)$; c) $R(t_m)/R_0 = f(\theta_1)$; d) $B_m/B_\infty = f(\theta_1)$. 1) $\theta_1 = 0$; 2) 0.2; 3) 0.4; 4) 0.6; 5) 0.8; 6) 1.0.

calculated curves for a linearly increasing current (Fig. 2) are close to one another if the strength parameter $\theta_1 \leqslant 0.2$–0.4. The function $B_m/B_\infty = f(x)$ has a weak maximum and then the induction approaches the limiting value

$$\lim_{x\to\infty}\frac{B_e}{B_\infty}=\left(\sqrt{1+\frac{\theta_1^2}{6}}-\frac{\theta_1}{\sqrt{6}}\right)^{-1/2}. \tag{5}$$

In the special case $\theta_1 = 0$, $B_e = B_\infty$. The solution of the equation for $\sigma_s = 0$ is also obtained in the limiting case of a source of "infinite strength" with a voltage $U_0 \approx d(\pi R^2 B_e)/dt$. In this case the induction first increases linearly ($B_e = U_0 t/\pi R_0^2$), reaches a maximum value of $B_m = 0.96(U_0/\pi R_0)^{1/2}(8\mu_0\gamma_0/9\pi)^{1/4}$ at time $t_m = 1.3R_0^{3/2}\cdot(8\mu_0\gamma_0/9\pi)^{1/4}(\pi/U_0)^{1/2}$, and then decreases: $B_e \approx [(8\mu_0\gamma_0)\cdot(9\pi t)^{-1}]^{1/3}$.

The value of the induction also depends on the skin effect and electric explosion; in short coils the most important mechanism is slow explosion – the ejection of molten metal across the faces.[7,11] To take account of the skin effect it is important to know the effective depth of penetration, the thickness of the skin layer, $\Delta' = B_e/\mu_0\delta_0$ at each time, where δ_0 is the current density at the surface of the solenoid. We have found approximation expressions[11] for Δ'. If Δ' is known the effect of the skin effect on the value of the induction at the center of a biconical solenoid can be estimated from the expression

$$B(0,\ 0)=\frac{a_0\mu_0 i}{R+\frac{\Delta'}{\pi}}=\frac{a_0\mu_0 i}{R'}, \tag{6}$$

where R' is the effective radius. Equation (6) can be obtained by assuming that the current is concentrated in the region $0 < x_1 < \Delta'/2$, with its density depending only on x_1: $\delta(x_1) = \text{const}\,[1-(2x_1/\Delta')^2]^{-1/2}$. This relation corresponds to a stationary explosion of the skin layer when the velocity of the field-conductor boundary $\Omega = dR'/dt$ is constant or slowly varying.[11] Equation (6) will be used later in the composite model of the distortion of a solenoid.

General relations giving an approximate description of a slow explosion are obtained in ref. 11. For a sinusoidal current in a biconical solenoid the slow explosion process is described by the following system of differential equations, which can be obtained from Eqs. (23)-(25) of ref. 11 by using the supplementary relation[2)] $l = \xi_0 R$ and Eq. (1):

$$P\frac{d}{dt}(B_e\Delta')=\frac{\rho_s B_e}{\mu_0(\Delta'-k_1 S)}-\frac{2B_e^2 S}{\xi_0 R\sqrt{\mu_0\gamma_0}}, \tag{7}$$

$$\frac{dS}{dt}=\frac{B_e^2\rho_0 3}{\mu_0^2 k_1\Delta'}-\frac{2SB_e}{\xi_0 R\sqrt{\mu_0\gamma_0}}, \tag{8}$$

$$B_e=\frac{1}{R}a_0\mu_0 J_m\sin\omega t, \tag{9}$$

$$\Omega=\frac{2SB_e}{\xi_0 R\sqrt{\mu_0\gamma_0}}=\frac{dR}{dt}. \tag{10}$$

The system (7)-(10) determines the field in the solenoid, the change of radius, the thickness of the skin layer, and the thickness S of the layer of molten metal ejected along the lines of force across the faces by the magnetic pressure. In Eqs. (7)-(10) ρ_s is the specific resistance of the melt, and β is the coefficient in the linearized relation for the specific resistance as a function of the volumetric energy density Q: $\rho = \rho_0(1+\beta Q)$. Specific values of the parameters P and k_1 can only be found from an exact solution of the partial differential equations describing the diffusion of the field into a medium heated by eddy currents. In the most interesting case, however, when the characteristic values vary slowly, one can take[11] P = 0.33 and k_1 = 2. Assume that the calculated peak induction $\mu_0 a_0 J_m/R_0 \gg B_s$, where $B_s = [2\mu_0(\rho_s-\rho_0)/\rho_0\beta]^{1/2}$, R_0 is the initial radius of the solenoid when the explosion begins on the linear part of the current sinusoid, and the initial conditions for the solution of system (7)-(10) can be found from a calculation of the process preceding the explosion: $t = t_s = R_0 B_s/\mu_0 a_0 J'$; $B(t_s) = B_s$; $R(t_s) = R_0$; $S(t_s) = 0$; $\Delta'(t_s) \approx (6\rho_s t_s/5\mu_0)^{1/2}$.

Equations (7)-(10) and the initial conditions can be put in dimensionless form by choosing B_s as the reference induction, $\rho_s B_s^2\mu_0^{-3}(a_0 J')^{-2}$ as the reference time, and $\rho_s B_e/\mu_0^2 a_0 J'$ as the reference length. For a sinusoidal current the behavior of the function $B_e/B_s = b = f(\tau)$ is determined by three dimensionless parameters:[3)] $\bar{r}_0 = R_0\mu_0^2 a_0 J'/\rho_s B_s$, $\eta_1 = (\mu_0\gamma_0)^{-1/2}(2B_s^2/\xi_0 a_0\mu_0 J')$, and $\eta_2 = \omega\rho_s B_s^2\mu_0^{-3}(a_0 J')^{-2}$. Numerical calculations show that when the induction is appreciably smaller than its calculated value the field at first increases linearly with a growth rate characterized by $\bar{r}_0$, and then as the current increases a quasistationary explosion regime is established with the left-hand sides of Eqs. (7) and (8) close to zero. At large values of η_1 the explosion is nearly "idealized",[11] and in this case the amplitude of the induction remains close to the threshold value B_s. For small values of η_1 the amplitude $B_m > B_s$. In the quasistationary regime the following approximate dimensionless equation can be obtained for the induction:

$$\frac{d}{d\tau}\left(\frac{\sin n_2\tau}{\eta_2 b}\right)=b\sqrt{\frac{\eta_1\eta_2(b^2-1)}{2\sin\eta_2\tau}}, \tag{11}$$

where $b = B_e/B_s$. When $b_m = B_m/B_s \gg 1\,(\eta_1\eta_2 \ll 1)$ its solution has the form

$$b\approx\left(\frac{2}{9\eta_1\eta_2}\right)^{1/3}\sin\eta_2\tau\left[\int_0^{\eta_2\tau}(\sin x)^{2/3}\,dx\right]^{-1/3}. \tag{12}$$

Hence in a slow explosion the amplitude of the induction is

$$B_m \approx \chi\mu_0\left(\frac{\gamma_0}{\mu_0}\right)^{1/12}\left(\frac{\xi_0\tau_0}{\rho_0^3}\right)^{1/6}(a_0J')^{1/2}, \tag{13}$$

where $\tau_0 = \pi/2\omega$ is the rise of time of the current, and $\chi = [(4/\pi)\sin x_m \cos^2 x_m]^{1/6} \approx 0.8$. The maximum of the induction is very flat and occurs at the time $\tau_m = \chi_m/\eta_2$, where x_m is the first nonzero root of the equation

$$3\int_0^{x_m}(\sin x)^{4/3}\,dx = \operatorname{tg} x_m \sin^{4/3} x_m.$$

The limiting regime which the system enters for a linearly increasing current ($i = J't$) is given by the following relations, which follow from Eqs. (7)-(10):

$$B_e = \mu_0\left(\frac{\gamma_0}{\mu_0}\right)^{1/12}\left(\frac{25\xi_0 t}{18\rho_0^3}\right)^{1/6}(a_0J')^{1/2}, \tag{14}$$

$$\Delta' \approx 2S = \left(\frac{\gamma_0}{\mu_0}\right)^{1/4}\left(\frac{\xi_0}{2}\rho_0\beta a_0J't\right)^{1/2}, \tag{15}$$

$$R = \left(\frac{18\rho_0^3}{25\xi_0}\right)^{1/6}\left(\frac{\mu_0}{\gamma_0}\right)^{1/12}(a_0J')^{1/2}t^{5/6}. \tag{16}$$

It is characteristic that the induction increases slowly with time ($B_e \sim t^{1/6}$) and is proportional to $\sqrt{J'}$.

2. COMPOSITE MODEL FOR THE DISTORTION OF A SOLENOID IN AN EXTREMELY HIGH MAGNETIC FIELD

Each of the models discussed above takes account of only one aspect of the distortion of a solenoid. For example, Eqs. (1) and (9) contain the geometrical inside radius R instead of the effective radius, while the slow explosion model does not take account of hydrodynamic flow outside the skin layer.

It is possible to calculate the increase in effective radius of a biconical solenoid under the combined action of the diffusion of the field, deformation, and slow explosion. This can be done by taking account of the fact that the change in inside radius is due both to the shift of the field-conductor boundary as a result of ejection, and to the hydrodynamic flow

$$\frac{dR}{dt} = \Omega + u(R). \tag{17}$$

The spherically symmetric flow velocity of an incompressible fluid at a point M(r) has the form $U_r(M) = R^2u(R)/r^2$. Substituting this value into Euler's equation

$$\gamma_0\left(\frac{\partial u_r}{\partial t} + u_r\frac{\partial u_r}{\partial r}\right) = -\frac{\partial p}{\partial r},$$

and integrating over r from R to ∞ we obtain

$$\frac{1}{\gamma_0}\left(\frac{B_e^2}{2\mu_0} - \sigma_s\right) = -\frac{1}{2}\left(\frac{dR}{dt} - \Omega\right)^2 + \int_R^\infty \frac{d}{dt}\left[R^2\left(\frac{dR}{dt} - \Omega\right)\right]\frac{dr}{r^2}$$
$$= R\frac{d^2R}{dt^2} + \frac{3}{2}\left(\frac{dR}{dt}\right)^2 - \Omega\frac{dR}{dt} - R\frac{d\Omega}{dt} - \frac{\Omega^2}{2}. \tag{18}$$

This equation must be solved together with (7), (8), (10), and the equation

$$B_e \approx B(0,\,0) = \frac{a_0\mu_0 J_m \sin\omega t}{R + \frac{\Delta'}{\pi}}, \tag{19}$$

which is used instead of (9) to take account of the skin correction in the value of the effective radius according to Eq. (6). Equations (7), (8), (10), (18), and (19) are valid when $B_e \geq B_s$; before this time $\Omega = dS/dt = 0$, and Eq. (7) has the form

$$P\frac{d}{dt}(B_e\Delta') = \frac{\rho_0 3B_e^3}{2\mu_0^2\Delta'}. \tag{20}$$

If $B_e^2/2\mu_0 < \sigma_s$ the left-hand side of Eq. (18) must be set equal to zero, and $dR/dt = \Omega$. The initial conditions for the system (7), (8), (10), (18), and (19) are: at $t = 0$, $R = R_0$, $\Delta' = 0$. For numerical calculations this system is put into dimensionless form. The reference quantities are chosen the same as in the hydrodynamic flow calculation. The details of the calculations will be published separately. Here we merely point out that the form of the relation $B/B_\infty = f(t/t_r)$ for a sinusoidal current is determined by the set of dimensionless parameters mentioned above: $k_0, \theta_1, \eta_1, \eta_2$, and ξ_0. The results of a numerical solution of the system for the specific conditions of the experiment are shown in Figs. 4-7.

3. SIMILITUDE CONDITIONS

Another approach to an estimate of the field in a coil being distorted is based on dimensional considerations. Let us assume that a sinusoidal current with an amplitude J_m and a rise time τ_0 flows through a biconical solenoid with a cylindrical opening of initial radius R_0.

The peak induction can be written as a function of the characteristic parameters4)

$$B_m = f_1(R_0,\ \xi_0,\ J_m,\ \tau_0,\ \rho_0,\ \beta,\ \gamma_0,\ \mu_0,\ \sigma_s,\ Q_s), \tag{21}$$

where $Q_s = B_s^2/2\mu_0$ is the volume energy density at the beginning of the slow explosion. Four parameters with independent dimensions can be eliminated from Eq. (21). We choose μ_0, J_m, R_0, and τ_0. With this we have

$$B_m = B_r f_2(\eta_0,\ g_1,\ g_2,\ g_3,\ g_4,\ g_5,\ g_6), \tag{22}$$

where $B_r = \mu_0 J_m/R_0$ is the reference induction,5) $g_1 = \rho_0\tau_0/\mu_0R_0^2$; $g_2 = J_m\mu_0\beta/R_0^2$; $g_3 = J_m\tau_0(\mu_0\gamma_0)^{1/2}R_0^{-2} = (1/k_0^2)\cdot(\sqrt{2}/a_0)$; $g_4 = \mu_0J_m^2/R_0^2\sigma_s = \theta_1$; $g_5 = \mu_0J_m^2/R_0^2Q_s$.

For very weak currents ($g_2 = g_3 = g_5 = 0$) we have a linear relation between B_m and J_m: $B_m = (\mu_0J_m/R_0)\varphi(\xi_0, g_1)$. The parameter g_1 takes account of the skin effect in weak fields but does not play an important role in strong fields, where there is a significant increase in the specific resistance because of heating. In such fields a characteristic quantity is the ratio of the depth of penetration Δ' to R_0 at the time t_m when the induction is maximum:12

$$\frac{\Delta'}{R_0} \approx \frac{B_m}{\mu_0R_0}\left(\frac{\rho_0 3t_m}{2}\right)^{1/2} = \frac{J_m}{R_0^2}(\rho_0\beta\tau_0)^{1/2}\left(\frac{t_m}{2\tau_0}\right)^{1/2}\frac{B_mR_0}{\mu_0J_m} = \left(\frac{t_m}{2\tau_0}\right)^{1/2}(g_1g_2)^{1/2}f_2. \tag{23}$$

Hence it follows that in a strong field the value of B_m/B_r depends on the combination $G = (g_1g_2)^{1/2} = (8\pi\eta_2)^{1/2}$.

$(a_0\xi_0\eta_1 R_0^3)$ and not on g_1 and g_2 separately. Since the amplitude of the induction varies slowly with σ_S and Q_S in strong fields one can expect f_2 to be only weakly dependent on the parameters g_1 and g_5. Consequently we have

$$\frac{B_m R_0}{\mu_0 J_m} = f_3(\xi_0,\ G,\ g_3) = f_3\left[\xi_0,\ \frac{J_m}{R_0^2}(\rho_0\vartheta\tau_0)^{1/2},\ \frac{J_m\tau_0}{R_0^2}\left(\frac{\mu_0}{\gamma_0}\right)^{1/2}\right] \tag{24}$$

or for samples of a given material and for a fixed rise time

$$\frac{B_m R_0}{\mu_0 J_m} = f_4\left(\frac{J_m}{R_0^2}\right), \tag{25}$$

since both parameters G and g_3 are proportional to J_m/R_0^2. In the experiments to be described later an attempt is made to test this conclusion.

4. DESCRIPTION OF EXPERIMENTS. COMPARISON OF THEORY AND EXPERIMENT

Preliminary results of experiments with copper and steel biconical solenoids (φ_0 = 53°; ξ_0 = 1.5) are reported in ref. 9.

Experiments have been performed on a large number of copper and steel solenoids with various initial inner radii R_0. The smallest value[6] of $R_0 = R_0^{(1)}$ = 1.7 mm. The solenoids are 20 mm in outside radius and are supported by rigid steel clamps. The insulating gap is about 1 mm wide. The field is measured with calibrated probes about 0.8 mm in radius with three to six turns. The current is measured with a Rogowski loop. Oscillograms of the induction, the current, and their derivatives are taken simultaneously. The error in the first peak of the current and the induction is 5-7%. The capacitor bank has a capacitance of 100 mF and an inductance of ~80 nH. Because of the variation in the initial voltage of the capacitor bank the current varies from 1.2 to 2.6 mA with a rise time τ_0 = 4.5 ± 0.2 μsec. The first peak induction is 190 Wb/m².

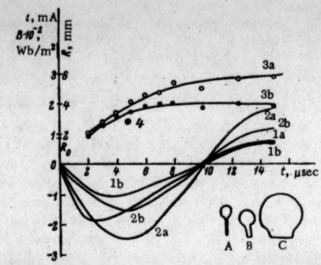

Fig. 3. Time dependence of induction, current, and effective inside radius during discharge. 1a) B(t); 2a) i(t); 3a) R'(t), copper, J_m = 2.44 mA, B_m = 184 Wb/m²; 1b, 2b, 3b) the same for steel, J_m = 1.53 mA, B_m = 113 Wb/m²; 4) value from x-ray photograph of steel; A, B, C are respectively typical x-ray photographs taken before the experiment, during the discharge, and after the experiment.

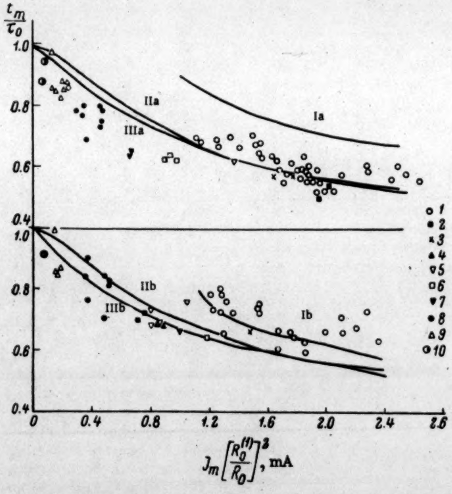

Fig. 4. Experimental points and calculated curves for the time of maximum induction as a function of the current amplitude. I) Calculated with the slow explosion model; II) calculated with the hydrodynamic model; III) calculated with the composite model. a) copper; b) steel. The points correspond to the initial radii of the samples. For copper: 1) R_0 = 1.7; 2) 1.8; 3) 1.9; 4) 2.05; 5) 2.15; 6) 2.5; 7) 3; 8) 3.4; 9) 5.1; 10) 6.8 mm; for steel: 1) 1.7; 2) 2.8; 3) 1.9; 4) 2.05; 5) 2.15; 6) 2.2; 7) 2.3; 8) 3.4; 9) 5.1; 10) 6.8 mm.

In addition to the oscilloscope measurements, in some experiments x-ray photographs are taken of the contour of the opening of the solenoid at a specified time using an exposure of $\sim 10^{-7}$ sec (Fig. 3). Examples of processed oscillograms of B(t) and i(t) are shown in Fig. 3.

It is typical that the induction maximum is reached earlier than the current maximum. This shows indirectly the increase in the effective radius at the front of the current pulse.

Figure 4 shows t_m/τ_0 as a function of $J_m(R_0^{(1)}/R_0)^2$, proportional to J_m/R_0^2. Here $R_0^{(1)} = 1.7$ mm, so that for points corresponding to this initial radius the measured rather than the calculated value of J_m is plotted along the axis of abscissas. As predicted by dimensional analysis the points for all samples lie on a common curve. For large R_0 (weak fields) the curve approaches unity. As the argument $J_m(R_0^{(1)}/R_0)^2$ increases, the ratio t_m/τ_0 decreases to 0.5-0.6 in the copper samples and to 0.6-0.7 in the steel specimens. As can be seen from Fig. 5 the

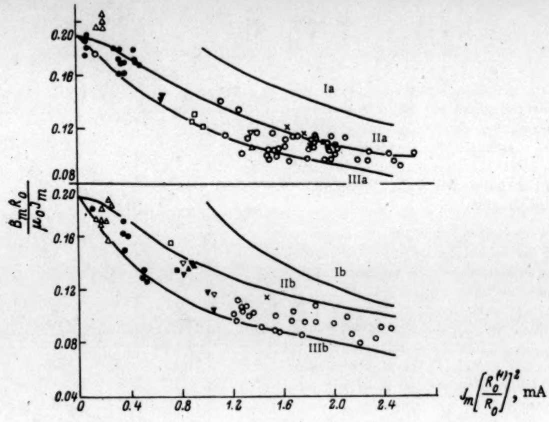

Fig. 5. Ratio of the amplitude of the induction to its calculated value. Notation is the same as in Fig. 4.

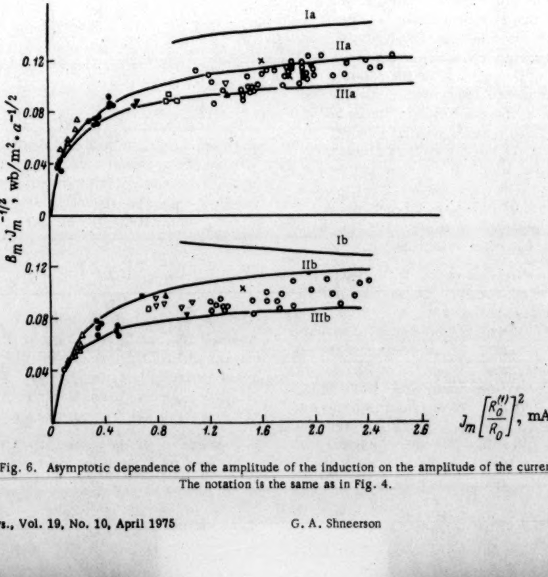

Fig. 6. Asymptotic dependence of the amplitude of the induction on the amplitude of the current. The notation is the same as in Fig. 4.

TABLE 1. Comparison of the Inside Radius R Calculated from an X-ray Photograph and the Effective Radius R'

R_0, mm	Copper			Steel		
	t_0, μsec	R, mm	R', mm	t_0, μsec	R, mm	R', mm
1.7	4.0	2.7	2.7	4.0	2.5	3.3
	4.1	2.9	3.3	4.1	2.8	3.5
	4.2	3.0	3.3	4.7	2.8	3.3
	4.2	3.5	3.0	5.1	3.4	3.8
	5.0	3.5	3.7	6.6	3.4	4.3
	7.4	4.6	5.0	7.1	3.7	4.6
	7.4	4.6	4.7			
3.4	6.5	4.3	4.3	6.9	3.7	4.5
	6.6	4.5	4.5	6.9	4.0	4.7
	7.1	4.4	4.5			

experimental points for small values of the argument lie close to the curve, clustered about the point $B_mR_0 = \mu_0J_m = 0.19$, which corresponds to the field in a perfectly conducting solenoid with a vanishingly narrow gap. As the current increases, this ratio decreases to 0.08-0.09, which corresponds to a decrease in the amplitude of the induction to less than half the calculated value.

Figure 6 shows the maximum induction as a function of the peak current in a strong field. The ratio $B_m/J_m^{-1/2}$ in strong fields does not depend on the argument $J_m \cdot (R_0^{(1)}/R_0)^2$. This agrees with the assumption in ref. 9 that the peak induction in a strong field increases as $\sqrt{J'}$ or, for a fixed rise time τ_0, as $\sqrt{J_m}$. It was shown above that this behavior of B_m in biconical solenoids follows from both the hydrodynamic model and the slow explosion model. A special consideration shows that it follows from the composite model also.

The geometrical radius R of a solenoid at a given time t_0 can be determined from the x-ray photographs (Fig. 3). The photographs show that the opening retains its shape during the first half-period of the discharge. The results of processing the x-ray photographs for a number of experiments are shown in Table 1. These results are compared with the values of the effective radius R' obtained by the processing of the oscillograms of B(t) and i(t). As in refs. 2-4, the processing technique consists in determining the instantaneous value of the effective inside radius R' from the experimental value of the ratio $g'(t) = B(t)/J(t)$, since it is known that $g' = f(R') = 0.19\ \mu_0/R'$. Examples of the curves R'(t) are shown in Fig. 3. The error in determining R'(t) is estimated as 0.2-0.3 mm for R' = 2-3 mm. The values of $R'(t_m)$, the effective radius at maximum induction, lie between 2.1 and 2.5 mm for copper solenoids with R_0 = 1.7 mm, and between 2.4 and 2.9 mm for steel solenoids.

The variation in the effective radius up to the instant of maximum induction is appreciably larger. Against the background of the spread, apparently related to the experimental errors, $R(\tau_0)/R_0$ increases monotonically with the argument $J_m(R_0^{(1)}/R_0)^2$ (Fig. 7). A comparison of the effective radius found from the oscillograms of B(t) and i(t) with the results of the x-ray measurements (Table 1) illustrates the role of the diffusion of the field into the conductor. The value of $R'(t_0)$ is always larger than the radius of the opening of the solenoid. The error in determining R_0 prevents an exact calculation of the depth of penetration and a verification of the diffusion calculation.

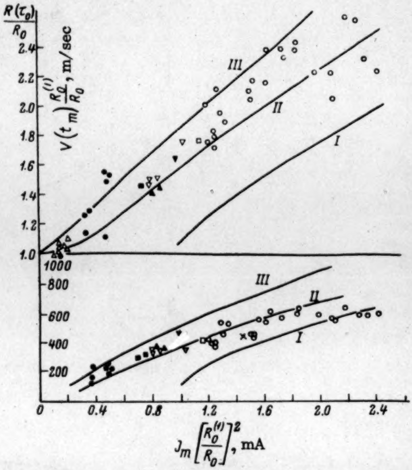

Fig. 7. Effective inside radius of a solenoid at the instant of maximum current, and the velocity at the instant of maximum induction. Copper. The notation is the same as in Fig. 4.

Because of the error in determining R' there is an appreciable error in the estimate of dR/dt, the rate of increase of the effective radius. It is simplest to determine this rate at the point of maximum induction t_m, where $dB/dt = 0$ and, consequently, $i(dg'/dt) + g'(di/dt) = 0$. Since $g' = \text{const}/R'$, the velocity at time t_m is

$$V(t_m) = \frac{dR'}{dt}(t_m) = \frac{R'(t_m)}{i(t_m)}\frac{dJ}{dt}(t_m) \approx \frac{\pi a_0\mu_0 J_m}{2B_m\tau_0}\cos\frac{\pi t_m}{2\tau_0}. \qquad (26)$$

The error in determining $V(t_m)$ is about 20%. The experimental results are shown in Fig. 7 in the form of curves of $V(t_m)R_0^{(1)}/R_0$ as functions of $J_m(R_0^{(1)}/R_0)^2$. The ratio $V(t_m)R_0^{(1)}/R_0$ is plotted: For fixed τ_0 the ratio $R_0/R_0^{(1)}$ is proportional to the reference velocity R_0/τ_0 in the system of defining parameters μ_0, J_m, R_0, and τ_0.

In our experiments the absolute value of $V(t_m)$ reaches 600-700 m/sec. The spread of experimental points in Figs. 4-7 pertaining to solenoids with various initial radii lies within the limits of experimental error. This confirms the dimensional-analysis conclusion that in strong fields the quantities $B_m R_0/\mu_0 J_m$, $R(\tau_0)/R_0$, and $V(t_m)R_0^{(1)}/R_0$ are functions of J_m^2/R_0 for a fixed rise time. Figures 4-7 show the results of numerical calculations using the hydrodynamic model (neglecting the strength term), and the slow explosion and composite models approximately satisfying the experimental conditions with $R_0 = 1.7$ mm. Under our experimental conditions the slow explosion model overestimates the amplitude of the induction and appreciably overestimates the rate of distortion. Hydrodynamic flow is the main process. Calculations with the hydrodynamic model give values of the peak induction, the radius, and the velocity close to the experimental results, although the values of B_m are somewhat overestimated. The quantitative agreement is even better than could be expected, taking account of the calculational assumptions about the nature of the flow in the distortion of a solenoid. As expected, going over to the composite model gives a smaller correction for copper solenoids than for steel, since the skin layer is thicker in steel. For both materials the composite model underestimates the induction and overestimates the velocity and the effective radius. Apparently ejection plays a somewhat smaller role than assumed in the present calculations, which do not take account of the time to establish a steady flow of heated metal in the skin layer.

The author thanks A. Kruchinin for the computer calculations.

Dependence of the basic parameters of $Al_xGa_{1-x}As$–GaAs solar converters on temperature and optical intensity

E. B. Vinogradova, M. B. Kagan, N. S. Koroleva, T. L. Lyubashevskaya, and T. A. Nuller

(Submitted October 8, 1973)
Zh. Tekh. Fiz. 44, 2229-2234 (October 1974)

We have investigated the basic parameters of p-$Al_xGa_{1-x}As$–n-GaAs solar converters over wide ranges of temperatures and optical intensity. The low inverse saturation currents, the high constant collection coefficients over the entire spectrum, and the specific features of the electrical characteristics result in a high temperature stability of the power output and certain features over a wide range of temperatures and optical intensity.

Solar converters made of $Al_xGa_{1-x}As$-GaAs heterosystems retain their high efficiency at high temperatures. An efficiency factor of about 3% is obtained in ref. 1 and about 5% in ref. 2 at 300°C. It is noted for comparison that the best Si solar elements have an efficiency factor close to zero at T ≈ 170°C, whereas solar elements in which diffused GaAs p–n junctions are employed still have an efficiency factor[3] of about 1% at 300°C. The peculiar electrical characteristics which are described in ref. 4 may be the reason for the high temperature stability of the power delivered by the solar converters and for their efficiency. The electrical characteristics, in turn, result in a specific performance at low temperatures and at high illumination intensities; those conditions have not been considered in the literature.

The present paper reports on an investigation of the basic parameters of solar converters made of p-Al_xGa_{1-x}As–n-GaAs in the temperature range 100-200°C. In addition, the dependence of the basic parameters upon the illumination intensity in the interval (1-40)·10^3 W/m^2 is described. The results are compared with the data on homogeneous solar elements made of GaAs.

1. EXPERIMENTAL INVESTIGATIONS AND RESULTS

Figures 1 and 2 depict typical temperature dependences of the optimum power, the current delivered to an optimum load, and the short-circuit current for Al_x·Ga_{1-x}As–GaAs converters; these have been measured in the temperature range 20-200°C at a constant illumination intensity of ≈800 W/m^2. Figures 1 and 2 include, for comparison, the temperature dependence of the basic parameters which have been measured for GaAs photoelements with diffused p–n junctions under similar experimental conditions. In contrast to the latter, a decrease in the optimum power at increasing temperatures of Al_xGa_{1-x}As–GaAs converters cannot be described by a linear function with a constant negative gradient: The value $\delta = \partial P_{opt}/\partial T P_{opt}$ is much lower at temperatures up to +100°C than at higher temperatures, being 0.03-0.1 %/deg C for the various samples. The δ value for the interval 100-200°C coincides with the values which are typical for GaAs converters (≈0.25%/deg C). The Al_x·Ga_{1-x}As–GaAs converters are characterized by 1) an increase in the current $I_{sat.opt}$ at the optimum point with increasing temperature (up to 120-140°C) and 2) a positive gradient of the short-circuit current (which is much greater than in GaAs elements) $\gamma = \partial I_{sh.c.}/\partial I I_{sh.c.}$, with the gradient amounting to 0.25%/deg C in some cases. The photo-emf U_{ph} (open-circuit emf) decreases linearly at increasing temperatures and has a constant negative gradient $\delta = \partial P_{ph}/\partial T U_{ph}$ = (0.20-0.25)%/deg C (see Fig. 3).

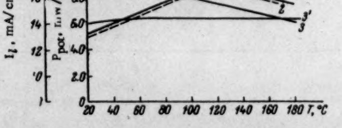

Fig. 1. Temperature dependences of the optimum power P_{opt} and the current I_l obtained with optimum load at positive temperatures. 1, 2) P = f(T) for $Al_xGa_{1-x}As$–GaAs photoconverters (experimental values); the dot–dash line indicates P = f(T) for $Al_xGa_{1-x}As$–GaAs photoconverters (computed values); 3) P = f(T) for GaAs photoconverters; 1',2') $I_l = f(T)$ $Al_xGa_{1-x}As$–GaAs photoconverters.

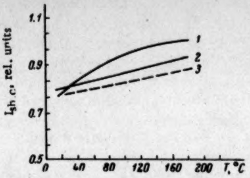

Fig. 2. Temperature dependence of the short-circuit current $I_{sh.c.}$ 1) $I_{sh.c.} = f(T)$ for $Al_xGa_{1-x}As$–GaAs photoconverters corresponding to spectral curves 1 and 1' of Fig. 4; 2) $I_{sh.c} = f(T)$ for $Al_xGa_{1-x}As$–GaAs photoconverters corresponding to spectral curves 2 and 2' of Fig. 4; 3) $I_{sh.c} = f(T)$ for GaAs photoconverters.

At low temperatures (temperatures below −100°C have been considered), the behavior of the $Al_xGa_{1-x}As$–GaAs converters is characterized by the inflection of the functions P(T) and U_{ph}(T) at a certain critical temperature which is characteristic of solar elements of Si (ref. 5) and GaAs (ref. 6), with the inflection being related to changes in the mechanism of current flow (Fig. 3). In diffused GaAs elements the sharply increased influence of surface leakage currents at $T_{cr} \approx -60$°C leads to a saturation point of the functions $I_0 = f(T)$ and $\beta = f(T)$, which, in turn, limits the increase in power at decreasing temperatures.

It is shown in ref. 4 that two exponential sections in the forward branch of the voltage–current characteristic are typical for Al_xGa_{1-x}As–GaAs converters. The experimental curves $I_0 = f(T)$ and $\beta = f(T)$ shown in Fig. 3 have a typical exponential decrease in the inverse saturation current at decreasing temperatures in the region of lowest I_0 and β. No substantial changes of the parameter β are observed.

We have investigated the temperature dependence of the spectral collection coefficient Q(λ) of $Al_xGa_{1-x}As-GaAs$ converters in order to determine the reasons for the positive temperature gradients of the photocurrent, which, when compared with GaAs elements, are abnormally large in the interval +20 to + 200°C (Fig. 4). It is observed that the form of the collection coefficient dependence on wavelength depends strongly on the initial (T = 300°K) form of the function Q(λ) at increasing temperatures. The greatest change of Q(λ) = *f*(T) and, hence, the maximum increment of the integrated photocurrent $\gamma \sim 0.25\%$/deg C are observed in converters with an initial function Q(λ) of type 1 (Fig. 4), i.e., with a sharp drop of the collection coefficient in the long-wave part of the spectrum. A wavelength dependence of type 2 (Fig. 4) corresponds to a smaller temperature gradient of the photocurrent ($\gamma \sim 0.1\%$/deg C). A shift of both long-wave and short-wave edges of the function Q(λ) is observed in all cases in accordance with the temperature dependences of the widths of the forbidden-energy gaps in GaAs and $Al_xGa_{1-x}As$.

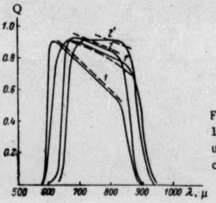

Fig. 4. The collection coefficient Q(λ). 1, 2) Q(λ) at 300°K (experimental values); the dashed curves refer to calculated Q(λ) values.

The dependence of the basic parameters of $Al_xGa_{1-x}As-GaAs$ converters on the illumination intensity has been studied in the interval (1-40) $\cdot 10^3$ W/m² at T = 300°K; a K-22 cinema projector lamp provided with lenses and neutral filters is used as the illuminating source. Converters having different initial parameters I_{ph}, I_0, and β are examined. As in the case of the measurements of the temperature dependence the initial parameters are determined from the forward branch of the voltage–current characteristic, i.e., from the branch which corresponds to the high-current region. The experimental dependences $I_{ph} = f(E)$, $I_{sh.c.} = f(E)$, and $P_{opt} = f(E)$ are shown in Fig. 5. Figure 5 includes, for comparison, the relations for a typical GaAs element. The measurements of the photocurrent are made in the range of high light fluxes while an inverse bias voltage is applied to the illuminated sample. This makes it possible to establish differences in the behavior of the measured short-circuit current $I_{sh.c.}$ and the photocurrent I_{ph}, which is independent of the series resistance of the units. A linear dependence of I_{ph} on the light flux is observed in all cases, but the slope of the dependence is usually much greater than for GaAs. At light fluxes corresponding to approximately 25 solar constants, a photocurrent density of ~600 mA · cm^{-2} is reached in some of the samples. With series resistances which are the same as in the case of GaAs elements, the deviations of $I_{sh.c}$ from the linear dependence are observed at much greater light fluxes. The flux value at which the deviations begin depends upon the current I_0. The optimum power also depends on the current I_0 at increasing light fluxes and is characterized by two sections: a linear section extending to fluxes of (10-20) $\cdot 10^3$ W/m² at various I_0, and a section on which the power depends upon the flux like $P \sim E^{1/2}$. A linear dependence $P_{opt} = f(E)$ of GaAs elements is usually observed only to (10-12) $\cdot 10^3$ W/m².

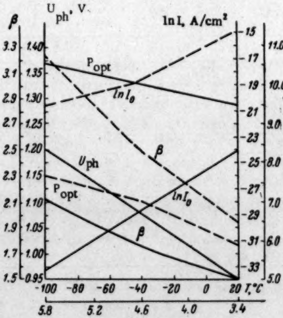

Fig. 3. Temperature dependences of the optimum power P_{opt}, the open-circuit voltage U_{ph}, the inverse saturation current I_0, and the parameter β at negative temperatures. The solid lines indicate P = *f*(T), U_{ph} = *f*(T), I_0 = *f*(T), and β = *f*(T) for $Al_xGa_{1-x}As-GaAs$ photoconverters; the dashed curves indicate P = *f*(T), U_{ph} = *f*(T), I_0 = *f*(T), and β = *f*(T) for GaAs photoconverters.

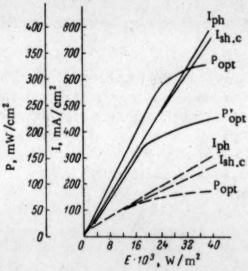

Fig. 5. Dependences of the photocurrent I_{ph}, the short-circuit current $I_{sh.c}$, and the optimum power P_{opt} upon the light flux. The solid curves refer to I_{ph} = *f*(E), $I_{sh.c}$ = *f*(E), and P_{opt} = *f*(E) for $Al_xGa_{1-x}As-GaAs$ photoconverters (P_{1opt} refers to photoconverters with $I_0 \approx 10^{-13}$ A/cm² and P_{2opt}, to photoconverters with $I_0 \approx 10^{-11}$ A/cm²); the dashed curves indicate I_{ph} = *f*(E), $I_{sh.c}$ = *f*(E), and P_{opt} = *f*(E) for GaAs photoconverters.

2. DISCUSSION OF RESULTS

The observed temperature and intensity dependences of the basic parameters of $Al_xGa_{1-x}As-GaAs$ converters result from two factors: an inverse current I_0, which is smaller than that of GaAs elements, and a higher integrated sensitivity, due to the integrated collection coefficient approaching the value unity.

The temperature dependence of the optimum power is

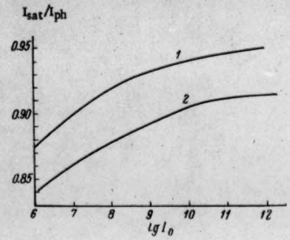

Fig. 6. Dependence of the ratio I_{sat}/I_{ph} upon $\log I_0$. 1) $R_{series} = 0$; $R_{series} = 16\Omega$.

of greatest interest as far as practical applications are concerned. The temperature dependence of the power is anomalous relative to that of the usual diffused GaAs elements at temperatures up to + 100°C and is associated with the low (less than 10^{-9} A/cm^2) inverse saturation current, which, in this temperature interval, is described by the equation

$$I_0 = Ce^{-\frac{E_g}{\beta kT}} \quad (\beta = 1.6). \tag{1}$$

and with a current which is almost equal to the photocurrent at the optimum point (Fig. 6). The increase in the inverse saturation current at increasing temperatures in the range of large inverse currents implies that the current increasingly deviates from the photocurrent at the optimum point. The latter determines the usual temperature dependence of the power of GaAs elements with a temperature gradient dP/PdT ~ 0.25%/deg C. Figure 1 shows the computed temperature dependence of the power of elements with realistic parameters. It is assumed in the calculations that the inverse saturation current is given by Eq. (1) and amounts to 10^{-13} A/cm^2 at 300°K. The temperature dependence of the photocurrent corresponds to the experimentally obtained dependence in Fig. 2. Good agreement between calculated and experimental values is observed in Fig. 1.

It has been shown[4] that the collection coefficient as a function of the wavelength can be calculated with the equation

$$Q = q\left\{\frac{1 - \exp(-\alpha l)}{1 + \alpha L}\right\}, \tag{2}$$

where α denotes the absorption coefficient, l the width of the depletion region in GaAs, and L the diffusion length of holes in the GaAs base.

Figure 4 depicts experimental values of the collection coefficients and collection coefficient figures calculated with Eq. (2) for the temperatures 300°K and 423°K. Good agreement between the calculated and experimental functions is obtained even when only the temperature dependence of the collection coefficient is taken into account (curves 1, 2, 1', and 2').

The temperature dependence of the photocurrent is strongly affected by the temperature dependence of the absorption coefficient, because when the temperature dependence of the absorption coefficient is taken into account good agreement between calculated and experimental collection coefficients as functions of the wavelength is obtained (Fig. 4). Two spectral dependences of the collection coefficient are characteristic of the units examined[4] (Fig. 4). Since the influence of the absorption coefficient on the spectral sensitivity is reduced in the case of high initial collection coefficient values, a unit with a "drop" of the spectral sensitivity in the long-wave part of the spectrum is characterized by a high temperature gradient of the photocurrent (γ ~ 0.2%/deg C, curve 1 of Fig. 4). This figure is twice that of conventional GaAs photoelements. When high temperature gradients of the photocurrent appear in combination with low inverse currents (I_0 ~ 10^{-13} A/cm^2), temperature stability of the power is obtained up to + 100°C. This corresponds to a temperature gradient of the power of ∂P/PdT ~ 0.08%/deg (Fig. 1).

At low temperatures the characteristic feature of $Al_xGa_{1-x}As$–GaAs converters is the absence of the inflection of the functions P(T) and U_{ph}(T) at a "critical temperature," which is typical[5] for Si and GaAs elements. The inflection is associated with a change in the mechanism of the current flow. The absence of this inflection in $Al_xGa_{1-x}As$–GaAs converters is attested by the parameter β, which is constant in the temperature interval under consideration.

The low inverse currents of the units, along with their high temperature stability, cause a peculiar behavior at high illumination fluxes. As has been shown in ref. 7, the light flux intensity at which the increase in the optimum power begins to slow down depends strongly upon the inverse saturation current I_0 and the series resistance R_{series} of the unit. The units examined had identical series resistance (~ 5 Ω) and similar photocurrents I_{ph}. The dependence of the optimum power upon the light flux is in this case determined by the inverse saturation current I_0. It follows from Fig. 5 that the deviation of the optimum power from the linear dependence begins at light fluxes of about (1.4–1.6) · 10^4 W/m^2 in the case of the elements with $I_0 = 10^{-12}$–10^{-13} A/cm^2 and at light fluxes of (1.3–1.4) · 10^4 W/m^2 in the case of units with $I_0 = 10^{-11}$ A/cm^2, i.e., the linear increase in optimum power continues to higher light fluxes than in the case of diffused GaAs units having inverse saturation currents[7] I = 10^{-9}–10^{-10} A/cm^2. The region of light fluxes at which the linear dependence of the power upon the light flux no longer exists is characterized by the function P(E) ~ $E^{1/2}$. This function results from the distributed series resistance. Our investigations have shown that the function P(E) ~ $E^{1/2}$ holds to light fluxes of 40 · 10^3 W/m^2 and a substantial saturation of the power produced by the light flux does not set in.

The high constant collection coefficients of the entire spectral interval imply a high integrated sensitivity K. Since I_{ph} = KE, an increased dependence of both the photocurrent and the optimum power upon the light flux is observed in the units examined. This, in turn, makes it possible to obtain a specific power P > 200 mW/m^2 at light fluxes E ~ 35 · 10^3 W/m^2.

Excitation of thermoelastic vibrations of a thin plate by a beam of fast charged particles

A. I. Kalinichenko and V. T. Lazurik-Él'tsufin

A. M. Gor'kii Khar'kov State University

(Submitted October 30, 1973; resubmitted February 21, 1974)
Zh. Tekh. Fiz., 44, 2235-2238 (October 1974)

The acoustic signal and the stress in a thin plate produced by a dense beam of fast charged particles which penetrates the plate have been calculated. Amplitudes for various particle distribution functions in the beam are presented. It is concluded that the acoustic signal can be used to determine the number density distribution in the beam.

1. When a beam of charged particles passes through a solid various acoustic oscillations are excited in the solid. One cause of the excitation is the superheating of the interaction zone caused by energy losses of the beam particles in the solid. In refs. 1 and 2 the thermoelastic stresses that arise in instantaneous[1] and gradual[2] heating of a free surface of a semiinfinite solid are investigated theoretically. The results can be used to find the thermoelastic response in a solid penetrated by a beam of particles when the depth of penetration into the solid is small in comparison with the characteristic thermal-conductivity length. Experiments based on the one-dimensional thermoelastic response of a solid to collision with a beam of low-energy electrons[3] show good agreement with the theory. The one-dimensional thermoelastic response of a solid when the depth of penetration cannot be neglected is studied experimentally and theoretically in refs. 4 and 5.

Recent experiments have been concerned with the excitation of acoustic vibrations in a thin plate by a beam of relativistic electrons[6] when the acoustic detector is fastened to the lateral face rather than the rear surface of the plate.[7] In this case the acoustic vibrations are diverging cylindrical waves. There is interest in the theoretical thermoelastic response in this case and a comparison of the calculation with experiment.

In the present work we consider fast particles [$h(dE/dx)_{\text{ion}} \ll E$, where h is the plate thickness, E is the energy of the beam particles, $(dE/dx)_{\text{ion}}$ are the ionization losses of a particle per unit path in the target material], thin plates ($h \ll t_0$, where t_0 is the radiation length of the target material), and dense beams.

2. We consider the acoustic signal from a cylindrical beam of charged particles whose current density j(r) depends only on the distance r to the beam axis. The ionization losses of fast charged particles of the beam lead to the generation (in the solid) of a volume thermoelastic force

$$\mathbf{F}_T(r,\ t) = -\Gamma \nabla P(r,\ t), \tag{1}$$

where Γ is the Grüneisen constant of the target material (we assume that Γ is independent of direction in the target material as is the case in polycrystalline media and in single crystals with cubic symmetry); P(r, t) is the density of the absorbed energy. Assuming that in a thin plate only the ionization losses are of basic importance, and all other forms of loss of charged particles (bremsstrahlung, Cerenkov radiation, transition radiation) can be neglected, we obtain the following expression for the density of absorbed energy:

$$P(r,\ t) = j(r)\left(\frac{dE}{dx}\right)_{\text{ion}}[t - (t - t_b)\,\theta(t - t_b)], \tag{2}$$

where t is the time measured from the beginning of the interaction of the beam with the solid plate:

$$\theta(t - t_b) = \begin{cases} 0, & t - t_b < 0, \\ 1, & t - t_b \geqslant 0, \end{cases}$$

t_b is the time that the beam acts. We assume that both the time that the beam acts t_b and the acoustic relaxation time between the beam and the plate $\tau_S = R/c_l$ are considerably smaller than the time for temperature $\tau_T = R^2/4a$ which, for real beams, is 0.01-0.1 sec. (Here R is the beam radius, c_l is the velocity of longitudinal sound in the target material, and a is the thermal-conductivity coefficient of the target material.) Thus, during the time of energy deposition and generation of the acoustic signal the temperature field in the target depends only on the density of the absorbed target material of energy

$$T(r,\ t) = \frac{P(r,\ t)}{C\rho}, \tag{3}$$

where C and ρ are the specific heat and density of the target material.

Taking account of the axial symmetry of the problem, we use the wave equation for longitudinal vibrations with a thermoelastic load on the right side[8]

$$\frac{\partial^2 u(r,\ t)}{\partial t^2} - c_l^2\left(\frac{\partial^2 u(r,\ t)}{\partial r^2} + \frac{1}{r}\frac{\partial u(r,\ t)}{\partial r} - \frac{u(r,\ t)}{r^2}\right) = \frac{F_T(r,\ t)}{\rho}, \tag{4}$$

where u(r, t) is the amplitude of the diverging cylindrical sound wave.

An exact solution for Eq. (4) can be obtained by the Laplace-transform method; in view of the cumbersomeness of this solution we do not present it here. In actual experiments, as a rule, the condition

$$R \ll r_0 \tag{5}$$

is satisfied, where r_0 is the distance from the beam axis to the observation point. When condition (5) is satisfied the solution of Eq. (4) is simplified considerably:

$$u(r_0,\ \tau) = \frac{\Gamma}{\pi\rho c_l^2 t_b\sqrt{2r_0}} \int\limits_0^{\min(2R,\ c_l\tau)} f(\xi)\,d\xi\,\Big[\sqrt{c_l\tau - \xi} - \sqrt{(c_l\tau - c_l t_b - \xi)\,\theta(c_l\tau - c_l t_b - \xi)}\Big], \tag{6}$$

where τ is the time measured from the time that the acoustic signal arrives at the observation point; ξ is the vari-

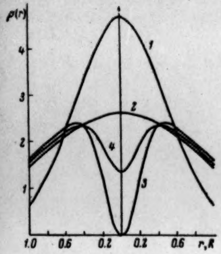

Fig. 1. Radial distribution functions for beam particles.

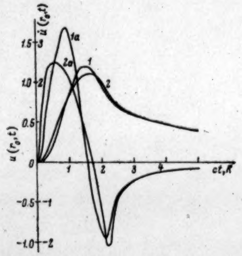

Fig. 2. Time dependence of acoustic amplitudes and stresses, for the case of a Gaussian particle distribution in the beam.

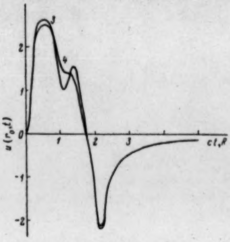

Fig. 3. Time dependence of acoustic stresses, for the case of a non-Gaussian particle distribution in the beam.

able of integration over the cross section of the beam; and $f(\xi)$ is the distribution of heat sources

$$f(\xi)=2\int\limits_{R-\xi}^{R}\frac{S(r)\,rdr}{\sqrt{r^2-(R-\xi)^2}}, \tag{7}$$

$S(r) = j(r)(dE/dx)_{ion}t_b$ is the source density.

3. By comparing the amplitudes of the acoustic signals calculated for various t_b, for $t_b < 10^{-7}$ sec and R = 1 cm we see that it is valid to assume that the energy is produced instantaneously. Then the expression for acoustic signal can be simplified further. We obtain

$$u(r_0,\ \tau)=\frac{\Gamma}{2\pi\rho c_l^2\sqrt{2r_0}}\int\limits_0^{\min(2R,\,c_l\tau)}\frac{f(\xi)\,d\xi}{\sqrt{c_l\tau-\xi}}. \tag{8}$$

Since the integral in Eq. (8) is a universal function of the variable $c_l\tau$, the acoustic signal in different materials reaches maximum for the same value of $c_l\tau$. Thus, the condition

$$c_l\tau_m = \text{const} \tag{9}$$

should be satisfied for different materials, where τ_m is the rise time of the acoustic signal. In different materials the ionization losses of a fast charged particle are usually proportional to the density of the material; thus the ratio of the amplitude in two different materials is

$$\frac{u_{\max}^{(1)}}{u_{\max}^{(2)}}=\frac{\Gamma_1}{\Gamma_2}\frac{c_{l_2}^2}{c_{l_1}^2}. \tag{10}$$

4. The distribution functions for the beam particles, normalized to unit flux are given in Fig. 1, and the corresponding acoustic signals are given in Figs. 2 and 3.

Figure 2 refers to the case of a Gaussian distribution of particles in the beam (curves 1 and 2 in Fig. 1); curves 1 and 2 correspond to acoustic displacements, curves 1a and 2a correspond to the stresses that are generated. Figure 3 shows the acoustic stresses for the case of particle distributions in the beam represented by curves 3 and 4 in Fig. 1.

Evidently, the shape of the acoustic signal can be used, in principle, to determine the distribution of particles in the beam. From this point of view, it is not favorable to measure the displacements of the material. Instead, the stresses that are generated in the material are measured. It follows from Fig. 2 that the stresses in the material are more sensitive to the distribution of particles in the beam than the acoustic displacement.

In conclusion we thank I. A. Akhiezer and V. D. Volovik for valuable discussion.

Diffraction of electromagnetic waves by a dielectric wedge

A. A. Aleksandrova and N. A. Khizhnyak

A. M. Gor'kii Khar'kov State University

(Submitted November 5, 1973)
Zh. Tekh. Fiz., 44, 2241-2249 (November 1974)

A rigorous solution for the problem of plane-wave scattering by a rectangular dielectric wedge is obtained with the help of Maxwell's equations in integral form. Solutions in the internal and external regions are obtained in the form of a combination of plane waves and a wave from the edge in the form of a Sommerfeld integral.

The diffraction of an arbitrarily incident plane electromagnetic wave by a dielectric wedge is analyzed in this paper. As is well known, the problem of wave diffraction by a metal wedge has been solved,[1,2] but generalization of this solution to the case of a dielectric wedge entails serious mathematical difficulties. These difficulties can be avoided if the integral form of Maxwell's equations is used.[3] Solution of the boundary-value problem using integral equations for the field is characterized by a number of features which are also discussed here.

The original integral field equations, which have an $e^{-i\omega t}$ dependence on time, have the form

$$\left.\begin{aligned}\mathbf{E}(\mathbf{r})&=\mathbf{E}_0(\mathbf{r})+\frac{1}{4\pi}(\operatorname{grad}\operatorname{div}+k^2)\int\limits_V(\varepsilon-1)\mathbf{E}(\mathbf{r}')f(|\mathbf{r}-\mathbf{r}'|)\,d\mathbf{r}\\&\quad+\frac{ik}{4\pi}\operatorname{curl}\int\limits_V(\mu-1)\mathbf{H}(\mathbf{r}')f(|\mathbf{r}-\mathbf{r}'|)\,d\mathbf{r}',\\\mathbf{H}(\mathbf{r})&=\mathbf{H}_0(\mathbf{r})+\frac{1}{4\pi}(\operatorname{grad}\operatorname{div}+k^2)\int\limits_V(\mu-1)\mathbf{H}(\mathbf{r}')f(|\mathbf{r}-\mathbf{r}'|)\,d\mathbf{r}'\\&\quad-\frac{ik}{4\pi}\operatorname{curl}\int\limits_V(\varepsilon-1)\mathbf{E}(\mathbf{r}')f(|\mathbf{r}-\mathbf{r}'|)\,d\mathbf{r},\\f(|\mathbf{r}-\mathbf{r}'|)&=\frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|},\end{aligned}\right\}\quad(1)$$

where $k = \omega/c$; ε and μ are the dielectric and magnetic constants of the medium; $\mathbf{E}_0$ and $\mathbf{H}_0$ are the fields in the incident wave; V is the volume of the scattering body.

The first feature of the solution of (1) is that the internal field in the medium is determined directly through the unperturbed field of the incident wave ($\mathbf{r} \in V$). The scattered field is determined through the known internal field by the same relations (1) for ($\mathbf{r} \ni V$).

The second feature is that a formal expression for the desired field in the medium is the sum of the fields of the unperturbed wave and of the waves formed by the integral terms.[3] In the performance of all integrations this term should yield a series of terms including a wave with a propagation constant coinciding with the propagation constant for the unperturbed wave. As a result of the "extinction" of the field of the unperturbed wave, the amplitudes of the fields of the penetrating waves are determined by these terms. In point of fact, this means there is no unperturbed incident wave inside the dielectric wedge. This condition is known formally in electrodynamics as the Oseen–Ewald "extinction principle," the universal nature of which has been demonstrated.[4]

We consider the specific problem of scattering of a plane electromagnetic wave

$$\left.\begin{aligned}\mathbf{E}_0(\mathbf{r})&=\mathbf{E}_0e^{i(k_{20}y+k_{30}z)},\\\mathbf{H}_0(\mathbf{r})&=\mathbf{H}_0e^{i(k_{20}y+k_{30}z)}\end{aligned}\right\}\quad(2)$$

by a rectangular dielectric wedge (y > 0, z > 0) with a permittivity ε (we assume the magnetic permeability is unity). We choose a polarization of the incident wave such that $\mathbf{E} = (E_x, 0, 0)$, and $\mathbf{H} = (0, H_y, H_z)$. We then have from Eq. (1) for $\mathbf{r} \in V$ the following fundamental integral equation for the determination of the internal fields:

$$E_x(\mathbf{r})=E_{0x}(\mathbf{r})+\frac{k^2(\varepsilon-1)}{4\pi}\int\limits_V E_x(\mathbf{r}')\frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|}\,d\mathbf{r},\quad(3)$$

for the magnetic fields

$$\left.\begin{aligned}H_y(\mathbf{r})&=H_{0y}(\mathbf{r})-\frac{ik(\varepsilon-1)}{4\pi}\frac{\partial}{\partial z}\int\limits_V E_x(\mathbf{r}')\frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|}\,d\mathbf{r}',\\H_z(\mathbf{r})&=H_{0z}(\mathbf{r})+\frac{ik(\varepsilon-1)}{4\pi}\frac{\partial}{\partial y}\int\limits_V E_x(\mathbf{r}')\frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|}\,d\mathbf{r}',\end{aligned}\right\}\quad(4)$$

where the region of integration V is one quadrant ($-\infty < x < \infty$, $y > 0$, $z > 0$; Fig. 1).

We seek a solution in the form of a superposition of plane refracted waves and an unknown wave from the edge

$$\begin{Bmatrix}E\\H\end{Bmatrix}=\sum_j\begin{Bmatrix}A_j\\B_j\end{Bmatrix}e^{i(k_{2j}y+k_{3j}z)}+\int\limits_\alpha\frac{e^{ity+isz}}{s}\begin{Bmatrix}f_E(t)\\f_H(t)\end{Bmatrix}dt,\quad(5)$$

where $k_{2j}^2 + k_{3j}^2 = \varepsilon k^2$; $s = \sqrt{\varepsilon k^2 - t^2}$; the contour α is defined below by the conditions of the problem; the subscript "j" determines the number of waves produced in the wedge because of diffraction at its faces. The wave from the edge is sought in the form of a Sommerfeld integral with unknown weight functions $f_{E,H}(t)$. To determine these functions we reduce the integral equation (3) to a well known singular integral equation of the first kind.

Before turning to specific calculations, we note there

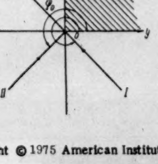

Fig. 1. Schematic diagram of incident ray. Ray I is a plane wave which illuminates one face of the wedge. Ray II is a plane wave which illuminates both faces of the wedge. The angle of incidence is measured from the plane z = 0.

can be one of two possible cases in the arbitrary incidence of a plane wave on the wedge: 1) A plane wave illuminates a single face of the wedge ($\pi/2 \leq \varphi_0 \leq \pi$ or $3\pi/2 \leq \varphi_0 \leq 2\pi$); 2) the plane wave illuminates both faces of the wedge simultaneously ($\pi \leq \varphi_0 \leq 3\pi/2$), where φ_0 is the angle of incidence of the wave measured from the plane $z = 0$. The calculations are somewhat different in these two cases and we discuss them separately.

Substituting Eq. (5) into Eq. (3) and noting that

$$\int_{-\infty}^{\infty} \frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|} dx' = \pi i H_0^{(1)}\left(k\sqrt{(y-y')^2+(z-z')^2}\right)$$
$$= \begin{cases} i \int\limits_{-\infty}^{\infty} \frac{\exp[i(\omega|y-y'|+v|z-z'|)]}{v} d\omega \quad \text{for} \quad \pi \leqslant \varphi_0 \leqslant 2\pi, \\ i \int\limits_{-\infty}^{\infty} \frac{\exp[i(v|y-y'|+\omega|z-z'|)]}{v} d\omega, \text{ for } \frac{\pi}{2} \leqslant \varphi_0 \leqslant \frac{3\pi}{2}, \end{cases} \tag{6}$$

where $v = \sqrt{k^2 - \omega^2}$, Im $v > 0$, we carry out the integration over y' and z'. In doing this we assume that the surrounding space is characterized by certain losses which ensure convergence of the integrals at infinity ($e^{ivy}|_{y \to \infty} \to 0$). In the integration over y' and z' the region of integration for each of the integrals is divided into two areas: $y' < y$ and $y' > y$ (correspondingly, $z' < z$ and $z' > z$) since the exponential in Eq. (6) contains the modulus of the differences of these quantities. As a result of the calculation we have

$$\int_V E(\mathbf{r}') \frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r}' = S_1 + S_2 =$$
$$= i\sum_j A_j \left\{ 2\int_{-\infty}^{\infty} \frac{e^{i(\omega y + k_{3j}z)} d\omega}{(k_{2j}-\omega)(k_{3j}^2+\omega^2-k^2)} - \int_{-\infty}^{\infty} \frac{e^{i(\omega y + vz)} d\omega}{v(k_{3j}-v)(k_{2j}-\omega)} \right\}$$
$$+ i\int_a \frac{f(t)\,dt}{s} \int_{-\infty}^{\infty} d\omega$$
$$\times \left\{ \frac{2e^{i(\omega y + sz)}}{(t-\omega)[k^2(\varepsilon-1)+\omega^2-t^2]} - \frac{e^{i(\omega y + vz)}}{v(t-\omega)[\sqrt{\varepsilon k^2 - t^2} - \sqrt{k^2-\omega^2}]} \right\} \tag{7}$$
$$(\text{for } \pi \leqslant \varphi_0 \leqslant 2\pi).$$

For the subsequent discussion it is convenient to introduce the notation

$$\left.\begin{aligned} k_{2j}y + k_{3j}z &= \sqrt{\varepsilon}\, k\rho(\cos\varphi\cos\psi_j + \sin\varphi\sin\psi_j), \\ \omega y + vz &= k\rho(\cos\varphi\cos\xi + \sin\varphi\sin\xi),\ t = k\sqrt{\varepsilon}\cos\eta, \end{aligned}\right\} \tag{8}$$

where ψ_j is the angle of refraction of the waves; ξ is a new variable of integration; ρ and φ are the running coordinates of the point of observation. In this notation, the integrals S_1 and S_2 take the forms

$$S_1(\rho, \varphi) = -\frac{i}{k^2}\sum_j A_j \left[2\int_{F_1} \frac{\exp[ik\rho(\sqrt{\varepsilon}\sin\varphi_j\sin\psi + \cos\xi\cos\varphi)]\sin\xi\, d\xi}{(\sqrt{\varepsilon}\cos\psi_j - \cos\xi)(\varepsilon\sin^2\psi_j - \sin^2\xi)} \right.$$
$$\left. - \int_{F_2} \frac{\exp[ik\rho\cos(\xi-\varphi)]\, d\xi}{(\sqrt{\varepsilon}\cos\psi_j - \cos\xi)(\sqrt{\varepsilon}\sin\psi_j - \sin\xi)} \right], \tag{9}$$

$$S_2(\rho, \varphi) = 2i\int_{G_0} f(\eta)\, d\eta\, e^{i\sqrt{\varepsilon}\, k\rho\sin\eta\sin\varphi}$$
$$\times \int_{F_1} \frac{\exp[ik\rho\cos\xi\cos\varphi]\, d\xi}{k^2(\sqrt{\varepsilon}\cos\eta - \cos\xi)(\varepsilon\sin^2\eta - \sin^2\xi)}$$
$$- i\int_{G_0} f(\eta)\, d\eta \int_{F_2} \frac{\exp[ik\rho\cos(\xi-\varphi)]\, d\xi}{k^2(\sqrt{\varepsilon}\cos\eta - \cos\xi)(\sqrt{\varepsilon}\sin\eta - \sin\xi)}. \tag{10}$$

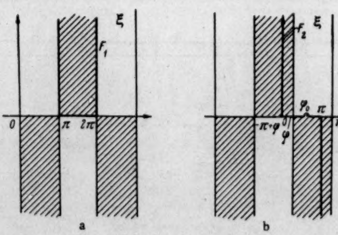

Fig. 2. Integration contours F_1 and F_2 in the plane of the complex variable ξ.

The integration contours F_1 and F_2 are shown in Figs. 2a and 2b. The shaded portions in the plane of the complex variable indicate regions for which Im $\cos\xi > 0$ (2a) and Im $\cos(\xi - \varphi) > 0$ (2b).

Each of the integrals in Eqs. (8) and (9) has singularities. Depending on the value of the angle ψ_j, the poles of the integrand will be located either inside or outside the shaded region. This result is in accordance with the fact that two cases are possible for arbitrary incidence of a plane wave on a dielectric wedge: only one face is illuminated and the first and second integrals in S_1 have the poles $\cos\xi_1 = \sqrt{\varepsilon}\cos\psi$, $\sin\xi_2 = \sqrt{\varepsilon}\sin\psi$ ($3\pi/2 \leq \varphi_0 \leq 2\pi$), or both faces of the wedge are illuminated and the second integral in S_1 has the poles $\cos\xi_{1,2} = \sqrt{\varepsilon}\begin{Bmatrix}\sin\psi_2 \\ \cos\psi_1\end{Bmatrix}$ and the first integral in S_1 has the poles $\cos\xi_1 = \sqrt{\varepsilon}\cos\psi_1$ and $\cos\xi_2 = \sqrt{\varepsilon}\sin\psi_2$. We consider the singularities in S_2 in similar fashion. Using the Cauchy theorem we calculate the corresponding integrals in Eqs. (9) and (10) separately for each of the possibilities. Furthermore, knowing the location of the poles, we deform the integration contour F_1 or F_2 into the contour $G\begin{pmatrix}-\pi/2 + i\infty \\ \pi/2 - i\infty\end{pmatrix}$, as a result of which we obtain the following:

$$S_1^{(1)} = \frac{2\pi A}{k^2}\left[\frac{2\exp[ik\rho\sqrt{\varepsilon}\cos(\varphi-\psi)]}{\varepsilon-1} \right.$$
$$\left. - \frac{\exp[ik(\sqrt{\varepsilon}\, y\cos\psi + \sqrt{1-\varepsilon\cos^2\psi}\, z]}{[\sqrt{\varepsilon}\sin\psi - \sqrt{1-\varepsilon\cos^2\psi}]\sqrt{1-\varepsilon\cos^2\psi}} \right]$$
$$+ i\int_G \frac{A\exp[ik\rho\cos(\varphi-\xi)]\, d\xi}{k^2(\sqrt{\varepsilon}\cos\psi - \cos\xi)(\sqrt{\varepsilon}\sin\psi - \sin\xi)},\quad \frac{3\pi}{2} \leqslant \varphi_0 \leqslant 2\pi, \tag{11}$$

$$S_1^{(2)} = \frac{2\pi}{k^2}\sum_{j=1}^{2} A_j \left[\frac{2\exp[ik\rho\sqrt{\varepsilon}\cos(\varphi-\psi_j)]}{\varepsilon-1} \right.$$
$$- \frac{\exp[ik(\sqrt{\varepsilon}\, y\cos\psi_j + z\sqrt{1-\varepsilon\cos^2\psi_j}]}{[\sqrt{\varepsilon}\sin\psi_j - \sqrt{1-\varepsilon\cos^2\psi_j}]\sqrt{1-\varepsilon\cos^2\psi_j}}$$
$$- \frac{\exp[ik(\sqrt{\varepsilon}\, z\sin\psi_j + y\sqrt{1-\varepsilon\sin^2\psi_j})]}{[\sqrt{\varepsilon}\cos\psi_j - \sqrt{1-\varepsilon\sin^2\psi_j}]\sqrt{1-\varepsilon\sin^2\psi_j}}$$
$$\left. + \frac{i}{2\pi}\int_G \frac{\exp[ik\rho\cos(\varphi-\xi)]\, d\xi}{(\sqrt{\varepsilon}\cos\psi_j - \cos\xi)(\sqrt{\varepsilon}\sin\psi_j - \sin\xi)} \right],\quad \pi \leqslant \varphi_0 \leqslant \frac{3\pi}{2}, \tag{12}$$

$$S_2^{(1,2)} = \frac{4\pi}{k^2(\varepsilon-1)}\int_{G_0} \exp[ik\rho\sqrt{\varepsilon}\cos(\eta-\varphi) f(\eta)\, d\eta\ -$$

$$-\frac{i}{k^2}\int_G \exp[ik\rho\cos(\xi-\varphi)\,d\xi\int_{G_0}\frac{f(\eta)\,d\eta}{(\sqrt{\varepsilon}\cos\eta-\cos\xi)(\sqrt{\varepsilon}\sin\eta-\sin\xi)},\tag{13}$$

where the contour G_0 is defined by the equation for the curve $\arccos(\cos\xi/\sqrt{\varepsilon})$, $\xi \in G$. In the last integral, the order of integration is interchanged in accordance with a corollary to the Poincaré–Bertrand formula.[5]

We consider the structure of the resultant expressions. The first term in $S_1^{(1,2)}$ represents a wave with a propagation constant equal to the propagation constant in the medium. The second term in $S_1^{(1)}$ also represents a plane wave and, in accordance with the extinction principle, this wave must have a propagation constant equal to the propagation constant of the wave in free space. This means that $k\sqrt{\varepsilon}\cos\psi = k\cos\varphi_0$, where φ_0 is the angle of incidence of the wave at the face $z = 0$. Hence

$$\cos\psi=\frac{\cos\varphi_0}{\sqrt{\varepsilon}}.\tag{14}$$

The second and third terms in $S_1^{(2)}$ represent two plane waves produced by the faces $z = 0$ and $y = 0$ respectively. Consequently, it is necessary to set

$$\sqrt{\varepsilon}\sin\psi_2=\sin\varphi_0,\tag{15}$$

for the first wave (from the face $y = 0$), which is the well-known law for wave refraction at the boundary of a dielectric, and to set

$$\sqrt{\varepsilon}\cos\psi_1=\cos\varphi_0.\tag{16}$$

for the second wave (from the face $z = 0$).

These relations do not contradict each other; if φ_0 is the angle of incidence of the wave at the face $y = 0$, this angle, measured from the plane $y = 0$, is $(\pi/2 - \varphi_0)$ at the face $z = 0$ (the relation given also holds for the angle of refraction), and Eq. (15) becomes Eq. (16).

Thus for the chosen polarization of the incident wave, only a single plane wave is propagated in the dielectric wedge and it is sufficient to determine only a single weight function $f(\eta)$ to determine the wave from the edge.

We now substitute the expressions obtained for the integral term (7) into the integral equation (3); in this case, terms with spatial dependence $\exp[ik\rho\sqrt{\varepsilon}\cos(\varphi-\psi)]$ cancel. The remaining exponential terms have the same phase velocity as the incident wave. These terms give zero when added to the field of the incident wave and hence we find the amplitudes of the plane waves in the medium for each of the possible cases are

$$A=\frac{2E_0\sin\varphi_0\cos\psi}{\sin(\varphi_0+\psi)},\quad \sqrt{\varepsilon}\sin\psi=\sqrt{\varepsilon-\cos^2\varphi_0}.\tag{17}$$

It is easy to verify that the resultant expression is a Fresnel equation for the corresponding electrodynamic problem when $3\pi/2 \le \varphi_0 \le 2\pi$,

$$A_1=\frac{2E_0\sin\varphi_0}{\sqrt{\varepsilon}\sin\psi_1+\sin\varphi_0}\tag{18}$$

$$\sqrt{\varepsilon}\cos\psi_2=\sqrt{\varepsilon-\sin^2\varphi_0},\quad \sqrt{\varepsilon}\sin\psi_1=\sqrt{\varepsilon-\cos^2\varphi_0},$$
$$A_2(\varphi_0)=A_1\left(\frac{\pi}{2}-\varphi_0\right)$$
$$\text{for}\quad \pi\leqslant\varphi_0\leqslant\frac{3\pi}{2},$$

where E_0 is the amplitude of the incident wave and φ_0 is the angle of incidence at the face $z = 0$. If the angle of incidence is such that $\pi/2 \le \varphi_0 \le \pi$, we find the corresponding expression for A from Eq. (17) by replacing φ_0 with $\pi/2 - \varphi_0$.

The remaining terms of the equation, which vary as $\int_G \exp[ik\rho\cos(\xi-\varphi)]L(\xi)d\xi$, form an equation which contains the desired function $f(\eta)$,

$$\int_G e^{ik\rho\cos(\xi-\varphi)}d\xi\left\{\frac{A}{(\sqrt{\varepsilon}\cos\psi-\cos\xi)(\sqrt{\varepsilon}\sin\psi-\sin\xi)}\right.$$
$$\left.-\int_{G_0}\frac{f(\eta)\,d\eta}{(\sqrt{\varepsilon}\cos\eta-\cos\xi)(\sqrt{\varepsilon}\sin\eta-\sin\xi)}\right\}=0.$$

This equation is clearly satisfied if

$$\frac{A}{(\sqrt{\varepsilon}\cos\psi-\cos\xi)(\sqrt{\varepsilon}\sin\psi-\sin\xi)}$$
$$=\int_{G_0}\frac{f(\eta)\,d\eta}{(\sqrt{\varepsilon}\cos\eta-\cos\xi)(\sqrt{\varepsilon}\sin\eta-\sin\xi)}.\tag{19}$$

Equation (19) is also the desired singular integral equation of the first kind for the function $f(\eta)$. Construction of a solution for this equation reduces to a Riemann boundary-value problem.[6]

We consider the generalized curvilinear Cauchy integral

$$U(z)=\frac{1}{2\pi i}\int_{G_0}\frac{f(\eta)\,d\eta}{Q(\eta,\ z)}.\tag{20}$$

The value of this integral depends significantly on the behavior of the function $Q(\eta, z)$. On some contour Γ in the plane of the complex variant η let

$$Q(\eta,\ z)=0,\ \text{but}\ Q'_\eta\neq 0,\ Q'_z\neq 0,\tag{21}$$

i.e., $z = \varphi(\eta)$ on this contour. Since η takes on all values in the integration over the contour G_0, we indicate its values on the contour Γ by $t = \varphi^{-1}(z)$. We indicate the region lying within Γ by D^+ and the region complementary to $D^+ + \Gamma$, including the point at infinity $z \to \infty$, by D^-. We divide the function $U(z)$ into a sum of functions analytic in D^+ (the function U^+) and in the region D^- (the function U^-). The generalized integral (20) is then given by

$$U^\pm(z)=\pm\frac{1}{2}\frac{f(z)}{Q'_t(t,\ z)}+\frac{1}{2\pi i}\int\frac{f(\eta)\,d\eta}{Q(\eta,\ z)},\tag{22}$$

which is similar to the Sokhotskii formula for a Cauchy integral; the solution of the integral equation (19) then reduces to the following Riemann boundary-value problem. It is required to find two functions U^+ and U^- which are respectively analytic in the regions D^+ and D^- and which satisfy the condition

$$U^+(z)=-U^-(z)+g(z),\tag{23}$$

on the contour Γ, where

$$g(z)=\frac{A}{(\sqrt{\varepsilon}\cos\psi-\cos z)(\sqrt{\varepsilon}\sin\psi-\sin z)}.$$

Then,

$$f(z)=Q'_t(t,\ z)[U^+(z)-U^-(z)].\tag{24}$$

In our case, the index of the integral equation is zero and therefore $U^+(z) = g^+(z)$ and $U^-(z) = g^-(z)$, which simplifies the problem considerably.

Since the function g(z) has isolated singularities in the form of simple poles in the plane of the complex variable z its partition into regular functions is easily performed. The value of the angle ψ is such that both poles of the function g(z) belong to the region D^-. Then

$$g^+(z) = 0, \tag{25}$$

$$g^-(z) = -g(z). \tag{26}$$

Calculating the quantity $Q'_t(t, z)$ on the contour Γ we have

$$f_1(\eta) = \frac{A\left(\varepsilon \sin\eta - \sqrt{1 - \varepsilon\cos^2\eta}\right)\varepsilon \sin\eta}{2\pi i\left(\cos\varphi_0 - \sqrt{\varepsilon}\cos\eta\right)\left(\sqrt{\varepsilon - \cos^2\varphi_0} - \sqrt{1 - \varepsilon\cos^2\eta}\right.} \tag{27}$$

in the first case if $3\pi/2 \le \varphi_0 \le 2\pi$, and

$$f_2(\eta) = \frac{1}{2\pi i}\left\{\frac{A_1\left(\varepsilon\cos\eta - \sqrt{1 - \varepsilon\sin^2\eta}\right)\varepsilon\cos\eta}{\left(\sin\varphi_0 - \sqrt{\varepsilon}\sin\eta\right)\left(\sqrt{\varepsilon - \sin^2\varphi_0} - \sqrt{1 - \varepsilon\sin^2\eta}\right)}\right.$$
$$+ \frac{A_2\left(\varepsilon\sin\eta - \sqrt{1 - \varepsilon\cos^2\eta}\right)\varepsilon\sin\eta}{\left(\cos\varphi_0 - \sqrt{\varepsilon}\cos\eta\right)\left(\sqrt{\varepsilon - \cos^2\varphi_0} - \sqrt{1 - \varepsilon\cos^2\eta}\right)} \tag{28}$$

in the second if $\pi \le \varphi_0 \le 3\pi/2$.

Thus one can represent the internal field in the dielectric wedge by the following expressions:

$$E_x(\mathbf{r}) = \frac{2E_{x0}\sin\varphi_0\cos\psi}{\sin(\varphi_0 + \psi)}\exp\left[ik\rho\left(\cos\varphi\cos\varphi_0 + \sin\varphi\sqrt{\varepsilon - \cos^2\varphi_0}\right)\right]$$
$$+ \int\limits_{G_0}\exp\left[ik\rho\sqrt{\varepsilon}\cos(\eta - \varphi)\right]f_1(\eta)\,d\eta, \quad \sqrt{\varepsilon}\cos\psi = \cos\varphi_0 \tag{29}$$

in the first case if $3\pi/2 \le \varphi_0 \le 2\pi$, and

$$E_x(\mathbf{r}) = A_1\exp\left[ik\rho\left(\sin\varphi_0\sin\varphi + \cos\varphi\sqrt{\varepsilon - \sin^2\varphi_0}\right)\right]$$
$$+ A_2\exp\left[ik\rho\left(\cos\varphi_0\cos\varphi + \sin\varphi\sqrt{\varepsilon - \cos^2\varphi_0}\right)\right]$$
$$+ \int\limits_{G_0} f_2(\eta)\exp\left[ik\rho\sqrt{\varepsilon}\cos(\eta - \varphi)\right]d\eta \quad \text{for} \quad \pi \leqslant \varphi_0 \leqslant \frac{3\pi}{2}. \tag{30}$$

The remaining components of the field, H_y and H_z, are found from the known E_x through Eq. (4).

One can now set up the scattered field from the known internal fields. The same relations (3) are used but points **r** are considered which are outside the boundaries of the dielectric wedge (**r** $\ni$ V) and the previously obtained expressions (29) and (30) for the internal fields are used in the integrals.

We consider the case where only the single face z = 0 is illuminated. Using the following representation for the Green's function:

$$H_0'\left(k\sqrt{d^2 + z^2}\right) = \frac{i}{\pi}\int\limits_{-\infty}^{\infty}\frac{\exp(ivd + i\omega z)}{v}\,d\omega \tag{31}$$

($v = \sqrt{k^2 - \omega^2}$, Im v > 0, d > 0), we investigate the scattered field in the three quadrants in accordance with the rules for integration of functions containing the modulus of the difference of two quantities. To determine the scattered field in the second quadrant $\pi < \varphi < \pi/2$, it is necessary to divide the region of integration over y' into two (y < y' and y > y'); in the third quadrant $\pi < \varphi < 3\pi/2$, y' < y and z' < z always; in the fourth quadrant $3\pi/2 < \varphi < 2$, it is necessary to divide the region of integration over z' into two (z' < z and z' > z).

As a result of the calculations, we have the three types of expressions

$$\text{a)}\ i\left\{\int\limits_{-\infty}^{\infty}\frac{2e^{ik_3 z - i\omega y}}{(k_3^2 - v^2)(k_{20} + \omega)} - \int\limits_{-\infty}^{\infty}\frac{e^{ivz - i\omega y}}{v(k_3 - v)(k_{20} + \omega)}\right.$$
$$- \int\limits_{G_0} f(\eta)\,d\eta\int\limits_{-\infty}^{\infty}\left[\frac{2e^{ik\sqrt{\varepsilon}\sin\eta z - i\omega y}}{(k^2\varepsilon\sin^2\eta - v^2)(k\sqrt{\varepsilon}\cos\eta + \omega)}\right.$$
$$\left.\left. - \frac{e^{ivz - i\omega y}}{v(k\sqrt{\varepsilon}\sin\eta - v)(k\sqrt{\varepsilon}\cos\eta + \omega)}\right]d\omega\right\}, \quad \frac{\pi}{2} \leqslant \varphi \leqslant \pi, \tag{32}$$

$$\text{b)}\ -i\left[\int\limits_{-\infty}^{\infty}\frac{e^{-i\omega y - ivz}d\omega}{v(k_3 + v)(k_{20} + \omega)}\right.$$
$$\left. - \int\limits_{G_0} f(\eta)\,d\eta\int\limits_{-\infty}^{\infty}\frac{e^{-i\omega y - ivz}d\omega}{v(k\sqrt{\varepsilon}\sin\eta + v)(k\sqrt{\varepsilon}\cos\eta + \omega)}\right], \quad \pi < \varphi < \frac{3\pi}{2}, \tag{33}$$

$$\text{c)}\ -i\left[\int\limits_{-\infty}^{\infty}\frac{e^{i\omega y - ivz}d\omega}{v(k_3 + v)(k_{20} - \omega)}\right.$$
$$\left. - \int\limits_{G_0} f(\eta)\,d\eta\int\limits_{-\infty}^{\infty}\frac{e^{i\omega y - ivz}d\omega}{v(k\sqrt{\varepsilon}\sin\eta + v)(k\sqrt{\varepsilon}\cos\eta - \omega)}\right], \quad \frac{3\pi}{2} < \varphi < 2\pi. \tag{34}$$

We carry out a detailed calculation for the third case only since the other calculations are similar. We make the change of variables

$$\omega = k\cos\xi, \quad v = k\sin\xi. \tag{35}$$

Then

$$I_3 = \frac{i}{k^2}\left[\int\limits_{F_2}\frac{e^{ik\rho\cos(\xi - \varphi')}d\xi}{\left(\sqrt{\varepsilon - \cos^2\varphi_0} + \sin\xi\right)(\cos\varphi_0 - \cos\xi)}\right.$$
$$\left. - \int\limits_{G_0} f(\eta)\,d\eta\int\limits_{F_2}\frac{e^{ik\rho\cos(\xi - \varphi')}d\xi}{\left(\sqrt{\varepsilon}\sin\eta + \sin\xi\right)\left(\sqrt{\varepsilon}\cos\eta + \cos\xi\right)}\right], \tag{36}$$

where φ' varies within the limits $(0, \pi/2)$ and $3\pi/2 < \varphi_0 < \pi$. The contour G_0 is the defined by the equation $\eta = \arccos(\cos\xi/\sqrt{\varepsilon})$, $\xi \in G$. The integration contour F_2 and the location of the singularities of the integrand in I_3 are shown in Fig. 2b.

Since $\varphi' < \varphi_0$, a reflected wave exists for all values of the angle φ_0. We deform the contour F_2 into the contour $G\begin{pmatrix}-\pi/2 + j\infty \\ \pi/2 - j\infty\end{pmatrix}$ and calculate the first integral in I_3 by means of the theorem of residues

$$\frac{2\pi e^{ik\rho\cos(\varphi + \varphi_0)}}{k^2\sin\varphi_0\left(\sqrt{\varepsilon - \cos^2\varphi_0} + \sin\varphi_0\right)}$$
$$+ \frac{i}{k^2}\int\limits_{G}\frac{e^{ik\rho\cos(\xi - \varphi')}d\xi}{\left(\sqrt{\varepsilon - \cos^2\varphi_0} + \sin\xi\right)(\cos\varphi_0 - \cos\xi)}. \tag{37}$$

In the second integral, we pick out the pole $\sin\xi_1 = -\sqrt{\varepsilon}\sin\eta$ (with subsequent deformation of the contour F_2 into G), which determines the wave from the edge in free space. The remaining integrals are brought to the form

$$i\int\limits_{G}\frac{e^{ik\rho\cos(\xi-\varphi)}d\xi}{k^2}\left[\frac{A_1}{\sqrt{\varepsilon}\,\sin\psi+\sin\xi)(\cos\varphi_0-\cos\xi)}\right.$$
$$\left.-\int\limits_{G_0}\frac{f(\eta)\,d\eta}{(\sqrt{\varepsilon}\,\cos\eta-\cos\xi)(\sqrt{\varepsilon}\,\sin\eta+\sin\xi)}\right], \qquad (38)$$

and since the function $f(\eta)$ satisfies the singular integral equation (19), this expression is identically zero.

Thus the scattered field in the region $3\pi/2 < \varphi < 2\pi$ is the superposition of a plane wave and the known boundary wave from the edge.

Finally, we have the following expressions for the field scattered from a dielectric wedge:

$$E_{\text{scat}}=E_{0z}$$
$$\times\begin{cases} e^{ik\rho\cos(\varphi-\varphi_0)}-\dfrac{(\varepsilon-1)\,e^{ik\rho\cos(\varphi+\varphi_0)}}{(\sqrt{\varepsilon-\cos^2\varphi_0}+\sin\varphi_0)^2}+P(\varphi,\varphi_0), & 3\pi-\varphi_0\leqslant\varphi\leqslant 2\pi,\\ e^{ik\rho\cos(\varphi-\varphi_0)}+P(\varphi,\varphi_0), & -\pi+\varphi_0\leqslant\varphi\leqslant 3\pi-\varphi_0,\\ P(\varphi,\varphi_0), & \dfrac{\pi}{2}\leqslant\varphi\leqslant\varphi_0-\pi, \end{cases} \qquad (39)$$

where

$$P(\varphi,\varphi_0)=-2\pi\int\limits_{G_1}\frac{f_1(\arcsin(\sqrt{\varepsilon}\sin t))\,e^{-ik\rho\cos(\varphi+t)}dt}{k^2(\cos t+\sqrt{\varepsilon-\sin^2 t})\sqrt{\varepsilon-\sin^2 t}}, \qquad (40)$$

the integration contour G_1 is defined by the equation for the curve $t = \arcsin(\sqrt{\varepsilon}\sin\eta)$, $\eta \in G_0$; the function $f_1(t)$ is given by Eq. (27).

We have not derived the expressions for the scattered field in the case of illumination of both faces of the wedge; these can be obtained by means of similar calculations.

Thus, using the integral equation makes it possible to obtain a complete solution for the diffraction of a plane electromagnetic wave by a dielectric wedge with the expression for the boundary wave from the edge of the wedge in the form of a definite integral. The value of this integral can be found for specific values of the wedge permittivity, particularly by numerical methods. In the general case, the integral which determines the boundary wave is not expressed through known functions but its value when $k\rho\sqrt{\varepsilon} \gg 1$ can be obtained either by the method of steepest descent or by the method presented in ref. 7.

We consider the integral

$$\int\limits_{G_0} e^{ik\rho\sqrt{\varepsilon}\cos(\eta-\varphi)}f(\eta)\,d\eta. \qquad (41)$$

By using the short-wave asymptotic expansion previously obtained,[7] we have

$$\frac{\exp\left[i\left(k\rho\sqrt{\varepsilon}+\frac{\pi}{4}\right)\right]\Gamma\left(\frac{1}{2}\right)}{(2k\rho\sqrt{\varepsilon})^{1/2}}f(\varphi)+O\left(\frac{1}{(k\rho\sqrt{\varepsilon})^{1/2}}\right), \qquad (42)$$

i.e., the boundary wave for $k\rho\sqrt{\varepsilon} \gg 1$ is described by a cylinder function.

Propagation of shock waves in inhomogeneous media

R. A. Glatman

Gipronikel' Design and Research Institute, Leningrad

(Submitted December 10, 1973; resubmitted March 29, 1974)
Zh. Tekh. Fiz., 44, 2250-2254 (November 1974)

A new model is proposed for an approximate solution of the problem of shock-wave propagation in an inhomogeneous medium which makes it possible to interpret the method developed by Whitham physically and to establish its region of applicability. General conditions are given for which use of the Whitham method gives good results. Particular cases of shock-wave motion in media with stationary inhomogeneities are studied in hydrodynamics and magnetohydrodynamics; the propagation of weak shock waves is analyzed.

An exact solution for the problem of shock-wave propagation in an inhomogeneous medium is only available for the few particular cases in which the process is self-similar;[1] therefore the investigation of the various aspects of this problem usually rests on the approximate methods developed by Chisnell[2] and Whitham.[3] Chisnell considered motion of a shock wave in a medium with a pressure p_0 = const and a variable density ρ_0 for hydrodynamics; he replaced the continuous density distribution by a stepped distribution and investigated the behavior of refraction and reflection of shock waves passing through a sequence of thin layers of different densities. Whitham, pointing out the limited group of problems to which this method is applicable (with $p_0 \neq$ const the physical picture of the process[2] becomes unclear because the layer can not be in equilibrium), proposed another method in which simplicity is combined with near universality; in particular, this new method has been used by Whitham in both hydrodynamics and in magnetohydrodynamics. To determine the velocity D of the shock wave in this method, the supplementary condition

$$dp + \rho c dv = 0, \tag{1}$$

is used behind the shock front, where v is the gas velocity and c is the velocity of sound; this condition expresses the conservability of the Riemann invariant along the characteristic C_+. In this approach, however, there is no a priori physical interpretation whatever of the prescribed assumption (1) and, as pointed out by the author himself,[3] it is unclear to what extent the unexpected accuracy of the results in certain cases must be attributed to chance.

In the present paper, a special mode of the process is proposed on the basis of which the possibility of using Eq. (1) is justified; this model has a clear physical significance and makes it possible to determine in which cases the use of the Whitham method for solving the problem of shock-wave propagation in inhomogeneous media yields good results. We also present calculated results for limiting cases of weak shock waves in hydrodynamics and in magnetohydrodynamics (the magnetic field is perpendicular to the direction of wave propagation) for a stationary state of an unperturbed gas where one can count on good agreement of approximate data with the true values. In addition to a detailed analysis of these cases, relations are also obtained for the determination of the velocity of a shock wave of arbitrary intensity in a medium with a transverse magnetic field and stationary distribution of parameters.

During the motion of the shock front the values of the parameters q_i change; the magnitudes of these changes at the leading edge of the shock front during a small time interval δt can be written in the form

$$\delta q_{0i} = \left(\frac{dq_{0i}}{dt}\right)_{x=X(t)+0} \delta t = \left(\frac{\partial q_{0i}}{\partial t} + D\frac{\partial q_{0i}}{\partial x}\right)_{x=X(t)+0} \delta t, \tag{2}$$

where X(t) is the coordinate of the shock front in the laboratory system, with the x axis being in the direction of shock-wave motion. The actual picture of the process will be replaced by the following scheme: Starting at the time $t = t^*$, let a shock wave be propagated in a homogeneous medium with the parameters $q_{0i}(X(t^*), t^*)$ at a velocity $D = (dX/dt)_{t=t^*}$; at time $t^* + \delta t$, there is incident on the shock front a set of small perturbations (acoustic and entropy waves in ordinary hydrodynamics, fast and slow magnetoacoustic, Alfvén, and entropy waves in magnetohydrodynamics) which bring about parameter perturbations δq_{0i}. This gives rise to a perturbation δD in the velocity of the shock front. By letting the value of the interval δt go to zero one can approximate the true picture of the continuous variation of the parameters ahead of the shock front. Thus, a given inhomogeneity of a medium is specifically simulated by means of sets of small perturbations transmitted sufficiently often to the shock front (the means for this "transmission" plays no part).

If the perturbations arriving at the shock front are assigned specifically to reproduce a set of parameter variations δq_{0i}, the number and direction of the outgoing small perturbations for the evolving shock waves are rigorously determined. This makes it possible to use additional relations between the magnitudes of the parameter variations behind the shock front. For example, in hydrodynamics an acoustic wave and an entropy wave will be propagated behind the shock front; consequently one can write an additional relation between the velocity variation δv and the pressure variation δp behind the shock front: $\delta v = -\delta p/\rho c$ (the acoustic wave is propagated in a direction opposite to that of the x axis). This condition also leads to Eq. (1). Since the subsequent solution reduces to variation of the relations at the discontinuity (as done previously[4]) and the determination of the quantity δD from the resultant system, the quantitative aspect of this method is not different, in principle, from the method previously proposed.[3] One should also note that the representation of the parameters in the unperturbed gas in the form of piecewise constant functions used here is similar to what has been done before,[2] but now it plays a more formal role and does not limit the region of applicability of the method so significantly.

The basic limitations of this formulation of the problem are associated with the fact the parameter variations given by Eq. (2) must, in fact, not be propagated with velocities $v_0 + c_{0j}$ ($c_{0j} \gtrless 0$ is the velocity of the small perturbations transmitted to the shock front with the direction of propagation taken into account) but must be stationary with respect to the coordinate system. However, when the inequality

$$D \gg |v_0 + c_{0j}|, \tag{3}$$

is satisfied for all c_{0j}, the indicated deficiency in the formulation should not have a significant effect since the artificially created conditions under which the shock wave is propagated will approximate the true conditions. Thus, the use of this method yields results which are more accurate, the more significantly the velocity of the shock wave exceeds the velocity of each of the small perturbations in the set required to reproduce the necessary parameter variations in the gas ahead of the shock front.

The results obtained with this method for several specific problems are given below. The limiting case of a weak shock wave in hydrodynamics is not considered in refs. 2 and 3. Nevertheless, the Whitham method can give good results over the entire range of shock wave intensities for the case mentioned where $v_0 = 0$, $p_0 = \text{const}$, and ρ_0 is an arbitrary function of x since the density perturbation is only transmitted by the entropy wave and $v_0 + c_e = 0$. An expression for the velocity of a weak shock wave ($v_0 = 0$, $p_0 = \text{const}$) can be obtained in explicit form if D is represented as

$$D(t) = (c_0)_{x=X(t)}[1 + \zeta(t)], \quad \zeta \ll 1$$

[$c_0 = \sqrt{\gamma p_0/\rho_0(x)}$, γ is the ratio of the heat capacities] and X(t) is then used as the independent variable. We then have

$$\zeta = \tilde{\zeta}\left[\frac{\rho_0(X)}{\tilde{\rho}_0}\right]^{1/4}, \tag{4}$$

$$D - c_0 \sim \left[\frac{\rho_0(X)}{\tilde{\rho}_0}\right]^{-1/4}, \tag{5}$$

where $\tilde{\zeta}$ and $\tilde{\rho}_0$ are values of the corresponding quantities at t = 0, X = X(0). One should note that the exponent in Eqs. (4) and (5) does not depend on γ in contrast to the strong shock wave case already investigated.[3]

The analogous case of a stationary inhomogeneity can also be considered in magnetohydrodynamics, where the total pressure in the unperturbed gas

$$p_0 + \frac{H_0^2}{8\pi} = A = \text{const}, \tag{6}$$

is conserved in a medium with a transverse magnetic field H ($H = H_y$) and $v_0 = 0$. Arbitrary perturbations of density and also perturbations in pressure and magnetic field, which are related through Eq. (6), correspond to a stationary hybrid wave relative to the gas[5] which is a combination of an entropy wave and a degenerate (for $H_x = 0$) slow magnetoacoustic wave. In such a hybrid wave

$$\delta v_x = 0; \quad \delta H = -\frac{4\pi}{H}\delta p; \quad \delta w = \frac{\gamma}{\rho(\gamma-1)}\left(\delta p - \frac{p}{\rho}\delta\rho\right)$$

(w is enthalpy), and δp, $\delta\rho$, and δv_y are arbitrary functions of x. A fast magnetoacoustic wave and a hybrid wave will be propagated behind the shock front. Finally, the velocity of a shock wave of arbitrary intensity can be found from the equation,

$$\frac{dD}{dX} = \frac{D}{\eta}\,\frac{D\left(\frac{c_+}{\gamma-1} - \frac{1}{2}D\frac{\eta-1}{\eta}\right)\frac{d\rho_0(X)}{dX} + \frac{2-\gamma}{\gamma-1}\eta\frac{dp_0(X)}{dX}}{\frac{1}{2}\rho_0 D^2\frac{\eta-1}{\eta^2} - \frac{1}{\gamma-1}\rho_0 D\frac{1}{\eta}(c_+ + D) - \frac{2-\gamma}{\gamma-1}\frac{H_0^2}{8\pi}(\eta-1)}, \tag{7}$$

where

$$c_+ = \left\{c_{0+}^2 + (\eta-1)\left[\frac{\gamma-1}{2}D^2\frac{1}{\eta^2}(\eta+1) + (2-\gamma)\frac{H_0^2}{4\pi\rho_0}\right]\right\}^{1/2}.$$

The quantity $\eta = \rho/\rho_0$ is determined from the condition

$$\frac{2-\gamma}{\gamma-1}\frac{H_0^2}{8\pi\rho_0}\eta^2 + \eta\left(\frac{\gamma}{\gamma-1}\frac{p_0}{\rho_0} + \frac{\gamma}{\gamma-1}\frac{H_0^2}{8\pi\rho_0} + \frac{1}{2}D^2\right) - \frac{\gamma+1}{2(\gamma-1)}D^2 = 0. \tag{8}$$

Here, $c_{0+} = \sqrt{c_0^2 + H_0^2/(4\pi\rho_0)}$ is the velocity of the fast magnetoacoustic wave in the unperturbed gas. For a strong shock wave and $p/p_0 \gg H_0^2/8\pi p_0$, the result remains the the same as in ordinary hydrodynamics;[3] as follows from the inequality (3), this result possesses great universality and is not only applicable to a medium with stationary nonuniformity. A simpler relationship can also be obtained for a weak shock wave when the velocity D is represented in the form

$$D(X) = c_{0+}(X)[1 + \xi(X)], \quad \xi \ll 1.$$

In this case,

$$\eta = 1 + \frac{2c_{0+}^2}{\frac{\gamma+1}{2}c_0^2 + \frac{3H_0^2}{8\pi\rho_0}}\xi,$$

$$\xi = \tilde{\xi}\left[\frac{\rho_0(X)}{\tilde{\rho}_0}\right]^{1/4}\frac{\frac{6A}{(2-\gamma)(\gamma+3)} - p_0(X)}{\frac{6A}{(2-\gamma)(\gamma+3)} - \tilde{p}_0}\left[\frac{\frac{2A}{2-\gamma} - p_0(X)}{\frac{2A}{2-\gamma} - \tilde{p}_0}\right]^{-7/4}, \tag{9}$$

$$D - c_{0+} \sim [\rho_0(X)]^{-1/4}\left[\frac{6A}{(2-\gamma)(\gamma+3)} - p_0(X)\right]\left[\frac{2A}{2-\gamma} - p_0(X)\right]^{-5/4}, \quad \gamma < 2 \tag{10}$$

($\tilde{\xi}$, $\tilde{\rho}_0$, and $\tilde{p}_0$, as before, are initial values of the corresponding quantities). Equations (9) and (10) are valid for $\gamma < 2$; for $\gamma = 2$, the same relation is obtained as in the absence of a magnetic field [this is completely reasonable since the expressions in ordinary hydrodynamics and magnetohydrodynamics agree for a transverse magnetic field and $\gamma = 2$ except for the replacement of p by $p + H_0^2/8\pi$ (ref. 6)].

It is easy to verify that $(\partial/\partial p_0)(D - c_{0+}) < 0$ always, i.e., with an increase in the fraction of the hydrodynamic pressure p_0 in a constant total pressure A, the difference $D - c_{0+}$ decreases as does the quantity c_{0+} itself $[\partial c_{0+}/\partial p_0 \sim -(2A/(2-\gamma) - p_0)^{1/2} < 0]$. The nature of the dependence of $D - c_{0+}$ on $\rho_0(X)$ remains the same as with no magnetic field. When derivatives $\rho_0' = d\rho_0/dX$ and $p_0' = dp_0/dX$ have opposite signs, there are special regions of parameter values where the propagation of the magnetoacoustic and shock waves is different. The conditions $d(D - c_{0+})/dX < 0$ and $dc_{0+}/dX < 0$ are respectively satisfied when

$$p_0' + K_1\rho_0' > 0 \quad \text{и} \quad p_0' + K_2\rho_0' > 0,$$

where

$$K_1 = \frac{\left[\frac{6A}{(2-\gamma)(\gamma+3)} - p_0\right]\left(\frac{2A}{2-\gamma} - p_0\right)}{\rho_0\left[p_0 + \frac{2A(4\gamma-3)}{(2-\gamma)(\gamma+3)}\right]}; \quad K_2 = \frac{\frac{2A}{2-\gamma} - p_0}{\rho_0}.$$

Therefore, we have the following two possibilities.

1) $K_1 < K_2$. This corresponds to the inequality

$$\frac{p_0}{A} > \frac{2(3-2\gamma)}{(2-\gamma)(\gamma+3)}, \tag{11}$$

which is always satisfied when $\gamma > 3/2$ or when $p_0 > A/2$ (if $1 < \gamma < 2$). In this case, the magnetoacoustic wave loses velocity more rapidly than a weak shock wave in the region $K_1 < |p'_0/\rho'_0| < K_2$ when $\rho'_0 > 0$ and $p'_0 < 0$. Thus the weak shock wave will not be damped although its velocity also decreases. If $\rho'_0 < 0$ and $p'_0 > 0$, the shock wave is accelerated more weakly in this region than the fast magnetoacoustic wave and consequently is damped.

2) $K_1 > K_2$. This condition occurs when the inequality which is the reverse of (11) is satisfied, i.e., when $\gamma < 3/2$ and when the p_0 fraction of the total pressure A is sufficiently small. The region of permissible ratios between p_0 and A is more extensive for smaller γ and the inequality takes the form $p_0 < A/2$ when $\gamma = 1$. Then both waves are accelerated in the region $K_2 < |p'_0/\rho'_0| < K_1$ when $\rho'_0 > 0$ and $p'_0 < 0$, but the difference $D - c_{0+}$ decreases; deceleration of both waves occurs when $\rho'_0 < D$ and $p'_0 > 0$ but $D - c_{0+}$ increases.

For a strong magnetic field $H_0^2/(8\pi) \gg p_0$, the relation (10) takes the form

$$D - c_{0+} \sim \rho_0^{-1/4} H_0^{-1/2},$$

and in the opposite case of a weak field

$$D - c_{0+} \sim \rho_0^{-1/4} p_0^{-1/4}.$$

It is impossible to compare the results obtained directly with known accurate solutions for certain particular cases of inhomogeneity because such solutions were based on relations which were only satisfied for a strong shock wave.[1] Therefore a comparison of results obtained by the Whitham method with precise results is only possible for the case of a strong shock wave; the agreement is good in many cases[7] as also follows from the general conditions established on the basis of the physical model of the process proposed here.

Finally, if the inhomogeneity of the medium is merely a result of small oscillations of the magnetic field intensity about the x, y plane, i.e., $H_{z0} = H_{z0}(x, t)$, $H_{z0}^2 \ll H_0^2$ (H_{x0}, H_{y0}, p_0, and $\rho_0 = \text{const}$, $v_{x0} = v_{y0} = 0$), which produces oscillations of the z component of the velocity in accordance with the relation $v_{z0} = H_{z0}/\sqrt{4\pi\rho_0}$, the corresponding set of small perturbations will consist only of Alfvén waves. Since the interaction of a shock wave with an Alfvén wave does not lead to perturbation of the shock-front velocity,[6] oscillations of H_{z0} do not create variation in the propagation velocity of a shock wave for $D \gg c_{0A} = H_{x0}/\sqrt{4\pi\rho_0}$.

Ponderomotive forces on a rotating conducting sphere in a time-varying inhomogeneous magnetic field

R. V. Lin'kov and Yu. M. Urman

Scientific Research Institute for Applied Mathematics and Cybernetics, Gor'kii

(Submitted September 11, 1973)

Zh. Tekh. Fiz., 44, 2255-2264 (November 1974)

The forces and torques arising from the rotation of a conducting sphere in a time-varying, inhomogeneous magnetic field are calculated. The angular and frequency dependences of these forces and torques are investigated. It is shown that the signs of the components of the torques and force can change in a time-varying field; that in particular an accelerating torque can be produced. The effect of the magnetic permeability on the forces and torques is analyzed.

The development of instruments employing the contactless suspension of a rotor in a magnetic field has produced great interest in the ponderomotive interaction between the rotor and the supporting field.

The present authors have considered the forces and torques which arise when a conducting magnetic sphere rotates in a constant inhomogeneous magnetic field.[1] It is of interest to treat the analogous problem for a time-varying field.

The rotation of a conductor in a time-varying field leads to a series of new effects; one of these, the possibility of an accelerating torque, has already been pointed out in ref. 2. However, the torques were only found for a conducting nonmagnetic sphere in a homogeneous field and the frequency dependence was studied only for a decelerating torque.

In this paper we consider the rotation of a conducting magnetic ($\mu \neq 1$) sphere in an inhomogeneous field so that both torques and forces can be determined. For certain values of the parameters the frequency characteristics of the torques and forces change sign; under certain conditions the supporting force can, in fact, undergo two changes of sign.

The results obtained here can be considered as a generalization of earlier work[1-6] on the ponderomotive interaction between a conducting sphere and a magnetic field.

DETERMINATION OF THE MAGNETIC FIELD OUTSIDE AND INSIDE THE ROTATING SPHERE AND CALCULATION OF THE FORCES AND TORQUES

Suppose that a sphere of radius R with conductivity σ and magnetic permeability μ rotates in an external inhomogeneous magnetic field which varies periodically at frequency Ω. We assume that the external field has axial symmetry, that the center of the sphere lies on the symmetry axis, and that the sphere rotates with constant angular velocity ω at an angle α to the axis of the field. We calculate the fields under the assumption that the conditions for stationarity are satisfied.

As in ref. 1, we introduce two fixed rectangular coordinate systems oxyz and ox'y'z', which are related to the rotation axis of the sphere (oz) and to the field sources (the field axis is oz'); the origin of the systems lies at the center of the sphere, the oy and oy' axes are coincident, and the angle $\angle zoz' = \alpha$. We also use the related spherical coordinate systems r, θ', φ' and r, θ, φ with polar axes oz' and oz.

The field of the external sources is given by a scalar potential in the system OX'Y'Z:

$$U_0 = \sum_{n=1}^{\infty} \sqrt{\frac{4\pi}{2n+1}}\, a_n r^n Y_{n,0}(\theta') \cos \Omega t; \tag{1}$$

the a_n are coefficients which depend on the geometry of the sources and the distance to them and on the currents involved, and $Y_{n,m}$ is the normalized spherical function.

It can be shown[1] that the field $\mathbf{H}^i$ inside the sphere in the coordinate system related to the axis of rotation can be described by the equations

$$\left.\begin{aligned} \Delta \mathbf{H}^i &= \frac{4\pi\mu\sigma}{c^2}\left(\omega \frac{\partial \mathbf{H}}{\partial \varphi} + \frac{\partial \mathbf{H}}{\partial t}\right), \\ \operatorname{div} \mathbf{H}^i &= 0. \end{aligned}\right\} \tag{2}$$

The field outside the sphere $\mathbf{H}^e$ satisfies

$$\Delta \mathbf{H}^e = 0, \ \operatorname{div} \mathbf{H}^e = 0. \tag{3}$$

The solution of (2) is of the form

$$\mathbf{H}^i = \operatorname{curl} \hat{L} \Phi (r, \theta, \varphi), \tag{4}$$

where $\hat{L} = -i[\mathbf{r}\nabla]$, and the function Φ satisfies the scalar equation

$$\Delta \Phi + k_m^2 \Phi = 0, \tag{5}$$

and

$$k_m^2 = -i\, \frac{4\pi\mu\sigma}{c^2} (m\omega + \Omega). \tag{6}$$

The field outside the sphere has the solutions

$$\mathbf{H}^e = \operatorname{curl} \hat{L} \psi (r, \theta, \varphi), \tag{7}$$

where ψ satisfies the scalar equation

$$\Delta \psi = 0. \tag{8}$$

Since the general solutions of the Helmholtz and Laplace scalar equations are well known, the problem of determining the field reduces to vector operations with scalar functions.

The general solution of (5) which has no singularity at the origin is of the form

$$\Phi = \sum_{n,m} A_{n,m} j_n (k_m r)\, Y_{n,m}(\theta, \varphi)\, e^{i\Omega t}, \tag{9}$$

and the solution of (8) which is regular at infinity is

$$\phi=\sum_{n,m} B_{nm} r^{-(n+1)} Y_{n,m}(\theta, \varphi) e^{i\Omega t}. \tag{10}$$

Here, $j_n = \sqrt{\pi/2kr} J_{n+1/2}$ is the spherical Bessel function. The coefficients A_{nm} and B_{nm} are determined from the boundary conditions at the surface of the sphere r = R:

$$H_r^0 + H_r^e = \mu H_r^i, \; H_\tau^0 + H_\tau^e = H_\tau^i. \tag{11}$$

In order to satisfy the boundary conditions the field from the external sources (1) must be transformed to the coordinate system based on the axis rotation. If we carry out this transformation and then satisfy (11), we get the following values for the coefficients:

$$A_{nm} = i\sqrt{\frac{4\pi}{2n+1}} \frac{R^{n-1}(2n+1) b_{nm}}{(n+1)\left[\frac{\partial j_n(k_m r)}{\partial r} + (1+n\mu)\frac{j_n(k_m r)}{r}\right]_{r=R}}, \tag{12}$$

$$B_{n,m} = i\sqrt{\frac{4\pi}{2n+1}} \frac{R^{2n+1}}{n+1} b_{nm}\left[\frac{\mu(2n+1) j_n(k_m r)}{R\left[\frac{\partial j_n(k_m r)}{\partial r} + (1+n\mu)\frac{j_n(k_m r)}{r}\right]_{r=R}} - 1\right], \tag{13}$$

where

$$\left.\begin{aligned} b_{nm} &= a_n \sqrt{\frac{(n-m)!}{(n+m)!}} P_n^m(\cos\alpha), \\ b_{nm} &= (-1)^m b_{n,-m}. \end{aligned}\right\} \tag{14}$$

The forces and torques are found by means of the Maxwell stress tensor. The average values over the period of the time-varying field are defined by the following integrals:

$$\left.\begin{aligned} \mathbf{F} &= \frac{1}{8\pi}\operatorname{Re}\oint_s \left(\mathbf{H}^* H_r - \frac{1}{2}|H|^2 \mathbf{e}_r\right) ds, \\ \mathbf{M} &= \frac{1}{8\pi}\operatorname{Re}\oint_s [\mathbf{r}\mathbf{H}^*] H_r ds. \end{aligned}\right\} \tag{15}$$

The evaluation of these integrals is carried out by the same method as in ref. 1. In cyclic projections the forces and torques have the form

$$M_\nu = -\frac{i}{4}\mu \sum_{n=1}^{\infty}\sum_{m=0}^{n} \sqrt{\frac{n}{n+1}} \frac{n(2n+1)^2}{n+1+n\mu} R^{2n+1} \times b_{nm} b^*_{n,m+\nu} \begin{bmatrix} n & 1 & n \\ m & \nu & m+\nu \end{bmatrix} \{Q_{nm} - Q^*_{n,m+\nu}\}, \tag{16}$$

$$F_\nu = \frac{1}{4}\sum_{n=1}^{\infty}\sum_{m=-n}^{n} R^{2n+1} n \sqrt{\frac{2n+1}{n+1}} b_{nm} b^*_{n+1,m+\nu} \times \begin{bmatrix} n & 1 & n+1 \\ m & \nu & m+\nu \end{bmatrix} \left\{2\frac{(\mu-1)(n+1)}{n+1+n\mu} + \frac{\mu(2n+1)^2}{n+1+n\mu} Q_{nm}\right\}, \tag{17}$$

where

$$\left.\begin{aligned} Q_{nm} &= \frac{\chi_n(k_m^+ R)}{n+1+n\mu+n(\mu-1)\chi_n(k_m^+ R)} \\ &+ \frac{\chi_n(k_m^- R)}{n+1+n\mu+n(\mu-1)\chi_n(k_m^- R)}, \\ \chi_n &= \frac{j_{n+1}(k_m R)}{j_{n-1}(k_m R)}; \; k_m^\pm = \frac{1-i}{c}\sqrt{2\pi\mu\sigma(m\omega \pm \Omega)}, \end{aligned}\right\} \tag{18}$$

ν is the cyclic coordinate index, which takes the three values $\nu = -1, 0, 1$, $[F_0 = F_z, F_1 = -(1/\sqrt{2})(F_x + iF_y), F_{-1} = (1/\sqrt{2})(F_x - iF_y)]$, and the coefficient in square brackets is the Clebsch–Gordan coefficient.

Although the forces and torques have been evaluated for an axially symmetric external field, Eqs. (16) and (17) are valid for a field of arbitrary configuration if the b_{nm} are interpreted simply as the expansion coefficients of the external field in the coordinate system related to the axis of rotation.

The force equation (17) is best written in the system of coordinates related to the field axis as this makes the description of the behavior of the sphere most convenient and physically obvious (as in the case of magnetic, axially symmetric suspension, for example).

Transferring from cyclic to Cartesian coordinates and symmetrizing only over positive indices m in the OX'Y'Z' system we get

$$\begin{aligned} \mathbf{F}' &= \mathbf{e}_{z'}\frac{\mu-1}{2}\sum_{n=1}^{\infty}\frac{n(n+1)R^{2n+1}}{2n+1+n(\mu-1)} a_n a_{n+1} \\ &+ \mathbf{e}_{z'}\frac{\mu}{4}\sum_{n=1}^{\infty}\frac{n(n+1)(2n+1)^2}{(2n+1)+n(\mu-1)} R^{2n+1} a_n a_{n+1} \operatorname{Re} Q_{n0} \\ &+ \frac{\mu}{2}\sum_{n=1}^{\infty}\frac{n(2n+1)^2}{2n+1+n(\mu-1)} R^{2n+1} a_n a_{n+1} \sum_{m=1}^{n}\frac{(n-m)!}{(n+m)!} \\ &\times \Big\{\Big\langle \mathbf{e}_{z'}[P_n^m(\cos\alpha)]^2 + \mathbf{e}_{x'}\frac{1}{n+1} P_n^m(\cos\alpha)\big[m \operatorname{ctg}\alpha\, P_n^m(\cos\alpha) \\ &- 2P_n^{m+1}(\cos\alpha)\big]\Big\rangle \operatorname{Re}(Q_{nm} - Q_{n0}) + \mathbf{e}_y\frac{1}{n+1}\frac{2m}{\sin\alpha} \\ &\times [P_n^m(\cos\alpha)]^2 \operatorname{Im} Q_{nm}\Big\}. \end{aligned} \tag{19}$$

The first term in this equation describes the static force and the second term describes the force which arises in a time-varying field as a result of the conductivity of the sphere. The last term is related to the force due to the rotation.

We write the torques of the forces as projections on the Cartesian axes OXYZ

$$\begin{aligned} \mathbf{M} &= -\frac{\mu}{4}\sum_{n=1}^{\infty}\frac{n(2n+1)^2 R^{2n+1}}{(n+1)[2n+1+n(\mu-1)]} a_n^2 \sum_{m=0}^{n}\frac{(n-m)!}{(n+m)!} \\ &\times \{P_n^m(\cos\alpha) P_n^{m+1}(\cos\alpha)[\mathbf{e}_x \operatorname{Im}(Q_{n,m+1} + Q_{nm}) \\ &+ \mathbf{e}_y \operatorname{Re}(Q_{n,m+1} - Q_{nm})] + \mathbf{e}_z 2m [P_n^m(\cos\alpha)]^2 \operatorname{Im} Q_{nm}\}. \end{aligned} \tag{20}$$

It can be seen from (19) and (20) that the forces and torques have been derived in the form of series, each term of which is the product of amplitude (depending on a_n, n, m), angular [depending on $P_n^m(\cos\alpha)$], and frequency [depending on $\chi_n(\Omega, \omega)$] parts. The factors in (19) and (20) which depend on frequency are the most interesting and are considered in detail.

ANALYSIS OF THE FREQUENCY CHARACTERISTICS

1. The frequency characteristics of the forces and torques are defined by the function $\chi(\Omega, \omega)$ when $\mu = 1$, or by the rational function $N_n = (2n + 1)\varkappa_n/[2n + 1 +$

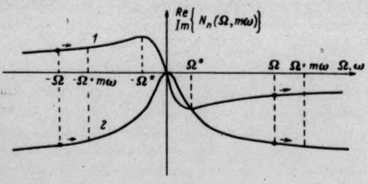

Fig. 1. The frequency variation with ω for fixed Ω. 1) Im $N_n(\Omega, m\omega$; 2) Re $N_n(\Omega, m\omega)$.

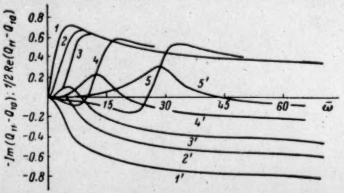

Fig. 2. Frequency characteristics of the torques in a homogeneous field and of the forces in the field of the first and second harmonics with $\mu = 1$ Im (1-5), Re (1'-5'); $\bar\Omega$: 1) 0; 2) 3.75; 3) 5.75; 4) 12.5; 5) 27.5.

$n(\mu-1)+n(\mu-1)\chi_n]$ when $\mu \neq 1$. The variation of the real and imaginary parts of $\chi_n(\omega)$ with the dimensionless frequency $\bar\omega = \omega(2\pi\mu\sigma R^2/c^2)$ is shown in Figs. 1-3 (curves 1 and 1').

For $\bar\omega > 0$ the real part is a monotonic function which decreases from 0 to −1, which is the asymptote for $\bar\omega \to \infty$ for Re χ_n of any index number.

The imaginary part is equal to zero at $\bar\omega = 0$, has a single minimum (for $\bar\omega > 0$), and tends to zero as $\bar\omega \to \infty$ (for all n). The qualitative form of the $N_n(\bar\omega)$ curves is similar to those of $\chi_n(\bar\omega)$, but the frequency scale is extended roughly by a factor of μ ($\mu \gg 1$).

The way that χ_n and N_n vary with ω, n, and μ can be seen in the Appendix, in which we derive a finite expression for χ_n in power and trigonometric functions, the asymptotic behavior of χ_n and N_n at small and large values of the argument, the position of the minimum in the real part for χ_n with n up to 10, the value at the minimum of $\left.\begin{matrix}\text{Re}\\ \text{Im}\end{matrix}\right\}\chi_n$, etc.

2. It follows from (16) and (17) that the equations for the forces and torques acting on a rotating sphere in a time-varying field can be obtained from the corresponding equations for a constant field,[1] if the frequency part is replaced by two terms with arguments expressed in terms of Bessel functions $[(1-i)/c]R\sqrt{2\pi\mu\sigma(m\omega\pm\Omega)}$.

The frequency function $Q_{nm}(\omega, \Omega)$ can be constructed from a knowledge of $N_n(\Omega, 0)$ given over the entire Ω axis. Since the argument of Q_{mn} depends on $m\omega \pm \Omega$, the construction of $Q_{nm}(\omega, \Omega)$ for fixed Ω reduces to the summation of two curves with the frequencies ωm measured in the positive direction from $+\Omega$ and $-\Omega$. The process is shown schematically in Fig. 1.

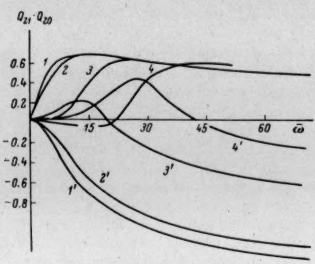

Fig. 3. Frequency characteristics of the torques in the field of the second harmonic a_2 and of the forces in the fields a_2 and a_3 with $\mu = 1$. Im (1-4), Re (1'-4'). $\bar\Omega$: 1) 0; 2) 3.75; 3) 13.75; 4) 27.5.

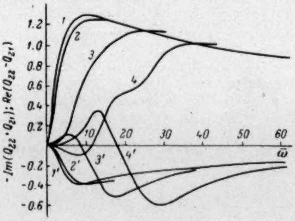

Fig. 4. Frequency characteristics of the torques in a field a_2 with $\mu = 1$. Im (1-4), Re (1'-4'); $\bar\Omega$: 1) 0; 2) 3.75; 3) 13.75; 4) 27.5.

We now consider the nature of the frequency variations $Q_{nm}(\bar\omega)$ for various external field frequencies $\bar\Omega$. For the curves described by the imaginary part, the critical value of the external field frequency is $\bar\Omega^*$, at which Im $N_n(\bar\Omega^*, 0)$ reaches its minimum. For $\bar\Omega < \bar\Omega^*$ the initial slope of the $Q_{nm}(\bar\omega)$ curve decreases and the minimum is shifted towards the right. An additional maximum appears when $\bar\Omega > \bar\Omega^*$ and the single-peaked curve for $\bar\omega > 0$, $0 \le \bar\Omega \le \bar\Omega^*$ is replaced by a double-peaked curve when $\bar\omega > 0$, $\bar\Omega > \bar\Omega^*$. If the frequency of the external field is high ($\bar\Omega \gg \bar\Omega^*$), the maximum is reached when $\bar\omega m \simeq \bar\Omega - \bar\Omega^*$, being equal to Im $[N_n(\bar\Omega^*) + N_n(2\bar\Omega - \bar\Omega^*)]$ and the minimum is reached when $\bar\omega m \simeq \bar\Omega + \bar\Omega^*$, being equal to Im $[N_n(\bar\Omega^*) + N_n(2\bar\Omega + \bar\Omega^*)]$. Thus the region where the frequency characteristics change most is the interval $\bar\Omega - \bar\Omega^* \le m\omega \le \bar\Omega + \bar\Omega^*$.

The frequency variation described by the real part has a critical frequency $\bar\Omega_1$ (turning point), which is somewhat smaller than $\bar\Omega^*$. For $\bar\Omega < \bar\Omega_1$ and $\bar\omega > 0$ the curve remains monotonic but for $\bar\Omega > \bar\Omega_1$ a maximum appears. At high frequencies $\bar\Omega \gg \bar\Omega_1$ (or $\bar\Omega^*$) the maximum occurs at $m\bar\omega = \bar\Omega$ and its value is Re $N_n 2\bar\Omega$. Re $Q_{nm}(\bar\omega)$ is an even function and Im $Q_{nm}(\bar\omega)$ is an odd function. Thus at small values of $\bar\omega$ the characteristics described by the real and imaginary parts begin with quadratic and linear terms respectively (except for special values of $\bar\Omega$).

These points are illustrated in Fig. 2, which shows the variation of $\left.\begin{matrix}\text{Re}\\ \text{Im}\end{matrix}\right\}[Q_{11} - Q_{10}]$ with $\bar\omega$ at various external field frequencies.

3. It is well known that no torques act on an isotropic nonrotating sphere. This can easily be seen from (20) by putting $\omega = 0$ and making use of the fact that $\mathrm{Im}\,N_n$ is an odd function and $\mathrm{Re}\,N_n$ an even function of Ω. If the sphere begins to rotate then torques M_x, $M_z \sim \omega$, and $M_y \sim \omega^2$ arise. For sufficiently high external field frequencies, ($\bar{\Omega} > \bar{\Omega}^*$) all the components of the torques in the initial frequency region for $\bar{\omega}$ have the opposite sign to the torques in a static field. This means that instead of deceleration and alignment of the rotation axis with the field axis which are observed in a constant field, the sphere accelerates to a stationary speed and its axis moves away from the field axis. The reverse precession about the field axis is replaced by direct precession.

At a high frequency $\bar{\Omega} \gg \bar{\Omega}^*$, the torque M_y grows very slowly in the initial frequency region and its asymptotic value as $\bar{\omega} \to \infty (m = 0)$ decreases from 2 in the case of a static field to $2\,[1 - |\mathrm{Re}\,N_n(\Omega)|\,]$ for a time-varying field. This last value decreases with increasing $\bar{\Omega}$ and tends to zero as $\bar{\Omega} \to \infty$.

The frequency parts of the torques for the first and second harmonic fields are shown in Figs. 2-4.

In the simplest case (homogeneous field) only one term remains in the series (20). If we substitute into (20) the explicit expression

$$\chi_1 = \frac{1}{z^2}(3 - z^2 - 3\,\mathrm{tg}\,z) = -1 + \frac{3}{2\varkappa}\frac{\mathrm{sh}\,3\varkappa - \sin 2\varkappa}{\mathrm{ch}\,2\varkappa - \cos 2\varkappa}$$
$$+ i\left[\frac{3}{2\varkappa^2} - \frac{3}{2\varkappa}\frac{\mathrm{sh}\,2\varkappa + \sin 2\varkappa}{\mathrm{ch}\,2\varkappa - \cos 2\varkappa}\right]$$

with $z = (R/c)(1 - i)\sqrt{2\pi\mu\sigma(\omega + \Omega)} = (1 - i)\varkappa$ and put $\mu = 1$, $\Omega = 0$, $a_1 = H$, we get values of the torques which coincide with those calculated in refs. 5 and 6; for $\Omega \neq 0$ the results agree with those in ref. 2.

The calculations show that the speeding up of the sphere in a uniform field occurs if the external field frequency $\Omega > \Omega^* = (c\varkappa^*)^2/R^2 2\pi\mu\sigma$, where $\varkappa^* = 2.409$ for $\mu = 1$ and $\varkappa^* = (\mu - 1)/\sqrt{2}$ for $\mu \gg 1$. With a copper sphere of radius 1 cm, for example, $f = \Omega^*/2\pi = 250$ Hz and with an iron sphere ($\mu = 200$), $f = 4.4$ kHz.

4. In an axially symmetric field with $\omega = \Omega = 0$ there is a single component of static force $F_{z'}$. If the field is time-varying ($\Omega \neq 0$) but the sphere does not rotate, then only $F_{z'}$ is nonzero as before, but it now contains a term with sign opposite to that of the static part ($\mu > 1$). At some frequency the ferromagnetic and diamagnetic parts become equal to each other and the force vanishes. The force is diamagnetic above this frequency.

At very high frequencies ($\Omega \to \infty$) $\lim\limits_{\Omega \to \infty} F_{z'}(\Omega, \mu, \omega = 0) = F_{z'}(\mu = 0)$ whatever the value of μ ($\mu < \infty$). A magnitude of 0.6-0.7 of the limiting value is reached quite rapidly as the frequency goes up, but thereafter the limit is approached quite slowly.

The limiting value of the lifting force developed by a loop of wire carrying a current is derived in ref. 3. This value can be obtained from (19) by putting $\mu = 1$, $\mathrm{Re}\,\chi_n(\infty) = -1$, $\cos\alpha = 1$, and

$$a_n = \frac{2\pi I r_l}{cb}\,\frac{P_n^1(\cos\beta)}{n}\,\frac{1}{b^n}$$

(where I is the current in the loop, b is the distance from the center of the sphere to the loop, and r_l is the radius of the loop).

If the sphere begins to rotate at an angle to the field then the frequency variation of the component $F_{z'}$ is changed and force components $F_{x'}$ and $F_{y'}$ appear. When $\bar{\Omega} \gg \bar{\Omega}^*$ the absolute value of the force $F_{z'}$ has a minimum at the frequency $m\bar{\omega} = \bar{\Omega}$ and retains its sign if $\mu \leq 1$. If, however, $\mu \gg 1$, then $F_{z'}$ (apart from the constant components) is similar to that of M_z. The characteristics of the forces Q_{nm} in the field of the first three harmonics for $\mu = 1$ are shown in Figs. 2 and 3.

As an example, we consider in somewhat more detail a very simple case: The force in the field of the first two harmonics (a_1 and a_2) is

$$\mathbf{F}' = \frac{a_1 a_2}{2}R^3\left\{\left\langle 2\frac{\mu - 1}{\mu + 2} + \frac{9\mu}{\mu + 2}\mathrm{Re}\,Q_{10}\right\rangle \mathbf{e}_{z'}\right.$$
$$+ \frac{9}{2}\frac{\mu}{\mu + 2}\left[\left(\mathbf{e}_{z'}\sin^2\alpha + \mathbf{e}_{x'}\frac{1}{4}\sin 2\alpha\right)\right.$$
$$\left.\left.\times\,\mathrm{Re}\,(Q_{11} - Q_{10}) + \mathbf{e}_{y} + \sin\alpha\,\mathrm{Im}\,Q_{11}\right]\right\}.$$

An analysis of this equation shows that for a nonrotating sphere the ferromagnetic and diamagnetic parts of the forces become equal at a frequency Ω_0 defined by the expression

$$\varkappa(\Omega_0) = \frac{R}{c}\sqrt{2\pi\sigma\mu\Omega_0} \approx \mu\frac{16(\mu - 1)(2\mu + 1)}{25\mu^2 - 12\mu - 16}\ (\mu \geqslant 3). \qquad (21)$$

At the same frequency $F_{z'}$ also vanishes in a constant field if the sphere rotates at an angle of $\alpha = 90°$.

An interesting effect occurs if (with $\mu \gg 1$) the frequency of the external field $\Omega > \Omega_0$ is chosen so that when $\omega = 0$, $F_{z'}(0, \Omega)$ is diamagnetic. Then as the sphere accelerates the force $F_{z'}$ decreases and over some frequency interval in the neighborhood of $\omega \approx \Omega$ the diamagnetic force becomes a ferromagnetic force (Fig. 5). This effect occurs if $\mu > 4$ and $\alpha > (2/3)\,[(\mu + 2)/\mu]$. The frequency Ω_0 is the minimum one for $\alpha = 90°$ and is defined by (21); with $\alpha = \arcsin\sqrt{(2/3)[\mu + 2)/\mu]}$, $\Omega_0 \to \infty$.

If $\mu \leq 1$, no change occurs in the sign of the lifting force $F_{z'}(\omega)$ but the absolute value drops sharply at $\omega =$

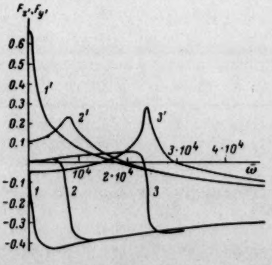

Fig. 5. Frequency variation of the forces $F_{y'}(\omega)$ (1-3) and $F_{z'}(\omega)$ (1'-3') in the field of the two harmonics a_1 and a_2 with $\mu = 100$ and $\alpha = 90°$. $\bar{\Omega}$: 1) 0; 2) $8\cdot10^3$; 3) $2.4\cdot10^4$.

Ω and can reach 0.5 of $F_{z'}(\omega = 0)$ at $\alpha = 90°$. Such a decrease in the lifting force can in principle lead to instability in the suspension of a conducting sphere in a time-varying field.

The forces $F_{x'}$ and $F_{y'}$ arise only when the sphere rotates. It is shown in ref. 4 that $F_{y'}$ leads to a loss of stability in the magnetic support of a conducting sphere in a constant field. This kind of instability remains in a time-varying field but only at the single point $\omega = \omega_{\text{synch}}$ does $F_{y'}$ fall. The force $F_{x'}$ does not seriously affect the stability of magnetic suspension if the static rigidity is sufficiently high. It produces a shift in the equilibrium state from the field axis towards the direction of slope of the rotation axis in the initial ω frequency region if $\Omega > \Omega^*$, and in the opposite direction when $\omega \to \infty$ (or if $\Omega = 0$ at any $\omega \neq 0$).

5. Thus the frequency characteristics of the forces and torques acting on a rotating sphere in a time-varying magnetic field are quite different from the case of a static field. If the frequency of the external field is greater than Ω^*, then in the initial ω regions the components M, $F_{x'}$, and $F_{y'}$ have the opposite sign to the static field case. The frequency curves of these components pass through zero and $F_{z'}$ can in fact pass through twice (if $\mu \gg 1$, $\alpha = 90°$, $\Omega > \Omega_0$). The characteristics of the components $F_{z'}$, $F_{x'}$, and M_y, which are monotonic in a static field, pass through a maximum at $m\omega \approx \Omega$ (for $\Omega \gg \Omega^*$) for a time-varying field and have a smaller asymptotic value as $\omega \to \infty$. The frequency characteristics of $F_{y'}$, M_z, and M_x, which are single-peaked in a static field, have a maximum and a minimum in a time-varying field.

6. The angular dependence of the forces and torques in (19) and (20) is defined by the adjoint Legendre polynomials. For arbitrary values of the frequencies Ω and ω and of the harmonic amplitudes a_n, the angular dependence can take many different forms. However, some general relationships can be discerned: 1) The components $F_{z'}$ and M_z have the factor $\sin^2\alpha$ since P_n^m has the factor $\sin^m\alpha$; 2) for the same reason $F_{y'} \sim (P_n^m)^2/\sin\alpha$ has the factor $\sin\alpha$; 3) $F_{x'}$, M_x, and M_y have the factor $\sin\alpha\cos\alpha$, since $P_n^m(\cos\alpha)$ $(m \neq 0)$ with an odd sum n + m is proportional to $\sin\alpha\cos\alpha$, and the product $P_n^m P_n^{m+1}$ always satisfies this condition.

Using (19) and (20) we get an expansion over small angles for the cases $\alpha \ll 1$ and $\pi/2 - \alpha \ll 1$, which are important in practice. In this case only 1-2 terms over the index m remain in the sums and the equations are simplified.

APPENDIX

The function $\chi_n(z) = j_{n+1}(z)/j_{n-1}(z)$ can be expressed in terms of trigonometric and power functions by the use of the representation[7]

$$j_n(z) = \frac{1}{z}\left\{\sin\left(z - \frac{\pi n}{2}\right)\sum_{p=0}^{\leqslant \frac{n}{2}}(-1)^p \frac{(n+2p)!}{(2p)!\,(n-2p)!}(2z)^{-2p}\right.$$
$$\left.+\cos\left(z - \frac{\pi n}{2}\right)\sum_{p=0}^{\leqslant \frac{n-1}{2}}(-1)^p \frac{(n+2p+1)!}{(2p+1)!\,(n-2p-1)!}(2z)^{-2p}\right\}. \quad \text{(A.1)}$$

For a sufficiently large value of the argument $z = (1 - i)\varkappa$, $\varkappa \gg 1$, χ_n can be represented as the ratio of polynomials with complex coefficients by means of the relationship

$$\operatorname{tg}\left[(1 - i)\varkappa - \frac{n-1}{2}\pi\right] \approx -i \quad (\varkappa \gg 1).$$

The asymptotic behavior of χ_n for large values of the argument can be found from (1) by retaining the two leading terms ($\sim 1/z$ and $1/z^2$):

$$\chi_n[(1 - i)\varkappa] = -1 + \frac{2n+1}{2\varkappa} - i\,\frac{2n+1}{2\varkappa}\left(\varkappa^2 \gg \frac{n^2}{2}\right). \quad \text{(A.2)}$$

For small values of the argument it is convenient to make use of the Bessel function representation[7]

$$j_n(z) = z^n \sum_{p=0}^{\infty} \frac{(-1)^p z^{2p}}{2^p p!\,[2(n+p)+1]!!}. \quad \text{(A.3)}$$

If we limit ourselves to two terms in (3), we get

$$\chi_n[(1 - i)\varkappa] = \frac{2}{(2n+1)(2n+3)}$$
$$\times\left[-\frac{4\varkappa^4}{(2n+1)(2n+5)} - i\varkappa^2\right](\varkappa^2 \ll 2n+1). \quad \text{(A.4)}$$

A characteristic point of the function $\chi_n[(1 - i)\varkappa]$ is the minimum of the real part. Table 1 gives the values of $\varkappa_{\max} = \varkappa^*$ and the magnitudes $\left.\begin{matrix}\text{Re}\\ \text{Im}\end{matrix}\right\}\chi_n[(1 - i)\varkappa^*]$ for functions of the first ten values of n.

The frequency-dependent function for $\mu \neq 1$ is

$$N_n = \frac{(2n+1)\chi_n(z)}{2n+1+n(\mu-1)+n(\mu-1)\chi_n(z)}.$$

The asymptotic variations for this are obtained in the same way as for χ_n and have the form

$$N_n[(1 - i)\varkappa] = \frac{1}{[(2n+1)+n(\mu-1)]^2}\left\{-\frac{4\varkappa^4[n(\mu-1)+2(2n+3)]}{(2n+3)^2(2n+5)}\right.$$
$$\left.-i\,\frac{2\varkappa^2}{2n+3}[2n+1+n(\mu-1)]\right\}, \quad \varkappa \ll \mu n,$$

$$N_n[(1 - i)\varkappa] = -1 + \frac{2n+1+n(\mu-1)}{2\varkappa}$$
$$-i\,\frac{2n+1+n(\mu-1)}{2\varkappa}, \quad \varkappa \gg \mu n.$$

TABLE 1

	Function number n									
	1	2	3	4	5	6	7	8	9	10
$\varkappa^*$	2.409	3.719	5.111	6.538	7.960	9.395	10.825	12.259	13.715	15.15
$-\text{Im}\chi_n$	0.355146	0.332728	0.322635	0.31724	0.313955	0.311738	0.310140	0.308933	0.307992	0.307242
$-\text{Re}\chi_n$	0.3660	0.3594	0.3623	0.3667	0.3687	0.3710	0.3721	0.3736	0.3752	0.3759

One case of interest is when the frequency is such that the expansion (4) is satisfied and μ is high ($\mu \gg n$). Then

$$N_n[(1-i)\varkappa]$$

$$= \frac{-1 + \frac{2n+1-n(\mu-1)}{2\varkappa} + \frac{(2n+1)n(\mu-1)}{2\varkappa^2} - i\frac{(2n+1)+n(\mu-1)}{2\varkappa}}{1 + \frac{n(\mu-1)}{\varkappa} + 2\frac{n^2(\mu-1)^2}{\varkappa^2}}$$

and the minimum of the imaginary part occurs at $\varkappa = n(\mu - 1)/\sqrt{2}$. The values of $\left.\begin{matrix}\mathrm{Re}\\ \mathrm{Im}\end{matrix}\right\} N_n$ at this point are respectively

$$\frac{1}{2}\left[-1 + \frac{2n+1}{n(\mu-1)}\right] \simeq -0.5, \quad \frac{1}{2(1+\sqrt{2})}\left[1 + \frac{2n+1}{n(\mu-1)}\right] \simeq 0.207.$$

We can conclude from the asymptotic behavior of the functions χ_n and N_n and from the position of $\max \mathrm{Im}\frac{\chi_n}{N_n}$ that the scale of the functions χ_n of $\varkappa$ varies approximately proportional to the number n and of N_n proportional to μn.

Electromagnetic levitation of a liquid metal droplet with strong skin effect (surface shape and internal pressure)

A. N. Tverdokhlebov and A. L. Shuster

(Submitted October 9, 1973; resubmitted March 13, 1974)
Zh. Tekh. Fiz., 44, 2265-2271 (November 1974)

The shape of a liquid metal droplet levitated in a stationary electromagnetic field is analyzed. The structure inside the drop and the first correction for the deviation from a spherical shape are found for a large surface tension σ and strong skin effect. These are expressed in terms of integrals of the magnetic field without a droplet. An upper bound is obtained for the power W which can be dissipated in a droplet equivalent to a sphere of radius a: $W < 8\pi\sigma a^2\omega$ (ω is the frequency).

1. INTRODUCTION

In various technological problems, e.g., melting of metals and alloys without a crucible,[1] the molten metal is levitated in a quasispherical shape and is heated by an electromagnetic field. The power introduced into the metal increases with decreasing skin-depth; therefore high-frequency electromagnetic fields are normally used, the frequency being such that the skin depth is much smaller than the characteristic size of the molten metal.

In this note we find the pressure inside a suspended metal droplet in an external stationary magnetic field (and gravity field) and the deviation from sphericity for the case of a strong skin effect and large surface-tension σ (for small deviations from sphericity). The desired quantities are expressed in terms of integrals of the squares of the fields with no droplet.

The calculations are based on the equation

$$\operatorname{div}\left\{\frac{\operatorname{grad} F}{|\operatorname{grad} F|}\right\} + F(\mathbf{r}) = \frac{1}{\sigma}\Psi(F,\ \mathbf{r}), \tag{1.1}$$

obtained in Sec. 2; the solution $F(\mathbf{r})$ defines a family of surfaces $F(\mathbf{r}) = \text{const}$, which includes the desired surface of the drop. The expression $\Psi(F,\ \mathbf{r})$ on the right side of (1.1) is the pressure difference $p(\mathbf{r}_0) - p(\mathbf{r})$, where $p(\mathbf{r})$ is the pressure created by external forces at the point $\mathbf{r}$ on one surface of the family $F(\mathbf{r}) = \text{const}$ (passing through $\mathbf{r}$), while $p(\mathbf{r}_0)$ is the pressure at some fixed point inside the droplet. The initial data, e.g., the total volume of the liquid droplet, make it possible to isolate the desired surface from the family $\varkappa(\mathbf{r}) = \text{const}$. The value of the constant is $p(\mathbf{r}_0)/\sigma$, so that $F(\mathbf{r})$ simultaneously determines both the surface shape and the pressure inside the droplet.

As $\sigma \to \infty$ the solution of (1.1) becomes the function $F_0(\mathbf{r}) = 2/|\mathbf{r} - \mathbf{R}|$, where $\mathbf{R}$ is an arbitrary vector. In Sec. 3 we obtain linear equation (3.2) for the first correction ($1/\sigma$) to $F_0(\mathbf{r})$. On the basis of this linear equation we find explicit expressions in Secs. 4 and 5 for the pressure at the center of gravity of the surface and for the extent to which its shape differs from a sphere [see (4.7) and (5.7)]. The desired quantities are expressed in terms of integrals of the squares of the field H as specified with no drop. The results are evaluated in Sec. 6.

2. EQUATION OF THE SURFACE

In static equilibrium we have the following pressure equation on the curved surface of a liquid with surface tension σ:

$$2\sigma\varkappa(\mathbf{r}) + p(\mathbf{r}) + p_{\text{ext}} = 0, \tag{2.1}$$

where $x(\mathbf{r})$ is the average curvature of the surface at $\mathbf{r}$, defined as the half-sum of the curvatures of any two mutually perpendicular cross sections, $p(\mathbf{r})$ is the pressure due to external forces (ponderomotive and gravitational) at the given point of the surface, and p_{ext} is the external pressure (atmospheric), which, without loss of generality, can be taken equal to zero. (Otherwise we can simply add the external pressure to the desired pressure within the droplet.)

The field of normals $\mathbf{n}$ to the family of surfaces $F(\mathbf{r}) = \text{const}$ is expressed in terms of the function $F(\mathbf{r})$:

$$\mathbf{n} = \frac{\operatorname{grad} F}{|\operatorname{grad} F|}, \tag{2.2}$$

while the average curvature $\varkappa(\mathbf{r})$ of a given family of surfaces is given by the following expression:[4]

$$2\varkappa(\mathbf{r}) = \operatorname{div}\mathbf{n} = \nabla\left\{\frac{\nabla F}{|\nabla F|}\right\}. \tag{2.3}$$

Isolating the pressure at some fixed interior point $\mathbf{r}_0$ from $p(\mathbf{r})$, we can rewrite (2.1) in the form

$$\sigma\left\{\nabla\left\{\frac{\nabla F}{|\nabla F|}\right\}\right\}_{\mathbf{r}\in S} + p(\mathbf{r}_0) = \{p(\mathbf{r}_0) - p(\mathbf{r})\}_{\mathbf{r}\in S}, \tag{2.4}$$

where S is the unknown surface.

The equations $F(\mathbf{r}) = C_0$ and $f(F(\mathbf{r})) = f(C_0)$ define the same surface provided that $df/dz|_{z=C_0} \neq 0$. Using this ambiguity and choosing $F(\mathbf{r})$ to be such that its value on the surface is $p(\mathbf{r}_0)/\sigma$, we obtain

$$\left\{\nabla\left\{\frac{\nabla F}{|\nabla F|}\right\} + F\right\}_{\mathbf{r}\in S} = \frac{1}{\sigma}\{\Psi(F(\mathbf{r}),\ \mathbf{r})\}_{\mathbf{r}\in S}. \tag{2.5}$$

The expression $\Psi(F(\mathbf{r}),\ \mathbf{r}) = p(\mathbf{r}_0) - p(\mathbf{r})$ is a functional of $F(\mathbf{r})$ and a function of $\mathbf{r}$ [see the clarifications to (1.1) in Sec. 1]. Once we have removed the condition $\mathbf{r} \in S$, we obtain the final equation (1.1).

The initial conditions, e.g., the total volume of the liquid V, make it possible to isolate the desired surfaces from the family of surfaces defined by $F(\mathbf{r})$. The value of $F(\mathbf{r})$ itself on this surface yields the pressure at the chosen point $\mathbf{r}_0$ (or, more precisely, the drop between the pressure at this point and the external pressure p_{ext}).

We note that

$$\oint_{F=\mathrm{const}} dS_\mu \Psi(F(\mathbf{r}),\ \mathbf{r}) = 0. \tag{2.6}$$

Physically this means that the metal droplet is at a point in space at which the resultant of the external forces is zero. Equation (1.1) satisfies this condition; indeed,

$$\oint_S dS_\mu F(\mathbf{r}) = \left(\frac{p_0}{\sigma}\right)\oint_S dS_\mu = 0,$$

and to prove that $\oint 2\sigma\varkappa dS_\mu$ is equal to zero we use expression (2.3). Assuming that the field of normals (2.2) satisfies the condition of being twice differentiable, we obtain

$$\sigma\oint_S dS_\mu 2\varkappa = \sigma\oint_S dS_\mu \nabla_\nu n_\nu = \sigma\int_V dV\nabla_\mu\nabla_\nu n_\nu = \sigma\int dV\nabla_\nu\nabla_\mu n_\nu$$
$$= \sigma\oint_S dS_\nu\nabla_\mu n_\nu = \sigma\oint dS n_\nu\nabla_\mu n_\nu = 0.$$

In the last integral, the integrand is identically zero, since $n_\nu\nabla_\mu n_\nu = 1/2\nabla_\mu(n_\nu^2) \equiv 0$, $\mathbf{n}^2 \equiv 1$.

3. SOLUTION OF (1.1) TO FIRST ORDER IN $(1/\sigma)$

Setting $(1/\sigma) = 0$ in (1.1), we obtain the zero-order equation

$$\nabla\left\{\frac{\nabla_0 F}{|\nabla F_0|}\right\} + F_0 = 0.$$

The solution is the function $F_0 = 2/|\mathbf{r}-\mathbf{R}_0|$, where $\mathbf{R}_0$ is determined from Eq. (2.6) with $F = F_0$. The surface $F_0(\mathbf{r}, \mathbf{R}_0) = \mathrm{const}$ is a sphere whose center is at $\mathbf{R}_0$. We will seek the first approximation in the form

$$F_1(\mathbf{r}) = \frac{2\left[1 + \frac{1}{\sigma}u(\mathbf{r})\right]}{|\mathbf{r}-\mathbf{R}_1|}. \tag{3.1}$$

We introduce the notation $\mathbf{r}-\mathbf{R}_1 = \rho\mathbf{n}(\mathbf{n}^2 = 1)$ and substitute $F_1(\mathbf{r})$ into (1.1). Retaining terms of order $(1/\sigma)$, we obtain the following linear equation for the function $u(\mathbf{r}) = u(\mathbf{R}_1 + \rho\mathbf{n})$:

$$(2 + \Delta_{\theta\varphi})u = \rho\Psi(F_0(\mathbf{r},\ \mathbf{R}_1),\ \mathbf{R}_1 + \rho\mathbf{n}), \tag{3.2}$$

where $\Delta_{\theta\varphi}$ is the angular part of the Laplacian Δ in the spherical coordinates specified by the vector $\rho\mathbf{n}$.

Before solving (3.2) let us consider the properties of the surface S defined by the equation $F_1(\mathbf{r}, \mathbf{R}_1) = \mathrm{const}$. The radius vector that describes this surface to order $1/\sigma$ is defined by the equation

$$\mathbf{r}_S = \mathbf{R}_1 + C\mathbf{n}\left[1 + \frac{1}{\sigma}u(\mathbf{R}_1 + C\mathbf{n})\right], \tag{3.3}$$

where C is a constant. We take $\mathbf{R}_1$ to be the center of gravity of the surface [i.e., $\oint_S dS(\mathbf{R}_1 - \mathbf{r}_S) = 0$], and we choose C to be such that the volume bounded by S is equal to that of a sphere of a radius a. This requirement imposes the following conditions on u:

$$\langle\mathbf{n}u\rangle = 0, \tag{3.4}$$

$$C = a\left(1 - \frac{1}{\sigma}\langle u\rangle\right) \tag{3.5}$$

[we use the notation $\langle f(\mathbf{r})\rangle = (1/4\pi)\int d\Omega_{\mathbf{n}} f(\mathbf{R}_1 + a\mathbf{n})$]. Allowing for these conditions, and taking the coordinate origin at $\mathbf{R}_1$, we can rewrite (3.3) as

$$\mathbf{r}_S = a\mathbf{n}\left(1 + \frac{1}{\sigma}[u(a\mathbf{n}) - \langle u\rangle]\right). \tag{3.6}$$

Correspondingly, Eq. (3.2) becomes an equation in $u(a\mathbf{n})$:

$$(2 + \Delta_{\theta\varphi})u(a\mathbf{n}) = a\Psi\left(\frac{2}{|\mathbf{r}|},\ a\mathbf{n}\right). \tag{3.7}$$

Here, we have allowed for the fact that $\mathbf{R}_1$ differs from $\mathbf{R}_0$, obtained from (2.6) in the zeroth approximation by a quantity of order $(1/\sigma)$; hence, in substituting into Ψ this difference should be neglected in the approximation in question. We expand $u(a\mathbf{n})$ and Ψ in spherical harmonics $J_m(\mathbf{n})$:

$$u(a\mathbf{n}) = \sum_m u_m J_m(\mathbf{n}),\quad \Psi = \sum_m \Psi_m J_m(\mathbf{n}),$$
$$\langle J_m J_l\rangle = \delta_{ml},\quad \Delta_{\theta\varphi}J_m = -m(m+1)J_m.$$

Then Eq. (3.7) becomes the system

$$\left.\begin{aligned} &[2 - m(m+1)]u_m = a\Psi_m \\ \text{or}\quad &u_m = -\frac{a\Psi_m}{(m-1)(m+2)},\quad m \neq 1. \end{aligned}\right\} \tag{3.8}$$

The indeterminacy for m = 1 is resolved by choosing the center of gravity of the surface as the coordinate origin ($u_1 = 0$) and by (2.6), which yields $\Psi_1 = 0$ in this approximation. Since the pressure of the force of gravity is $\lambda(\mathbf{g}\mathbf{r})$, λ being the density of the metal and g the acceleration of gravity, it makes a contribution only to Ψ_1 and hence [besides the definition of the equilibrium position from condition (2.6)] it does not appear more explicitly in the definition of the shape of the surface in the first approximation in $(1/\sigma)$.

4. DETERMINATION OF THE PRESSURE AT THE CENTER OF THE DROP

In accordance with Sec. 2, the pressure p_0 at the center of gravity of the drop is $\sigma F(\mathbf{r})|_{\mathbf{r}\in S}$. In the first approximation in $(1/\sigma)$ we have

$$p_0=\frac{2\sigma}{a}\left(1+\frac{1}{\sigma}\langle u\rangle\right); \tag{4.1}$$

from (3.8) we have

$$\langle u\rangle\equiv u_0=\frac{a}{2}\Psi_0\equiv\frac{a}{2}\langle p_{\text{magn}}\rangle, \tag{4.2}$$

where p_{magn} is the pressure of magnetic ponderomotive forces on a sphere of radius a. The pressure of gravity does not appear explicitly in the computations in this approximation, as noted at the end of the preceding section.

When there is a pronounced skin effect the surface pressure of the magnetic forces is[2]

$$p_{\text{magn}}=\frac{1}{8\pi}\mathscr{H}^2, \tag{4.3}$$

where $\mathscr{H}$ is the effective (not the amplitude) value of the exact field on the surface of the sphere. Inside the sphere the current density $\mathbf{j}(\mathbf{r})$ is $(1/4\pi)[\nabla\mathscr{H}]$. Because the field attenuates exponentially as we go into the interior of the sphere, we can make the substitution $\nabla = ik\mathbf{n}[k=(1+i)/\delta$; $\delta=(2\pi\omega\tau)^{-1}$; ω is the field frequency; and τ is the conductance of the metal, following the notation in ref. 3]. Then we have

$$p_{\text{magn}}=\pi\delta^2(\mathbf{j}\mathbf{j}^*).$$

On the surface of the sphere the quantity $\mathbf{j}(a\mathbf{n})$ can be determined from the expression [see Eq. (2.9) in ref. 3]

$$\mathbf{j}(a\mathbf{n})=-\frac{ik}{4\pi a}\frac{1}{a}\int_0^a dr\left(2r\frac{d}{dr}+1\right)[\mathbf{r}\mathbf{H}(\mathbf{r})], \tag{4.4}$$

where $\mathbf{H}(\mathbf{r})$ is the field with no sphere, for which we use the representation in terms of the scalar potential

$$\varphi=\sum_m A_m\left(\frac{r}{a}\right)^m J_m(\mathbf{n}),\quad -\nabla\varphi=\mathbf{H}.$$

Substituting (4.4) into (4.3), we obtain

$$\begin{aligned} p_{\text{magn}}&=\frac{1}{8\pi}\hat{G}_0\left(\frac{a}{r_1}\right)\hat{G}_0\left(\frac{a}{r_2}\right)\left(\frac{r_1}{a}\right)\left(\frac{r_2}{a}\right)\\ &\times[\nabla\varphi(r_1\mathbf{n})\nabla\varphi(r_2\mathbf{n})-(\mathbf{n}\nabla)\varphi(r_1\mathbf{n})(\mathbf{n}\nabla)\varphi(r_2\mathbf{n})], \end{aligned} \tag{4.5}$$

where

$$\hat{G}_0\left(\frac{r}{\rho}\right)f(\rho)=\left(2r\frac{d}{dr}+1\right)\frac{1}{r}\int_0^r d\rho f(\rho),$$

as in ref 3.

Evaluation of the integral $\langle p_{\text{magn}}\rangle$, which is similar to ref. 3 (see Sec. 5 in ref. 3, "Computation of the power"), leads to the following expression for $\langle u\rangle$ from (4.2):

$$\langle u\rangle=\frac{a}{8\pi}\left\{\langle\mathbf{H}^2\rangle-\frac{1}{4\pi a^3}\int_{|\mathbf{r}|<a}dV\left(\frac{r}{a}\right)\mathbf{H}^2(\mathbf{r})\right\}. \tag{4.6}$$

Substituting (4.6) into (4.1) yields an expression for the pressure p_0 at the center in terms of integrals of the squares of the fields with no droplet:

$$p_0=\frac{2\sigma}{a}+\frac{1}{4\pi}\left[\langle\mathbf{H}^2\rangle-\frac{1}{4\pi a^3}\int_{|\mathbf{r}|<a}dV\left(\frac{r}{a}\right)\mathbf{H}^2(\mathbf{r})\right]. \tag{4.7}$$

5. DEVIATION FROM SPHERICITY (FIRST CORRECTION)

We write the second harmonic of the expansion of $u(a\mathbf{n})$ in the form

$$u_2J_2(\mathbf{n})=(u_2)_{\alpha\beta}\left(n_\alpha n_\beta-\frac{1}{3}\delta_{\alpha\beta}\right),\quad (u_2)_{\alpha\alpha}=0.$$

Taking account of the second harmonic leads to an elliptical shape. With m = 2 Eq. (3.8) yields

$$(u_2)_{\alpha\beta}=-\frac{15a}{8}\left\langle\left(n_\alpha n_\beta-\frac{1}{3}\delta_{\alpha\beta}\right)\Psi\right\rangle. \tag{5.1}$$

In computing $(u_2)_{\alpha\beta}$ we omit terms proportional to $\delta_{\alpha\beta}$, since these do not appear in $(u_2)_{\alpha\beta}[n_\alpha n_\beta-(1/3)\delta_{\alpha\beta}]$. Substituting p_{magn} from (4.5) in place of Ψ in (5.1) and proceeding as shown in the appendix to [3], we obtain

$$\begin{aligned}(u_2)_{\alpha\beta}=\frac{15a}{32\pi}\Bigg\{&\sum_{m=0}^{\infty}\left[1+\frac{3}{(m+2)^2}+\frac{18}{2m+5}-\frac{11}{m+2}\right]\frac{(a^2\Delta)^m}{(2m+1)!}\left(\frac{\partial\varphi}{\partial x_\alpha}\frac{\partial\varphi}{\partial x_\beta}\right)\\ &+a^2\sum_{m=0}^{\infty}\left[\frac{1}{m+2}-\frac{2}{2m+5}\right]\frac{(a^2\Delta)^m}{(2m+1)!}\left(\frac{\partial\varphi}{\partial x_\mu}\frac{\partial^3\varphi}{\partial x_\mu\partial x_\alpha\partial x_\beta}\right)\Bigg\}_{\mathbf{r}=0}+\delta_{\alpha\beta}(\ldots).\end{aligned} \tag{5.2}$$

We use the following equations:

$$\left\{\sum_{m=0}^{\infty}\frac{(a^2\Delta)^m}{(2m+1)!}f(\mathbf{r})\right\}_{\mathbf{r}=0}=\langle f(\mathbf{r})\rangle\equiv\frac{1}{4\pi a^2}\oint_{|\mathbf{r}|=a}dS f(\mathbf{r}), \tag{5.3}$$

$$\left\{\sum_{m=0}^{\infty}\frac{1}{(m+q)}\frac{(a^2\Delta)^m}{(2m+1)!}f(\mathbf{r})\right\}_{\mathbf{r}=0}=\frac{1}{2\pi a^3}\int_{|\mathbf{r}|<a}dV\left(\frac{r}{a}\right)^{2q-3}f(\mathbf{r}), \tag{5.4}$$

$$\left\{\sum_{m=0}^{\infty}\frac{1}{(m+q)^2}\frac{(a^2\Delta)^m}{(2m+1)!}f(\mathbf{r})\right\}_{\mathbf{r}=0}=\frac{1}{\pi a^3}\int_{|\mathbf{r}|<a}dV\left(\frac{r}{a}\right)^{2q-3}\ln\left(\frac{a}{r}\right)f(\mathbf{r}). \tag{5.5}$$

Equations (5.4) and (5.5) can be obtained by expanding $f(\mathbf{r})$ in a Fourier integral, while (5.3) is obtained by going to the limit in (5.4) [we multiply both sides of (5.4) by q and and take the limit as q → ∞ on both sides].

Using (5.3)-(5.5) we write (5.2) in the form ($H_\mu = -\partial\varphi/\partial x_\mu$)

$$\begin{aligned}(u_2)_{\alpha\beta}=\frac{15a}{32\pi}\Bigg\{&\langle H_\alpha H_\beta\rangle+\frac{1}{2\pi a^3}\int_{|\mathbf{r}|<a}dV H_\alpha H_\beta\left[6\left(\frac{r}{a}\right)\ln\left(\frac{a}{r}\right)+9\left(\frac{r}{a}\right)^2\right.\\ &\left.-11\left(\frac{r}{a}\right)\right]-\frac{1}{2\pi a}\int_{|\mathbf{r}|<a}dV\left(H_\mu\frac{\partial^2 H_\mu}{\partial x_\alpha\partial x_\beta}\right)\left[\left(\frac{r}{a}\right)-\left(\frac{r}{a}\right)^2\right]\Bigg\}.\end{aligned} \tag{5.6}$$

Using the identity

$$\int\limits_{|\mathbf{r}|<a} dV f(r) H_\mu \frac{\partial^2 H_\mu}{\partial x_\alpha \partial x_\beta} = f(a) \oint\limits_{|\mathbf{r}|=a} dS_\mu H_\mu \frac{\partial H_\alpha}{\partial x_\beta} - \int\limits_{|\mathbf{r}|<a} dV \frac{df(r)}{dr} (\mathbf{nH}) \frac{\partial H_\alpha}{\partial x_\beta},$$

we obtain the final expression for the first correction for the deviation from sphericity:

$$(u_2)_{\alpha\beta} = \frac{15a}{32\pi} \left\{ \frac{1}{4\pi a^2} \oint\limits_{|\mathbf{r}|=a} dS H_\alpha H_\beta + \frac{1}{2\pi a^3} \int\limits_{|\mathbf{r}|<a} dV H_\alpha H_\beta \left[6\left(\frac{r}{a}\right) \ln\left(\frac{a}{r}\right) + 9\left(\frac{r}{a}\right)^2 - 11\left(\frac{r}{a}\right) \right] - \frac{1}{2\pi a^2} \int\limits_{|\mathbf{r}|<a} dV (\mathbf{nH}) \frac{\partial H_\alpha}{\partial x_\beta} \left[1 - 2\left(\frac{r}{a}\right) \right] \right\}. \quad (5.7)$$

6. REMARKS

1. We can obtain an explicit expression for the solution of Eq. (3.7) without expanding in spherical harmonics. We write $\Psi(2/|\mathbf{r}|, a\mathbf{n}) \equiv \Psi(a\mathbf{n})$ from (3.7) as the boundary value of a function $\psi(r\mathbf{n})$ that is harmonic within the sphere:

$$\psi(r\mathbf{n}) = \sum_m \left(\frac{r}{a}\right)^m \Psi_m J_m(\mathbf{n}).$$

Then the denominator $1/(m-1)(m+2)$ from (3.8) can be replaced by integration with respect to r from zero to a:

$$u(a\mathbf{n}) = -\frac{a}{3} \int\limits_0^a d\left(\frac{r}{a}\right) \left[\left(\frac{a}{r}\right)^2 - \left(\frac{r}{a}\right) \right] \psi(r\mathbf{n}). \quad (6.1)$$

Solving the Dirichlet problem for $\psi(r\mathbf{n})$ by means of the Green's function for a sphere, we obtain

$$\psi(r\mathbf{n}) = \frac{a}{4\pi} \int d\Omega_\nu \frac{r^2 - a^2}{[r^2 + a^2 - 2ar(\mathbf{n\nu})]^{3/2}} \Psi(a\boldsymbol{\nu}).$$

Thus we obtain the following representation for $u(a\mathbf{n})$:

$$u(a\mathbf{n}) = u_0 - \frac{a}{3} \int\limits_0^a d\left(\frac{r}{a}\right) \left[\left(\frac{a}{r}\right)^2 - \left(\frac{r}{a}\right) \right] \left[\psi(r\mathbf{n}) - \psi(0) - r \left.\frac{\partial\psi}{\partial r}\right|_{r=0} \right].$$

The integral in (6.1) has a singularity of order $(1/r)^2$ at zero. For this reason there is a double subtraction at zero in the above integral [$u_1 = 0$ in view of (2.6)]. Finally we write $u(a\mathbf{n})$ in the form

$$u(a\mathbf{n}) = u_0 - \frac{a}{4\pi} \int d\Omega_\nu \gamma((\mathbf{n\nu})) p_{\text{magn}}(a\boldsymbol{\nu}), \quad (6.2)$$

where

$$\gamma(z) = \frac{1}{3} \int\limits_0^1 dx \left(\frac{1 - x^3}{x^2}\right) \left(1 + 3xz - \frac{1 - x^2}{[x^2 + 1 - 2xz]^{3/2}}\right) = \frac{1}{3} \left[\frac{3}{2} + 5z - 3z \ln \frac{2}{1 - z} \right].$$

2. Equation (4.7) for the pressure at the center of gravity of the surface can be written in the following form, allowing for the results of ref. 3 [see Sec. 5, Eq. (5.2) in ref. 3]:

$$p_0 = \frac{2\sigma}{a} + \frac{1}{4\pi\omega a^2\delta} W,$$

where W is the power dissipated in the sphere. Because the sphere is closed and simply connected, there should be (at least two) points on the surface at which the current density is zero. At such points the pressure of ponderomotive forces is also zero and the internal pressure of the liquid is confined only by surface-tension forces. The radius of the average curvature $R_{\min}$ at this point (which obviously will be at a minimum at such point) is determined from the expression (gravity is neglected)

$$\frac{2\sigma}{R_{\min}} = \frac{2\sigma}{a} + \frac{1}{4\pi a^2\omega\delta} W. \quad (6.3)$$

From (6.3) we can obtain an upper bound for the power dissipated in a suspended liquid drop. The radius of mean curvature cannot be less than the skin depth δ, so that

$$\frac{2\sigma}{a} + \frac{1}{4\pi a^2\omega\delta} W < \frac{2\sigma}{\delta}.$$

Allowing for the fact that $a \gg \delta$, we obtain

$$W < 8\pi\sigma a^2\omega. \quad (6.4)$$

Taking account of the force of gravity introduces a slight correction in the form of the factor $(1 - \lambda gh\delta/\sigma)$, where h is the vertical distance between the center of the droplet and the point at which the current density is zero.

The authors thank M. L. Levin for comments.

Fifth-order spherical aberration in focusing and correcting quadrupole–octupole systems

Ya. G. Lyubchik and T. Ya. Fishkova

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted November 19, 1973)
Zh. Tekh. Fiz., 44, 2272-2279 (November 1974)

The third-order spherical aberration is treated in systems of quadrupole–octupole (Q–O) lenses used as a focusing system or as a correction system (with an axisymmetric lens) in the negative spherical aberration mode. Expressions are obtained for the fifth-order spherical aberration of a system consisting of an arbitrary number of Q–O lenses. A computer is used to design specific Q–O systems; on this basis the possible gain in resolution and current is evaluated for a number of existing scanning electron microscopes and microanalyzers. A new electrostatic lens is proposed that makes it possible to adjust third- and fifth-order spherical aberrations simultaneously with respect to magnitude and sign.

The interest in elements with multiple symmetry is primarily related to the possibility of compensating various aberrations in electron-optical systems. Of particular importance are quadrupole and octupole lenses, since such systems can correct for one of the major aberrations that limits the resolving power of electron-optical devices, namely spherical aberration.

Analysis of studies along these lines, e.g., refs. 1-3, shows that the difficulties are associated primarily with the cumbersomeness of correcting systems, and with the complexity of making the separate elements to precise tolerances and aligning them with respect to each other. The design problems for electrostatic lenses have recently been overcome in a combined five-element quadrupole–octupole (Q–O) element,[4] and new methods of aligning quadrupole systems have been developed.[5]

A more fundamental question is that of using quadrupole–octupole systems for correcting spherical aberration. Estimates given in ref. 6 for a complex electron-optical system (objective of a transmission electron microscope consisting of seven 12-pole electromagnetic lenses) show that when first-order chromatic aberration and third-order spherical aberration are corrected simultaneously it is possible to obtain a resolving power of 0.5 Å at an energy of 60 keV. The effectiveness of partial correction for an elementary system consisting of an axisymmetric lens and an octupole is evaluated in ref. 7. This system is intended for the condenser of an x-ray microanalyzer and can yield a current gain of 2-2.5.

Experience with nonaxisymmetrical lenses shows that it is best to use correction elements consisting of two or three (but not more than four) combined Q–O lenses of simplified design. A system of two such lenses can provide stigmatic focusing and simultaneously correct for spherical aberration of the width of a linear image, a fact which is of importance in spectrometers[8] and certain types of electron-beam devices.[9] In microprobe systems (scanning electron microscopes, x-ray microanalyzers, cathode-ray tubes) it is necessary to have three (or four) Q–O lenses, which can yield similar or equal linear magnification factors and zero or negative spherical aberration in all directions.

Complex systems of five to seven lenses in which each lens has eight to 12 electrodes are not feasible in practice, while one Q–O lens generally does not yield the desired effect.

The aim of the present paper is to consider fifth-order spherical aberration for systems consisting of an arbitrary number of quadrupole–octupole lenses. On this basis we determine the gain from correcting for third-order spherical aberration for various probe devices.

In ref. 10 we obtained expressions for the fifth-order spherical aberration coefficients in the central planes of an individual quadrupole–octupole lens for a point (aberration-free) source C_5. For each lens in the system, beginning with the second, the source can no longer be regarded as aberration-free, since fifth-order aberration will be contributed to by the third-order aberrations of the preceding part of the system. Let us determine the contribution.

The additional broadening of a Gaussian image as a result of third-order geometrical aberrations in the preceding system in the central planes of a Q–O lens can be written

$$\left.\begin{aligned}\Delta^0 x(z_i) &= M_x(c_{5-3,x}+c^*_{5-3,x})\,x_0'^5,\\ \Delta^0 y(z_i) &= M_y(c_{5-3,y}+c^*_{5-3,y})\,y_0'^5,\end{aligned}\right\}\qquad(1)$$

where M is the linear magnification factor of the lens; x_0' and y_0' are the slopes of the trajectories at the lens input. The asterisk everywhere denotes quantities referring to the octupole. The quantity c_{5-3} can be expressed in terms of the third-order coefficient

$$c_{5-3}+c^*_{5-3}=A(b+b^*)+3G(p+p^*).\qquad(2)$$

Here, p is the aberration coefficient in the corresponding principal plane for the cube of the angle (spherical aberration), while b are the aberration coefficients in the central planes for the square of the angle and the first power of the distance.[11] The constants A (associated with the broadening of the image because of third-order aberrations) and G (associated with the change of the angle of inclination of the third-order trajectory) depend on the aberrations of the system that the given lens represents as follows:

$$\left.\begin{aligned}A^n &= \mathscr{M}_n(P_n+P^*_n),\\ G_n &= \frac{1}{2}(1-\mathscr{M}^2_n)-\frac{\mathscr{M}^3_n}{F_n}(P_n+P^*_n)-\frac{1}{3}\mathscr{M}^2_n(B_n+B^*_n),\end{aligned}\right\}\qquad(3)$$

n is the number of lenses in the preceding system; $\mathscr{M}_n$ and F_n are the magnification and focal length of the system, expressed in terms of the magnifications M_i and focal length f_i of the individual lenses as follows:

$$\mathcal{M}_n = \prod_{i=1}^{n} M_i, \tag{4}$$

$$F_n = \frac{\mathcal{M}_n}{\sum_{i=1}^{n} \mathcal{M}_i \mathcal{M}_{i-1} f_i^{-1}}, \tag{5}$$

P_n is the spherical aberration coefficient, and B_n is the aberration coefficient to the term containing the square of the angle and the first power of the distance for the entire preceding system:[11]

$$P_n + P_n^* = \sum_{i=1}^{n} \frac{(p_i + p_i^*)}{\mathcal{M}_{i-1}^3}, \tag{6}$$

$$B_n + B_n^* = \sum_{i=1}^{n} \frac{(b_i + b_i^*)}{\mathcal{M}_{i-1}^3} - 3 \sum_{i=2}^{n} \frac{(p_i + p_i^*)}{(\mathcal{M}_{i-1}^3 F_{i-1})}. \tag{7}$$

The parameters of each lens are substituted into the expressions (2) and (4)-(7) taking into account whether they converge or diverge in the central plane of the system under consideration.

Using Eqs. (10)-(13) of ref. 10 for c_5, allowing for the corrections for nonzero inputs, we can determine the fifth-order spherical aberration for one quadrupole or quadrupole–octupole lens that is arbitrarily positioned in the system.

We will find the spherical aberration in the plane of the Gaussian image for a system consisting of k successive lenses:

$$\Delta_k = \Delta_k^{(3)} + \Delta_k^{(5)} + \ldots = \mathcal{M}_k [C_3 \alpha_0^3 + C_5 \alpha_0^5 + \ldots], \tag{8}$$

where

$$C_3 = P_k + P_k^*, \tag{9}$$

$$C_5 = \sum_{i=1}^{k} \frac{c_{5i}}{\mathcal{M}_{i-1}^5} + \sum_{i=2}^{k} \Big\{ (P_{i-1} + P_{i-1}^*) \Big[(B_i + B_i^*) + \frac{3}{2} (1 - \mathcal{M}_{i-1}^{-2}) \Big] - (P_i + P_i^*) \Big[(B_{i-1} + B_{i-1}^*) + \frac{3}{2} (1 - \mathcal{M}_{i-1}^{-2}) \Big] \Big\}, \tag{10}$$

α_0 being the slope of the extreme trajectory of the beam at the system input. The second sum in (10) determines the contribution to the fifth order from the trajectory perturbations resulting from third-order geometrical aberrations. It is proportional to the product of two third-order aberration coefficients. In a correction mode this contribution increases sharply as a result of the octupole component, this being larger, the larger the negative value of the third-order coefficient created by the correction element. We should expect, therefore, that it is this term which will yield the major contribution to the residual fifth-order spherical aberration (see ref. 7).

Let us consider a specific system consisting of combined electrostatic quadrupole–octupole lenses. It can function independently as a focusing system or in conjunction with an axisymmetrical lens in a negative spherical aberration mode. To achieve high resolving power it is best to use the correction element in front of an axisymmetric lens in a reduction mode.

The typical probe geometry for a quadrupole–octupole system consisting of four successive lenses is as follows: effective length of all lenses the same and equal to L = 2 cm, distances between edges of fields s = 3 cm, distance from crossover to system input a = 10 cm, distance from system output to image (working portion) g = 3 cm.

This system can be used either as a quadruplet [analog of an axisymmetrical lens (ref. 12)] or as a triplet (charged-particle trajectories are shown in Fig. 1).

Figure 2 shows triplet parameters as determined on a computer using the FAS-48 program:[13] excitation of quadrupole lenses β (curves 1-3), magnification in the CDC plane (curve 7) and third-order spherical aberration coefficient (curves 4-6) as functions of the magnification ratio in two characteristic planes.

On the basis of these calculations we choose the optimum modes of triplet operation. The first-order requirements mean in effect that the magnifications in two mutually perpendicular planes differ by a factor of not more than 2. It is also desirable that the excitations of two out of the three lenses be roughly the same. The correction element should have small octupole excitations and also low residual aberration values (Fig. 3). In accordance with the above requirements, we select two modes (I, II), shown in Figs. 2 and 3. The first-order trajectories for the optimum modes in question are shown in Fig. 1 (curves 2,3).

For the quadruplet (curve 1 in Fig. 1) we obtain the following results: excitation of first and fourth lenses

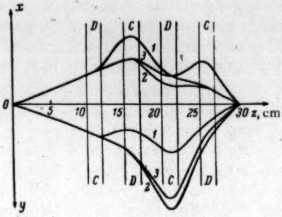

Fig. 1. Projections of electron-beam trajectories in two optimum triplet and quadruplet modes. 1) quadruplet, $\mathcal{M} = -0.6985$; 2) triplet, $\mathcal{M}_{CDC} = -0.751$, $\mathcal{M}_{DCD} = -0.372$; 3) triplet $\mathcal{M}_{CDC} = -0.266$, $\mathcal{M}_{DCD} = -0.498$.

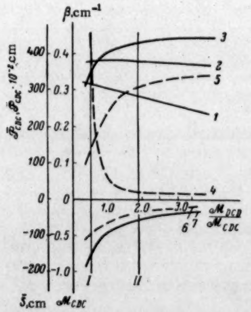

Fig. 2. First- and third-order electron-optical parameters of triplet: 1, 2, 3) excitation of first, second, and third lens respectively; 4) coefficient of spherical aberration $\bar{P}_{CDC}$ (in xoz plane); 5) $\bar{P}_{DCD}$ (in yoz plane); 6) third spherical aberration coefficient $\bar{S}$; 7) magnification in CDC plane.

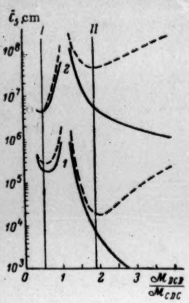

Fig. 3. Fifth-order spherical aberration coefficients of triplet C_5 for $C_3 = 0$ (curves 1) and $C_3 = -10^3$ cm (curves 2). The solid lines refer to the xoz plane, while the dashed lines refer to the yoz plane.

$\beta_{1,4} = 0.2715$ cm^{-1}, of second and third lenses $\beta_{2,3} = 0.3602$ cm^{-1}; magnification $\mathscr{M} = -0.6985$; aberration coefficients $\bar{P}_{CDCD} = 0.702 \cdot 10^3$ cm, $\bar{P}_{DCDC} = 2.554 \cdot 10^3$ cm, $\bar{S} = -0.225 \cdot 10^3$ cm. The aberration coefficients are adjusted to the state of the image of the system, so that $\bar{P} = P\mathscr{M}^4$.

Figure 3 shows the fifth-order spherical aberration coefficient for third-order spherical aberration corrected to zero and the negative value $\bar{C}_3 = -10^3$. Calculations are made on a computer using Eq. (10) in the "short-lens" approximation. The figure shows results for quadrupole fields without the sixth harmonic in the radial expansion of the potential ($K_6 = 0$). The role of nonlinear terms ($K_6 \neq 0$) will be discussed below. In addition, the calculations assume that the drop in the quadrupole field along the longitudinal axis is linear.

We should note that, according to the data of ref. 14, the difference between the fifth-order coefficients as measured on a model of a probe system and the computed values does not exceed a factor of 2-3.

For comparison we compute the fifth-order coefficients in certain modes (for $\bar{C}_3 = 0$), using the third-order coefficients appearing in c_{5-3} as found in the rectangular-field-model approximation. The discrepancy in using the two models is not great. This is due to the fact that the trajectories do not intersect the axis of the system and the assumption that a trajectory is constant within the limits of the lens field is met satisfactorily.

Our calculations indicate that the contribution to the total fifth-order aberration from the intrinsic coefficient of each lens $c_{5,i}$ is smaller by one to two orders of magnitude than the contribution from trajectory perturbation as a result of third-order geometrical aberrations, and the proportion decreases with increasing negative values of $\bar{C}_3$.

We will study in greater detail the effectiveness of correcting for third-order spherical aberration by using correction elements based on triplets in modes I and II and on the quadruplet analog of an axisymmetrical lens. For the range of variation of $\bar{C}_3 = 0\text{-}10^5$ cm created by the correction element we compute the fifth-order aberration coefficients of a quadrupole–octupole system, these being given in Fig. 4. For small $\bar{C}_3$ these coefficients are virtually constant; then they begin to increase and the dependence becomes quadratic for large negative $\bar{C}_3$.

In choosing the mode of a spherical-aberration correction element, we must allow for the residual spherical aberration (primarily fifth-order) of both the correction element and the lens being corrected. We compute the third- and fifth-order spherical aberration coefficient of a magnetic axisymmetrical lens. The lens that we have studied has a channel radius R equal to 1.25 the length of the nonmagnetic gap. The results are obtained by computer-implemented numerical methods using a program which N. I. Maleeva and L. A. Pavlova helped to write. Figure 5 shows the longitudinal spherical aberration coefficients, as adjusted to the image space, as functions of the size of the working segment g for fixed linear magnification M = −0.1. The third-order coefficients are in good agreement with the values in ref. 15. The fifth-order coefficients depend more sensitively on g, and there is a region with small working segments where $\bar{C}_5 < \bar{C}_3$. When the correction element is included the residual coefficients $\bar{C}_5^0$ differ sharply from $\bar{C}_5$ (the sign changes). For other electron-optical magnifications the nature of the above dependences remains the same.

On the basis of the fifth-order results we can evaluate the gain in resolving power and probe currents for spe-

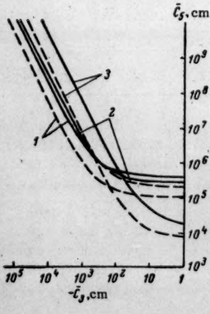

Fig. 4. Relationship between the third- and fifth-order spherical aberration coefficients in quadrupole–octupole systems. The solid curves refer to the yoz plane, while the dashed curves refer to the xoz plane. Notation is the same as in Fig. 1.

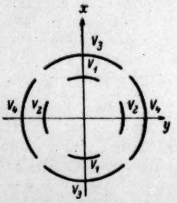

Fig. 6. Electrostatic quadrupole lens with adjustable spherical aberrations: $V_1 = V+u-v$, $V_2 = -V+u+v$, $V_3 = -u+v$, $V_4 = -u-v \pm V$ is the focusing potential, ±u and ±v are the correcting potentials.

cific devices. Assume that the probe diameter d in the plane of minimum cross section is given by the expression

$$d=\sqrt{d_g^2+d_s^2+d_d^2}, \tag{11}$$

where d_G is the diameter of the Gaussian image, d_s is the spreading due to spherical aberration, and d_d is the diameter of the diffraction-scattering circle.

For optimum aperture and reduction coefficients, the gain in probe size resulting from the correction of third-order spherical aberration for any nonzero $\bar{C}_5$ and constant probe current can be written as[16]

$$\frac{d_3}{d_5}=0.95\left[\frac{\bar{C}_3^2}{\frac{4I}{(\pi^2\rho)}+(1.22\lambda)^2}\right]^{1/24}\left(\frac{\bar{C}_3}{\bar{C}_5}\right)^{1/6}=\left(\frac{d_3}{d_5}\right)^{**}\eta^{1/6}. \tag{12}$$

Here d_3 is the probe diameter before correction, while d_5 is after correction; I is the probe current; ρ is the beam intensity; λ is the electron wavelength; $\eta = \bar{C}_3/\bar{C}_5$.

If the probe diameter is left unchanged, the current gain can be expressed as follows:

$$\frac{I_5}{I_3}=0.92\left(\frac{\bar{C}_3}{d}\right)^{4/15}f\left(\frac{\lambda}{d}\right)\left(\frac{\bar{C}_3}{\bar{C}_5}\right)^{2/5}=\left(\frac{I_5}{I_3}\right)^{**}\eta^{2/5}. \tag{13}$$

If $\lambda \ll d$, then we have $f(\lambda/d) \simeq 1$ in (13).

On the basis of (12) and (13) we evaluate the gain from correction for a number of existing scanning microscopes[17-20] and microanalyzers.[21,22] The results are shown in Table 1. The quantities $(d_3/d_5)^{**}$ and $(I_5/I_3)^{**}$ denote the gain in probe size and current for the case in which the third- and fifth-order aberration coefficients are roughly equal ($\eta \simeq 1$).

In computing η, we take only the residual correction-element aberrations as $\bar{C}_5$. Since no such data are available for the axisymmetric lenses used in the devices we have considered, it is assumed that they do not increase $\tilde{C}_5$. But the sign of $\tilde{C}_5$ for the magnetic axisymmetric lens that we have investigated (Fig. 5) – which is the reverse of that of $\bar{C}_5$ – permits us to hope that the gain from correction will increase. Moreover, an increase in resolving-power or current gain is possible when there is some overcorrection and partial compensation of the residual aberration by small negative values of the third-order coefficient.[23] In practice this mode is provided for automatically if the correction mode is chosen from the criterion of minimum probe size.

To further enhance the resolving power it is desirable to compensate for (or reduce) fifth-order spherical aberration. This is possible, for example, by appropriate choice of the shape of the electrodes of the quadrupole lens.[10,24] Because of the fixed harmonic in the expansion of the potential we find additional terms contributing to the fifth order; their value may be chosen so as to compensate for the remaining terms. In a five-electrode lens, this is accomplished technically by choice of the angle between electrodes. This procedure is not very effective, since it is adequate for only some single mode, and it is hardly feasible to vary lens geometry in the process of operation.

Simultaneous compensation of third- and fifth-order spherical aberration can be achieved by a new lens with aberrations that are electrically adjustable in magnitude and sign.[25] Electrostatic lenses of this type are formed by four inner electrodes arranged symmetrically with respect to mutually perpendicular planes xoz and yoz, and four external electrodes that surround them and are symmetric to the same planes (Fig. 6). The electrode shape can be arbitrary, but the symmetry conditions mentioned should be maintained.

Systems of such lenses can operate independently as focusing systems, and, moreover, can correct geometrical aberrations up to the fifth order inclusive of other electron-optical systems.

In conclusion we should note that, while technically difficult, quadrupole–octupole corrections make it possible to obtain a perceptible gain in microprobe devices. For charged-particle spectrometers, CRT's, and other electron-optical devices, the question merits further study.

Mechanism for plasma loss from a magnetic trap

V. I. Volosov

Institute of Nuclear Physics, Siberian Branch,
Academy of Sciences of the USSR, Novosibirsk

(Submitted March 18, 1974)
Zh. Tekh. Fiz., 44, 2280-2285 (November 1974)

The interaction between plasma particles in a magnetic well with helical magnetic field lines (for example, in a stellarator) and the electric field due to a low-frequency (drift) instability is considered. It is shown that even when the amplitude of the electrostatic oscillations is small, $\varphi < kT_e/e$, the radial displacement of the particles (ions and trapped electrons) can be larger than the displacement computed from the neoclassical theory. When $\varphi \approx kT_e/e$ the radial displacement of the particles is equal to the plasma dimension. The loss rate is determined by the time $\tau_p \approx \gamma^{-1}$. For the collisionless drift mode it follows that $\tau_p \approx k\tau_{\text{Bohm}}$, where τ_{Bohm} is the Bohm time. For most stellarator experiments k ~ 1-10; this quantity depends on both the magnetic parameters (average shear $\bar{\theta}$ and ε) and the plasma parameters (T_i/T_e and m_i/m_e). The present estimates are compared with experiment.

1. It is well known that in the classical approximation plasma loss from a closed magnetic well depends significantly on the presence of trapped particles in the plasma, i.e., particles whose longitudinal motion is localized in bounded regions of the magnetic field. The radial displacement of these particles is much larger than the Larmor radius and plasma loss from the traps across the magnetic field is largely due to these particles (so-called neoclassical diffusion[1,2]).

However, the presence of trapped particles can also have a considerable influence on plasma loss in the presence of low-frequency instabilities if the frequency ω is smaller than the characteristic frequency of trapped electrons in the local well Ω_e and if the ion thermal velocity v_{Ti} is smaller than the longitudinal phase velocity ω/k_z. These conditions are usually satisfied by drift oscillations – the most widely encountered low-frequency instabilities.[3,4]

2. Consider the radial displacement (drift) of individual plasma particles in the field of the drift wave Δr_j. Since the longitudinal phase velocity of the wave ω/k_z satisfies the condition

$$v_{Ti} \ll \frac{\omega}{k_z \ll v_{Te}}, \tag{1}$$

the ion longitudinal velocity can be neglected in estimating Δr_i (here, Δr_i is the ion radial drift and Δr_e is the same for the electrons). Assuming that the wavelength in the radial direction (or the correlation length of the oscillations l in this direction for $l < k_r^{-1}$) is larger than or of the order of Δr_i (this assumption is valid, for example, in stellarator experiments; see refs. 5 and 6), for monochromatic oscillations with $\omega = \omega_e \equiv cT_e k_{ye}/eHa_n$ we have

$$\Delta r_i = \int_0^{\pi/\omega} v_{\text{dr}}\, dt = \alpha a_n; \quad v_{\text{dr}} = c\frac{E_\varphi(t)}{H_z}, \tag{2}$$

where a_n is the characteristic plasma inhomogeneity scale length – $(\partial \ln n/\partial r)^{-1}$; $\alpha = e\varphi/T_e$, where φ is the potential associated with the wave.

For a spectrum that can be represented as a sum of Fourier components, the displacement $\Delta r_i(t)$ is

$$\Delta r_i(t) = a_n \sum_q \alpha_q \left(\frac{k_{yq}}{k_{ye}}\right)\left(\frac{\omega_e}{\omega_q}\right) \int_0^t \sin(\omega_q t + \psi_q)\, d\omega_q t.$$

The maximum value of Δr_i in this case (for appropriate values of ψ_q) is

$$\Delta r_i = a_n \sum_q \alpha_q \left(\frac{k_{yq}}{k_{ye}}\right)\left(\frac{\omega_e}{\omega_q}\right), \tag{3}$$

where q is the harmonic number; $\alpha_q = e\varphi_q/T_e$; φ_q is the amplitude of the q-th harmonic. If the lowest oscillation frequency ω_1 is much smaller than ω_e (and $k_{y1} \approx k_{ye}$) the particle displacement in the field of such a wave is larger than the transverse plasma dimensions (i.e., $\Delta r_i > a_n$) even when $e\varphi_1/T_e \ll 1$ (this is equivalent to $\Delta n_1/n \ll 1$, where n is the plasma density and Δn_1 is the fluctuation).[1)]

Since $v_{Te} \gg \omega/k_z$ a similar estimate for untrapped electrons gives

$$\Delta r_e \simeq \alpha a_n \left(\frac{\omega}{k_z v_{Te}}\right) \ll a_n. \tag{4}$$

Several properties of the motion of the trapped electrons are taken into account in calculating Δr_e. Let the longitudinal drift wavelength k_z^{-1} be larger than the longitudinal dimension of localization of the trapped electrons z_e, and thus $\Omega_e \gg \omega_e$; let k_y^{-1} be larger than electron displacement in the y direction in one oscillation period, and let $k_r^{-1} \geq \Delta r_e$ or $l \geq \Delta r_e$ for $l < k_r^{-1}$ (these assumptions have also been confirmed experimentally; see refs. 5-7). The calculation of Δr_e is carried out for the time period ω^{-1} so that the phase velocity of the wave ω/k_z should not be compared with the instantaneous velocity $v_{\parallel e}$, but with the average value of $v_{\parallel e}$ for time $\sim \omega^{-1}$ (it is denoted by $\bar{v}^{\omega}_{\parallel e}$. The distribution function $f(\bar{v}^{\omega}_{\parallel e})$ is given in Fig. 1. For the trapped electrons the average value of $\bar{v}^{\omega}_{\parallel e}$ is the same order of magnitude as $z_e(\omega + \nu_e)$, where ν_e is the effective collision frequency (below $\nu_e \leq \omega$). With these assumptions Δr_e for the trapped electrons is determined by (2).

The fraction of trapped electrons is $\sqrt{\varepsilon_1}$ ($\varepsilon_1 \equiv \Delta H/H$ is the ratio of the periodic magnetic field to the constant field along the line of force and usually ranges from 0.1 to 0.5, i.e., it is fairly large). Note also that the profile of the magnetic surfaces in magnetic wells like the stellarator type is usually not the same as the linear profile. Therefore, the azimuthal electric field (and thus the particle drift velocity) is nonzero in the neighborhood of the separatrix; thus, the plasma particles can be lost to the

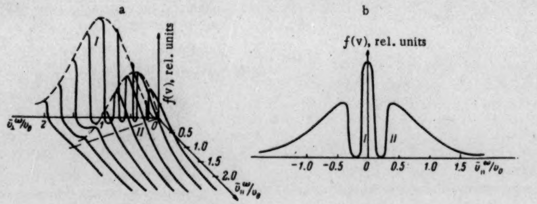

Fig. 1. Shape of the functions $f(\bar{v}_{\parallel e}^{\omega}, v_{\perp} = \text{const})$ (a) and $f(\bar{v}_{\parallel e}^{\omega}, \bar{v}_{\perp e}^{\omega})$ (b) at the point where the magnetic field is a minimum along the line of force. I) Region of trapped electrons; II) of untrapped electrons.

chamber wall due to radial drift.

For a high oscillation amplitude the fraction of electrons trapped by the electric field of the wave increases. However, the radial displacement of these particles in the wave field is small. The average value of Δr_e in one period of particle oscillation in the wave is zero; when $\alpha \approx 1$ the frequency is much larger than ω_e. In this case an estimate of the maximum Δr_e gives a value close to (4):

$$\Delta r_e \simeq 2\sqrt{\alpha}\, a_n \left(\frac{\omega}{k_z v_{Te}}\right)\left(\frac{z_0}{\lambda_z}\right), \tag{5}$$

where z_0/λ_z is the ratio of the particle localization dimension in the wave to the wavelength ($z_0/\lambda_z < 1$).

Thus, the maximum value of Δr_e is associated with electrons trapped in the troughs of the external magnetic field [see (2), (4), and (5)].

3. The expressions obtained above are now compared to the radial displacement of trapped electrons in closed magnetic wells given by neoclassical diffusion theory. When $\varepsilon_t \gg \varepsilon_h$ the maximum deviation of the trapped particles[8,9] is

$$\Delta r \simeq \left(\frac{\rho_{wj}}{\iota}\right)\left(\frac{R}{r_0}\right)^{1/2}, \tag{6}$$

where ι is the rotational transform.

In the opposite limit, $\varepsilon_t/\varepsilon_h \ll 1$, the radial deviation is determined by the precession of trapped particles in a banana orbit in the bounded region of the line of force:[1]

$$\sqrt{\frac{\varepsilon_t}{\varepsilon_h}}\, r_0 \geqslant \Delta r \geqslant \frac{2\varepsilon_t}{3\varepsilon_h} r_0. \tag{7}$$

Here, r_0 is the average radius of the magnetic surface. The majority of trapped particles suffer displacements close to the minimum value.

It follows from the estimates above that the radial displacement in the drift-wave field can be larger than or of the order of Δr in the neoclassical theory. Therefore, in calculating particle lifetimes in a plasma both of these processes must be taken into account. Obviously, the first process predominates when $\alpha \gg (\rho_{wj}/\iota a_n)(R/r_0)^{1/2}$ for $\varepsilon_t \gg \varepsilon_h$ or $\alpha \gg \varepsilon_t/\varepsilon_h$ for $\varepsilon_t \ll \varepsilon_h$.

4. We now estimate the plasma lifetime time when Δr is comparable to the transverse plasma dimensions (i.e., $\alpha \simeq 1$ for $\omega \simeq \omega_e$).

The growth rate of the radial motion is determined by the growth rate γ of the corresponding low-frequency instability. If the radial oscillation extends over the entire plasma the number of particles ΔN lost to the wall in one period is

$$\Delta N \simeq N \frac{\gamma}{\omega}, \tag{8}$$

which gives the decay time

$$\tau_p \simeq \gamma^{-1}. \tag{9}$$

Here, γ is the growth rate averaged over the volume. If only some of the particles (for example only the trapped electrons) participate in the radial oscillations and the fraction of trapped electrons is $\sqrt{\varepsilon_1}$ then

$$\tau_p \simeq (\gamma \sqrt{\varepsilon_1})^{-1}. \tag{9'}$$

The loss of plasma from the magnetic well in the case considered above is due to the flow of particles to the chamber wall, an anomalous "pumpout" effect.

In the case considered above the plasma decay time τ_p due to the instability is much smaller than the classical decay time of both the electron τ_e and ion τ_i components. When $\tau_e < \tau_p < \tau_i$ or when $\tau_i < \tau_p < \tau_e$ the nature of the plasma loss is somewhat different. In the first case ($\tau_e < \tau_p$) the plasma confinement time is determined by the ion confinement time, i.e., $\tau_p \simeq \gamma^{-1}$. If τ_e is determined by the loss of trapped particles, the plasma flow is in the direction of the separatrix angles. When $\tau_i < \tau_p$, the plasma decay time is determined by the trapped-electron confinement, i.e., $\tau_p \simeq \gamma^{-1}\varepsilon_1^{-1/2}$.

A somewhat more general approach to the problem is also possible. We can assume that the nonlinear mechanism that saturates the growth of the amplitude of low-frequency oscillations is the loss to the wall of a certain number of plasma particles due to a high amplitude of the radial oscillations $\tilde{n}$ ($\tilde{n}$ is the particle density when the amplitude of the radial oscillations becomes larger than some thereshold value Δr_0).

Due to the positive growth rate, the value of $\tilde{n}$ (and thus the amplitude of the electrostatic oscillations) increases with time; on the other hand the loss of plasma component to the wall reduces the trapped fraction and thus reduces the amplitude of the oscillations. Balancing these two processes we find

$$\frac{\partial n}{\partial t} = \delta n \gamma - \frac{n}{\tau_p} = 0 \qquad (10)$$

($\delta \leq 1$ is a factor that depends on the geometry and the parameters), from which (9) or (9') follows. This estimate is also valid when the condition $\alpha \simeq 1$ (or $\Delta r \simeq a$) is not satisfied.

5. As an example, we consider the particular case of the collisionless drift instability. We assume that $T_e > T_i$. This condition holds in the majority of experiments with closed traps. If the conditions $v_{Ti} \ll \omega/k_z \ll v_{Te}$, $\nu_e < k_z v_{Te}$, $s \equiv k_\perp^2 \rho_i^2/2 < 1$ are satisfied, the dispersion relation[10] is

$$\frac{k_\perp^2 T_e}{m_i \Omega_{0i}^2} + 1 + \frac{\omega_*}{\omega} - \left(\frac{k_z c_s}{\omega}\right)^2 + \frac{i\sqrt{\pi}}{k_z v_{Te}}(\omega - \omega_*) = 0. \qquad (11)$$

When $\omega/k_z \gg c_s$ or $\rho_i^* k_\perp / a k_z \gg 1$ [$\rho_i^* = \rho_e (m_i/m_e)^{1/2}$], the term $(k_z c_s/\omega)^2$ can be dropped. The solution of (11) for $\mathrm{Re}\,\omega \gg |\mathrm{Im}\,\omega|$ is

$$\mathrm{Re}\,\omega \simeq \frac{\omega_*}{1+b}; \quad \gamma \equiv \mathrm{Im}\,\omega = \sqrt{\pi}\frac{(\mathrm{Re}\,\omega)^2}{k_z v_{Te}}\frac{b}{1+b}, \qquad (12)$$

where $b = sT_e/T_i = k_\perp^2 \rho_i^{*2}/2$. When $a_n \gg \rho_i$ waves with $b \simeq 1.0$ have the maximum growth rate; an increasing ion collision frequency reduces the growth rate[11,12] and the maximum of $\gamma(k_\perp; \rho_i^*)$ is shifted towards longer wavelengths. In the opposite limit $a_n \ll \rho_i$ the maximum growth rate holds for waves with $k_\perp \simeq a^{-1}$. The longitudinal wavelength is determined by the relation

$$k_z = k_{z0} + k_y \bar{\theta}' x_1$$

or, for $k_{z0} \ll k_z$,

$$k_z \simeq k_y \bar{\theta}' x_1,$$

where $\bar{\theta}'$ is the average value of $\partial\theta/\partial r \simeq \theta(r)/r$ in the region of developed oscillations; θ is the shear (here $\theta = r^2 \partial[H_\varphi / r^2 H_z]/\partial r$). Using (9) and (12) and assuming that $x_1 \simeq r \simeq a$ we find the decay time

$$\tau_p \simeq \left(\frac{eH}{cT}\right)^2 \frac{a_n^2 \bar{\theta} v_{Te}}{k_y} \frac{(1+b)^2}{\sqrt{\pi}\, b}. \qquad (13)$$

We assume that the characteristic scale length and the radius of the plasma are related by $a_n = a/2.4$. For the case $\rho_i^* \ll a$ (i.e., $b \simeq 1.0$, $k_\perp \simeq \rho_i^{*-1}$) we find from (13)

$$\tau_p = A\bar{\theta}\left(\frac{m_i}{m_e}\right)^{1/2} \tau_{\mathrm{Bohm}}, \qquad (14)$$

where $\tau_{\mathrm{Bohm}} = a_n^2 (cT/16eH)^{-1}$ is the Bohm time; $\bar{\theta}$ is the mean shear; A is a constant, $A \simeq 1$ ($A \simeq 0.4/\sqrt{\varepsilon_1}$, where $\sqrt{\varepsilon_1}$ is the fraction of trapped electrons). In the opposite limit $\rho_i^* \geq a$ (i.e., $k_\varphi \simeq Ma$, where M is the mode number):

$$\tau_p \simeq A\bar{\theta}\left(\frac{m_i}{m_e}\right)^{1/2} \tau_{\mathrm{Bohm}} \left(\frac{a}{\rho_i^*}\right) \frac{(1+b)^3}{3.8M\sqrt{\pi}\, b}. \qquad (15)$$

One can obtain estimates for τ_p similar to those given above for an arbitrary ratio of T_e to T_i (assuming that $\rho_i^* \ll a$). For the cases $T_e = T_i$ and $T_e < T_i$ the maximum growth rate holds for $s \simeq 1.0$; the value of τ_p is determined by (14), where $A \simeq 0.5/\sqrt{\varepsilon_1}$ for $T_e = T_i$ and $A \simeq 0.3(T_e/T_i)^{1/2}/\sqrt{\varepsilon_1}$ for $T_e < T_i$. Obviously, these estimates are only valid when the drift wave is unstable [for example, see ref. 13, Eq. (57), and ref. 14].

Comparison of the above expressions with experiment (primarily involving stellarators) requires that the value of $\bar{\theta}$ be known. In most of the published papers, however, the maximum shear is given, i.e., the value of $\bar{\theta}$ on the last complete magnetic surface. In the general case a unique correspondence does not hold between $\theta_{\max}$ and $\bar{\theta}$. The value of $\theta_{\max}$ depends primarily on the quality of the helical windings, the amplitude of the different magnetic field disturbances, and the stellarator geometry, while $\bar{\theta}$ is determined only by the mean radius and the amplitude of the fundamental helical magnetic field harmonic, being independent of the above parameters of the magnetic system. We can obtain an estimate by assuming that $\bar{\theta}$ is the same order of magnitude as the shear in the region of the maximum drift oscillations $\bar{\theta} = \theta(\bar{r})$ (we assume that $\bar{r} = 0.7 - 0.8\, r_{\mathrm{sep}}$, where r_{sep} is the radius of the separatrix). In the center regions (i.e., $r/r_{\mathrm{sep}} < 0.9$–0.85) the shear is determined only by the fundamental magnetic field harmonic: $\theta(r) = 0.33\,(r/r_{\mathrm{sep}})^3 F(\beta_{\mathrm{sep}})$ for $n = 3$ and $\theta(r) = 0.26\,(r/r_{\mathrm{sep}})^3 F(\beta_{\mathrm{sep}})$ for $n = 2$, where $0.5 < F(\beta_{\mathrm{sep}}) < 1$ for $8° < \beta_{\mathrm{sep}} < 45°$ ($n = 3$) and $25° < \beta_{\mathrm{sep}} < 60°$ ($n = 2$); β_{sep} is the angle of incidence of the edge of the separatrix to the axis of the torus.[15] For most modern stellarators with an optimum separatrix dimension, $F \simeq 0.5$-1.0 and thus $\bar{\theta} \simeq 0.05$-0.1. Taking this estimate into account we find from (14)

$$\tau_p = A_1\left(\frac{m_i}{m_{\mathrm{pr}}}\right)^{1/2} \tau_{\mathrm{Bohm}}, \qquad (16)$$

where A_1 is a constant ($A_1 = 2A$ to $4A$), m_i is the plasma ion mass, and m_{pr} is the proton mass.

The dependence of plasma lifetime on temperature and magnetic field given above (proportional to the Bohm dependence) has been observed in many experiments both with stellarators[16–19] and with other types of closed systems.[20,21] Within the spread of the experimental points and the accuracy of the estimate of A_1, the absolute values of τ_p obtained from experiment and calculated from (16) also coincide (in many cases). In a number of cases the dependence of τ_p on the shear (or the rotational transform) and the ion mass agrees with (14) and (16) [see refs. 16 and 22].

However, to establish a unique relation between the above mechanism for radial displacement of a plasma and experiment requires detailed information on the radial plasma losses produced by the fluctuation fields and their spatial distribution. At the present time, such measurements have been performed only for a cold plasma. As a rule, they indicate a good agreement with the loss mechanism considered above.[5–7,23]

Thus, in the presence of low-frequency oscillations the mechanism considered above can determine the rate of loss of plasma and not only for closed systems, but for any system with trapped electrons.

In conclusion, the author thanks S. S. Moiseev, V. N. Bocharov, and Yu. N. Yudin.

Measurement of ion density by the dispersion relation for an ion-beam plasma

M. D. Gabovich, L. P. Katsubo, and I. A. Soloshenko

Physics Institute, Academy of Sciences of the USSR, Kiev

(Submitted January 30, 1974)
Zh. Tekh. Fiz., 44, 2286-2289 (November 1974)

An experimental study has been made of the dispersion properties of transverse ion modes excited by a fast ion beam which also ionizes the background gas. In accordance with theory, for $k^2d_e^2 \ll 1$ (d_e is the electron Debye radius) the frequency $\omega_k = kc_s$, where c_s is the ion acoustic velocity; in the opposite limit ($k^2d_e^2 \gg 1$), $\omega_k \approx \omega_{pi}$, where ω_{pi} is the ion plasma frequency. The ion plasma modes have the growth rate ($\omega \approx \omega pi$). This result, and the fact that the oscillations are localized, ($k^2d_e^2 \gg 1$), means that the radial density profiles of the slow ions can be measured.

In the transport of intense ion beams the space charge is usually neutralized by charges produced in the ionization of the residual gas in the beam. The degree of neutralization of the beam, the phase volume, and the specific power are then determined by the properties of the plasma which is formed. It is therefore important to know the parameters of this plasma. The use of the probe method is complicated in an ion-beam plasma because of the presence of the beam itself and because of the low density. The low density also hinders the use of the resonator method. In this note we consider the possibility of measuring the ion density using waves excited in the system.

The ion dispersion equation in a nonisothermal plasma ($T_i \ll T_e$) penetrated by a monoenergetic beam of ions with velocity v_0 is[1,4]

$$1+\frac{1}{k^2d_e^2}-\frac{\omega_{pi}^2}{\omega^2}+\frac{\omega_{bi}^2}{(\omega-k_zv_0)^2}=0, \tag{1}$$

where T_e and T_i are the electron and ion temperatures respectively in the plasma, ω_{pi} and ω_{bi} are the ion plasma frequencies in the plasma and the beam, d_e is the electron Debye radius. It follows from (1) that the maximum growth rate $\gamma = (\sqrt{3}/2^{4/3})\alpha^{1/3}\omega_k(\alpha = \omega_{bi}^2/\omega_{pi}^2)$ obtains for

$$\omega_k^2 \approx \frac{\omega_{pi}^2}{1+\frac{1}{k^2d_e^2}} \approx k_z^2v_0^2. \tag{2}$$

When $k^2d_e^2 \ll 1$ the frequency $\omega_k = kc_s$, where $c_s = (T_e/m_i)^{1/2}$ is the ion acoustic velocity; in the opposite limit ($k^2d_e^2 \gg 1$), $\omega_k \approx \omega_{pi}$. The growth rate peaks when $\omega_k \approx \omega_{pi}$. This result, and the fact that the ion plasma oscillations are localized ($k^2d_e^2 \gg 1$), mean that it is possible to determine the local density of the plasma ions. It must be noted, however, that for a high value of T_i the maximum amplitude can shift towards lower frequencies as a result of the severe attenuation near ω_{pi}. For this reason it is necessary to make an experimental check that the maximum amplitude coincides with the ion plasma frequency.

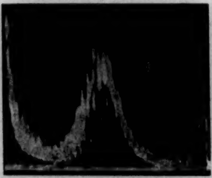

Fig. 1. Spectrum. $\dot{H}_2^+$ ion beam with energy eU_0 = 30 keV and current I_i = 15 mA passes through argon at a pressure of p = $5 \cdot 10^{-5}$ mm Hg. The calibration marks correspond to 0 and 750 kHz.

The experiments are carried out on the apparatus which has been described in detail in refs. 2-4. An H_2 ion beam with current I_i = 40 mA, energy eU_0 = 40 keV, and density $n_b \sim 10^7$ cm^{-3} passes through a chamber of length L = 500 cm to a grounded target. The pressure of the neutral gas is varied over the range p = $5 \cdot 10^{-6}$ - $1 \cdot 10^{-3}$ mm Hg. The waves excited in the system are recorded by means of insulated probes which can be moved in the radial direction.[4] The radial distribution of the static potential is measured by means of hot probes.

Ion oscillations are only excited when the pressure reaches a certain value[4] which depends on the type of gas. Figure 1 shows a typical spectrum. Measurements of the wave number as a function of frequency show that the maximum amplitude coincides with the ion plasma frequency. For the purpose of these measurements the beam is modulated by means of an external generator with a signal which is fed to a modulating probe at the entrance to the chamber. Since $v_0 \gg c_s$ and $k \gg k_z$, the wave number can be calculated by measuring the variation of the phase of the oscillations with distance along a radius by means of a recording probe.

Figure 2a shows the dispersion relationships obtained at various pressures. The dashed straight lines correspond to the oscillation frequency at which the amplitude is a maximum. In accordance with (2) the frequency increases linearly with k at long wavelengths; the phase velocity under these conditions $\omega/k \approx 3.2 \cdot 10^5$ cm/sec, in agreement with the value for the ion acoustic velocity $c_s \approx 2.5 \cdot 10^5$ cm/sec calculated for T_e = 2 eV. (The value of T_e for air has been measured experimentally.[3]

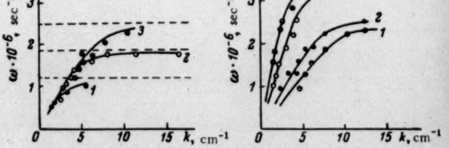

Fig. 2. Dispersion relationships for ion oscillations. a) Air, p(mm Hg): 1) $3 \cdot 10^{-5}$; 2) $5 \cdot 10^{-5}$; 3) $8 \cdot 10^{-5}$. b: 1) Krypton, p = $4 \cdot 10^{-5}$; 2) air, p = $6 \cdot 10^{-5}$; 3) helium, p = $2 \cdot 10^{-4}$; 4) hydrogen, p = $2 \cdot 10^{-4}$. Ion beam current I_i = 15 mA, energy eU_0 = 25 keV.

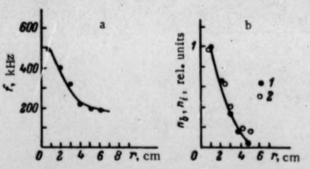

Fig. 3. a) Dependence of the frequency of the excited oscillations on the radius; b) radial distribution of beam current density (1) and density of slow ions (2). A beam of H_2^+ ions with I_i = 15 mA, energy eU_0 = 25 keV passes through air at a pressure of $p = 6 \cdot 10^{-5}$ mm Hg.

The measurements carried out on other gases (Fig. 2b) are also in agreement with theory. The phase velocities at long wavelengths for hydrogen, helium, and krypton are $9.3 \cdot 10^5$, $6.3 \cdot 10^5$, and $2.2 \cdot 10^5$ cm/sec respectively and these agree in order of magnitude with the corresponding ion acoustic velocities for T_e = 2 eV.

It can be seen from Fig. 2a that as the modulation frequency approaches the frequency corresponding to the maximum amplitude the wavelength tends to zero. We conclude that the maximum amplitude is observed at a frequency equal to the ion plasma frequency; therefore measurements of these frequencies can be used to calculate the density of slow ions.

Figure 3a shows the variation of the frequency of the spontaneously excited oscillations with maximum amplitude with distance along a radius; Fig. 3b gives the density profile of slow ions obtained from the data in Fig. 3a. For comparison the radial density profile of the beam particles is also given.

Figure 4 shows how the ratio of the slow-ion density n_i to the beam density n_b varies with pressure at the center of the beam for various gases (the beam parameters remaining constant).

The experimentally measured values of n_i are in qualitative agreement with the values calculated from a solution of the slow-ion continuity equation

$$n_i(r) = \int\limits_0^r \frac{n_b(r)\, v_0 n_a \sigma_i 2\pi x\, dx}{2\pi r \left(\frac{2e}{m_i}\right)^{1/2} \sqrt{\varphi(x) - \varphi(r)}}, \tag{3}$$

where n_a is the density of gas molecules and σ_i is the cross section for the formation of slow ions. If we assume that $n_b(z) = n_0(1 - r^2/r_0^2)$, and $\varphi = \varphi_0(1 - r^2/r_0^2)$, we can integrate (3) to get

$$\frac{n_i(r)}{n_b(r)} = \frac{n_a \sigma_i r_0 v_0}{\sqrt{2 \frac{e}{m_i} \Delta\varphi}} \frac{1 - \frac{2}{3}\frac{r^2}{r_0^2}}{1 - \frac{r^2}{r_0^2}}, \tag{4}$$

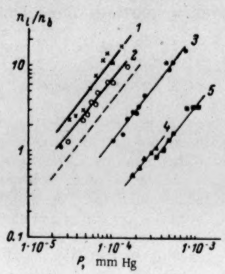

Fig. 4. Variation of the slow ion density with pressure. An H_2^+ ion beam with I_i = 15 mA and energy eU_0 = 25 keV passes through argon (1), air (2), neon (3), hydrogen (4), and helium (5).

where $\Delta\varphi$ is the radial drop in potential in the beam. The variation of $\Delta\varphi$ with the pressure of air has been measured experimentally. Substituting into (4) the values r_0 = 3 cm, $\sigma_i = 2 \cdot 10^{-15}$ cm², and the experimental values of $\Delta\varphi$, we can calculate the variation of n_i/n_b with pressure at r = 0. The results are shown in Fig. 4 by the dashed line. The calculated and experimental lines have the same slope and give nearly the same values of n_i/n_b. (The fact that n_i does not increase in proportion to the pressure is due to the reduction in $\Delta\varphi$ and the reduction in the velocity of the slow ions away from the beam region as the pressure increases.) The fact that the slow ion density at a given pressure is greater for gases with a high production cross section is also in agreement with the calculations. For argon and air, n_i/n_b exceeds unity when $p > 2 \cdot 10^{-5}$ mm Hg; for hydrogen and helium, n_i becomes significant only when $p > 1 \cdot 10^{-4}$ mm Hg.

Thus we have obtained experimental dispersion relationships for ion oscillations excited in a plasma by a fast ion beam. It has been shown that under the given experimental conditions the maximum amplitude corresponds to the ion plasma frequency. This means the radial distribution of slow ions in the ion-beam plasma can be measured.

We note in conclusion that the method we have described can be used for the diagnostics of an independently created nonisothermal plasma in a magnetic field.[5]

Axially symmetric neutralized electron beam

G. N. Vyalov, V. N. Evteev, Yu. M. Zolotaikin, and K. N. Ul'yanov

(Submitted October 12, 1973)
Zh. Tekh. Fiz., 44, 2290-2295 (November 1974)

The laminar approximation is frequently used to estimate the shape of a neutralized cold electron beam. It is based on the assumption that the electron trajectories do not intersect. For example, the laminar approximation has been used[1] to calculate the shape of an axially symmetric beam with parallel initial velocities and uniform initial density along the transverse coordinate. The assumption of a constant longitudinal velocity for the electrons in the beam has been used in addition to the assumption about the laminar state.[1] The calculations lead to a longitudinally periodic beam structure, in which the transverse profile of the beam is described by the error function.

The problem dealt with in this paper is the evaluation of the limits of applicability of the laminar approximation and the calculation of the shape of a neutralized cold beam.

I. LAMINAR MODEL

It is useful to analyze the laminar approximation without any assumption as to the constancy of the longitudinal velocity. Since the electron trajectories do not intersect, each trajectory with an initial transverse coordinate r_0 defines a region within which a constant electron current $I(r_0)$ flows. This trajectory is determined by the equations of motion (for the axially symmetric case)

$$m\ddot{r} = -\frac{e}{c}\dot{z}H_0, \qquad (1)$$

$$m\ddot{z} = \frac{e}{c}\dot{r}H_0, \qquad (2)$$

$H_0 = 2I(r_0)/cr$ along the trajectory,

$$I(r_0) = I\frac{r_0^2}{a^2} \qquad (3)$$

(the Gaussian system of units is used and the dots indicate differentiation with respect to time). Here, I is the total current and a is the initial radius of the beam. We have

$$\ddot{\eta} = \frac{\alpha\eta_0^2\dot{\xi}}{\eta}, \qquad (1')$$

$$\ddot{\xi} = \frac{\alpha\eta_0^2\dot{\eta}}{\eta}. \qquad (2')$$

Here, we have used the dimensionless variables

$$\eta = \frac{r}{a};\quad \xi = \frac{z}{a};\quad \tau = \frac{vt}{a}, \qquad (4)$$

$$\alpha = \frac{2I}{\beta I_0\gamma};\quad I_0 = \frac{m_0c^3}{|e|} \approx 17\ \text{kA}. \qquad (5)$$

The dots in Eqs. (1') and (2') indicate differentiation with respect to τ. The first integral of Eq. (2') yields

$$\dot{\xi} = \alpha\eta_0^2\ln\frac{\eta}{\eta_0} + 1. \qquad (6)$$

Using the condition for the conservation of total velocity,

$$\dot{\xi}^2 + \dot{\eta}^2 = 1 \qquad (7)$$

together with Eq. (6), we obtain

$$\dot{\eta} = -\sqrt{-\alpha\eta_0^2\ln\frac{\eta}{\eta_0}\left(2 + \alpha\eta_0^2\ln\frac{\eta}{\eta_0}\right)}. \qquad (8)$$

The shape of the trajectory is determined by

$$\frac{d\xi}{d\eta} = -\frac{1 + \alpha\eta_0^2\ln\frac{\eta}{\eta_0}}{\sqrt{-\alpha\eta_0^2\ln\frac{\eta}{\eta_0}\left(2 + \alpha\eta_0^2\ln\frac{\eta_0}{\eta}\right)}}$$

or

$$\xi = \int_{\eta}^{\eta_0}\frac{\left(1 + \alpha\eta_0^2\ln\frac{\eta}{\eta_0}\right)d\eta}{\sqrt{-\alpha\eta_0^2\ln\frac{\eta}{\eta_0}\left(2 + \alpha\eta_0^2\ln\frac{\eta}{\eta_0}\right)}}. \qquad (9)$$

The condition

$$\left|\alpha\eta_0^2\ln\frac{\eta}{\eta_0}\right| \ll 1 \qquad (10)$$

corresponds to the assumption of constant longitudinal velocity. We then have

$$\xi = \sqrt{\frac{2}{\alpha}}\int_0^{\sqrt{\ln(\eta/\eta_0)}} e^{-x^2}dx = \sqrt{\frac{\pi}{2\alpha}}\,\Phi\left(\sqrt{\ln\frac{\eta_0}{\eta}}\right), \qquad (11)$$

where $x^2 = \ln\eta/\eta_0$. Under the condition (10), there is a focus according to Eq. (11), i.e., all trajectories intersect at the point $\eta = 0$, $\xi = \sqrt{\pi/2\alpha}$.

Equation (9) indicates that such a focus does not exist under the approximation of a laminar state. Moreover, the longitudinal velocity vanishes and the electron velocity is reversed according to Eq. (6) when $\eta = \eta_0 e^{-1/\alpha\eta_0^2}$. According to Eq. (8), the trajectory does not reach the axis ($\eta = 0$). At the point $\eta = \eta_0 e^{-1/2\alpha\eta_0^2}$ the transverse velocity goes to zero and the electron begins to move away from the axis. The electron trajectory forms a sequence of loops, i.e., it crosses itself. In addition, different trajectories cross each other. This result contradicts the original assumption about the laminar nature of the electron flow, i.e., the absence of trajectory crossings.

There are at least two possibilities: 1) as a result of trajectory intersection the sign of the longitudinal velocity is unchanged and the trajectories intersect the beam axis; 2) the sign of the longitudinal velocity changes, the trajectories are reversed, and this model has no region of applicability. Assuming that there is a region of applicability for the model, we estimate its limits of applicability. Trajectories cross if (10) is violated. This condition breaks down primarily for the limiting trajectory for which η_0 is a maximum (equal to unity). The trajectory intersection condition can be written in the form

$$\frac{\partial\eta(\xi,\ \eta_0)}{\partial\eta_0}=0. \tag{12}$$

Differentiating both parts of Eq. (9) with respect to η_0 for $\eta_0 = 1$, we have

$$\frac{(1-\alpha x^2)}{\sqrt{2-\alpha x^2}}e^{-x^2}=2\alpha x\int_0^x\frac{3-\alpha x^2}{(2-\alpha x^2)^{3/2}}x^2e^{-x^2}dx. \tag{13}$$

Equation (13) determines the transverse coordinate of the limiting trajectory at which the first intersection occurs. For $\alpha \ll 1$, we have approximately

$$e^{-x_n^2}\approx 3\alpha x_n\int_0^{x_n}x^2e^{-x^2}dx \tag{13'}$$

or

$$\alpha=\frac{4}{3\sqrt{\pi}}\frac{e^{-x_n^2}}{x_n}=\frac{4}{3\sqrt{\pi}}\frac{\eta_n}{\sqrt{\ln\frac{1}{\eta_n}}}, \tag{14}$$

i.e., $\eta_n \ll 1$ when $\alpha \ll 1$.

Thus for small α there is a reasonably large region for which a laminar treatment holds ($\zeta_0 = \sqrt{\pi/2\alpha}$). When $\alpha \ll 1$ deviations from the laminar state begin near the focus.

II. NUMERICAL CALCULATION OF ELECTRON BEAM SHAPE

It is necessary to introduce trajectory crossing in order to determine the conditions for beam propagation and to calculate beam shape beyond the first focus. There is as yet no analytic solution of the problem with trajectory intersection. We have carried out a numerical solution of this problem which confirms the importance of including trajectory intersections near and beyond the focus.

In the general case with trajectory intersection, the electron trajectories are described by Eqs. (1)-(3), where one should understand the current $I(r_0)$ in Eq. (3) to be the quantity

$$I(r_0)=If(\eta_0,\ \xi)\eta_0^2. \tag{15}$$

The function

$$f(\eta_0,\ \xi)=2\int_0^1\Theta[\eta(\xi,\ \eta_0)-\eta(\xi,\ \eta_0')]\eta_0'd\eta_0' \tag{16}$$

takes account of the possibility of trajectory intersection,

$$\Theta(x)=\begin{cases}1 & \text{for } x>0,\\ 0 & \text{for } x<0.\end{cases}$$

This means that at each point ξ, η of a trajectory with an initial parameter value $\eta = \eta_0$, there the electron sees a magnetic field to which all trajectories located closer to the axis of the beam make a contribution, i.e., trajectories satisfying the condition $\eta(\xi, \eta'_0) < \eta(\xi, \eta_0)$. Using the conservation of total velocity, we can transform to the independent variable ξ; differentiation with respect to this variable is denoted by primes. In this case the trajectories are given by the infinite system of equations

$$\eta''(\eta_0,\ \xi)=-\alpha f(\eta_0,\ \xi)\frac{(1+\eta'^2)^{3/2}}{\eta(\eta_0,\ \xi)} \tag{17}$$

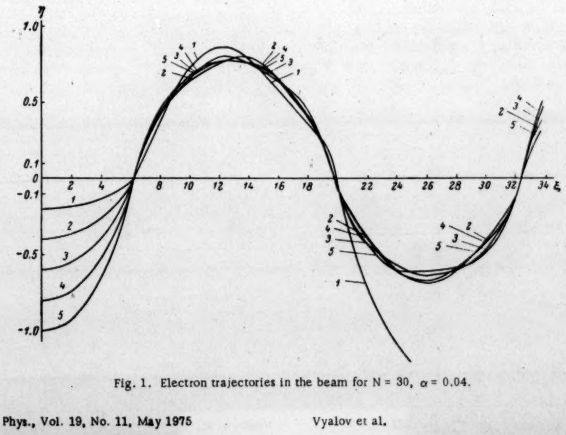

Fig. 1. Electron trajectories in the beam for N = 30, α = 0.04.

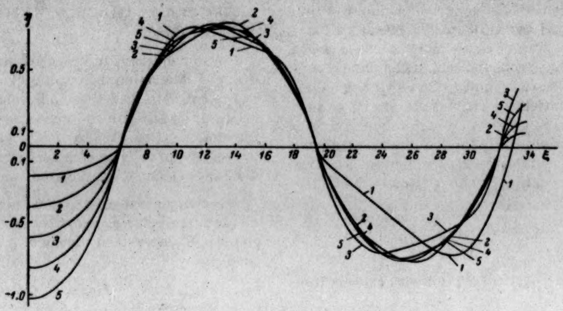

Fig. 2. Electron trajectories in the beam for N = 10, α = 0.04.

(η_0 varies continuously from 0 to 1). In a numerical solution the infinite system (17) is replaced by a system containing a finite number of equations. To accomplish this the cylindrical beam is divided into N concentric layers corresponding to division of the initial radius into N equal parts. Each layer is described by an equivalent trajectory with an initial parameter $\eta_{0i} = i/N$, i = 1, 2, ... , N. The initial system of N equations has the form

$$\left.\begin{aligned} \eta_i''(\xi) &= \frac{-\alpha f_i(\xi)\,(1+\eta_i'^2)^{3/2}}{\eta_i(\xi)}, \\ f_i(\xi) &= \sum_{j=1}^{N} \Theta(\eta_i-\eta_j)(\eta_{0j}^2-\eta_{0j-1}^2)\ (i=1,\ 2\ldots N) \end{aligned}\right\} \qquad (18)$$

and is integrated under the initial conditions $\eta_{0i} = i/N$ (i = 1, 2, ... , N). The numerical calculation of equivalent trajectories for α = 0.04 has been carried out on the Minsk-22 and BÉSM-6 computers. In addition, calculations for α = 0.5 and N = 20, 30, and 50 have been performed on the BÉSM-6 computer. However, calculations of the versions with N = 30 and 50 require a large amount of machine time and are not performed on the Minsk-22 computer. All these calculations give qualitatively identical results. The calculations for N = 10 and N = 20 are carried out over the range of ξ from 0 to 34 with all trajectories crossing the beam axis three times. The calculation for N = 50 is carried out to ξ = 6.6 to evaluate the effect of the number of equivalent trajectories (method of subdivision) on the accuracy of the calculation. In the region of laminar motion the corresponding trajectories calculated for different N agree within the accuracy of the calculations; in the region of trajectory intersection, the difference between corresponding trajectories (for example, the 24th in the case of N = 30 and the 40th in the case of N = 50) is insignificant. The maximum disagreement at the point ξ = 6.6 does not exceed 0.001. Thus a subdivision with N = 30 (Fig. 1) gives reasonably accurate results. The 6th, 12th, 18th, 24th, and 30th trajectories corresponding to N = 30 are sketched in Fig. 1. For comparison, Fig. 2 shows the corresponding trajectories for N = 10.

First, the results of the numerical calculation confirm the existence of an extended region of applicability for the laminar approximation up to the neighborhood of the first node.

Second, they confirm the importance of including trajectory intersections in the neighborhood of the first node and beyond it. A diagram of the trajectory intersections at the first node is shown in Fig. 3.

Third, the numerical calculation of the structure of the initially neutralized uniform beam reveals bunching of such a beam into a clearly expressed shell structure immediately beyond the first node (Figs. 1, 2). This struc-

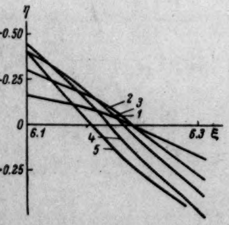

Fig. 3. Electron trajectories in the neighborhood of the first node for N = 30, α = 0.04.

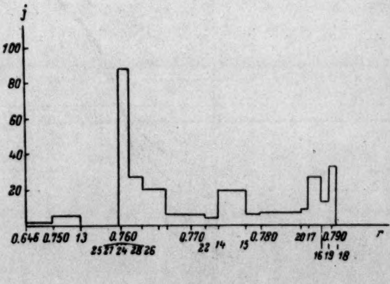

Fig. 4. Radial distribution of current density at the section ξ = 12 for N = 30, α = 0.04.

ture is maintained subsequently. The current density distributions in the two sections at $\xi = 12$ and $\xi = 26$ are shown in Figs. 4 and 5 and are of a semiquantitative nature. The structure of the shells has not been studied in detail.

Fourth, the beam has a longitudinally periodic spatial structure with the location of the nodes ("foci") being estimated sufficiently accurately by the laminar approximation.

Fifth, a reduction in the maximum transverse dimension of the beam is observed; the maximum dimension of the beam between the first and second nodes is about 0.8 times the initial dimension and about 0.7 times between the second and third nodes. The "escape" of individual trajectories, for example the trajectory numbered 1 in Fig. 1, does not change this conclusion since a comparatively small portion of the current is involved. In addition, it is impossible to consider that type of trajectory to have been established with sufficient accuracy. Its appearance is possibly associated with an error arising out of the finite number of subdivisions. For example, such an escape is not noted in the case N = 10. The question of the existence of "escape" trajectories has not been studied in detail.

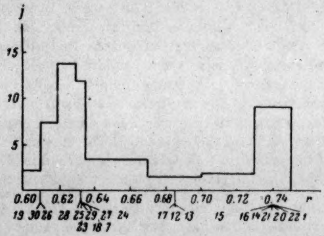

Fig. 5. Radial distribution of current density at the section $\xi = 26$ for N = 30, $\alpha = 0.04$.

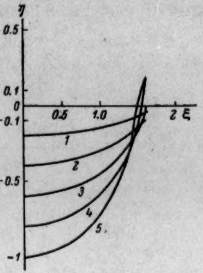

Fig. 6. Electron trajectories in the beam up to the first node for N = 30, $\alpha = 0.5$.

Results of the calculation for $\alpha = 0.5$ are shown in Fig. 6. It is clear that the first focus is located at $\xi = 1.5$ in accordance with the approximate theory.

Plasma synthesis by injection of an electron beam through an ion source

V. F. Virko, M. D. Gabovich, G. S. Kirichenko, and O. K. Nazarenko

Institute of Physics, Academy of Sciences of the Ukrainian SSR, Kiev

(Submitted October 2, 1973)
Zh. Tekh. Fiz., 44, 2296-2301 (November 1974)

A method is described for producing a plasma by injecting electrons through an ion source. Certain properties of the resulting plasma and its sensitivity to an external transverse magnetic field are studied.

INTRODUCTION

The production of neutral ion beams is an important and complicated physical and technical problem which has not yet been fully resolved. When the beam is to be used in a high vacuum the neutralization of the space charge, or of the space charge and the beam current, is usually achieved by means of a cold plasma.[3,4]

Without going into an analysis of the results which have been achieved so far, we wish to point out another method for neutralizing an ion beam; this involves the axial injection of electrons through the ion source. This system has been studied previously,[5,6] but no information has been reported on the properties of the neutralized ion beams.

In this paper[1] we describe a method for neutralizing an ion beam by means of electron injection through the ion source, and we report on the resulting plasma, in particular, on its sensitivity to a weak transverse magnetic field.

1. EXPERIMENTAL APPARATUS

The experimental apparatus (Fig. 1) consists of an ion source with a focusing system, an electron gun, and a vacuum chamber for studying the properties of the plasma. As a rule, a plasmatron ion source is used. The cathode of the source is moved in order to reduce the magnetic field at the axis of the system. The axisymmetric focusing system, which has a single lens, is used to extract, accelerate, and shape the ion beam. The electron gun, which consists of a planar hot cathode, a control electrode, an anode containing an aperture, and a magnetic lens, is used to shape a sharply focused electron beam and to guide it into the ion source along the axis of the system. The potential profile in the system and the elements of the high-voltage insulating and the pumping system are shown in Fig. 1. The electron beam passes through the ion source, the gap accelerating the ions (the gap retards electrons), and a single lens and moves into the region in which the ion beam propagates freely.

The ion–electron beam propagates in an evacuated cylindrical tube 10 cm in diameter and ~1 m long. Electrostatic probes are used to study the properties of the plasma. The ion-beam current and the spatial profile of the beam current density are determined by electrodes of a refractory material, whose temperature is controlled by thermocouples. The preliminary calibration of these power meters is carried out with the electron beam. The static distribution of the potential in the plasma with respect to the grounded tube is determined within a few hundredths of an electron volt by means of hot probes.

A homogeneous transverse magnetic field, H = 0-60 Oe, is produced in the evacuated tube by means of external conductors in which the current flows in the direction of the neutralized ion beam.

This apparatus is suitable for measurements under the following conditions: beam currents of 2, 1, and 0.5 mA at an energy of $\mathcal{E}$ = 15-20 keV for hydrogen, helium, and argon ions, respectively; electron injection current of 0-10 mA; a pressure of $(1\text{-}2)\cdot 10^{-5}$ torr in the drift tube.

2. NEUTRALIZATION OF THE ION BEAM BY INJECTED ELECTRONS; PLASMA PRODUCTION

The ion beam, moving in high vacuum, expands under the influence of its own space charge. The parameter governing the degree of neutralization of the beam by charges

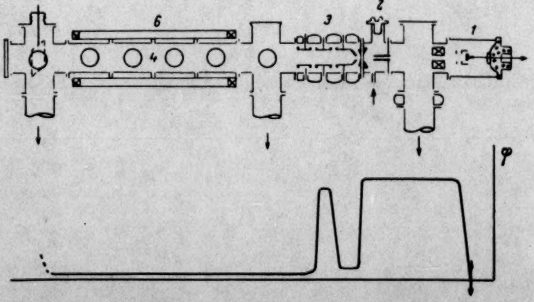

Fig. 1. The experimental apparatus. 1) Electron gun; 2) ion source; 3) electrostatic lens; 4) drift tube; 5) target; 6) conductors that produce the transverse magnetic field.

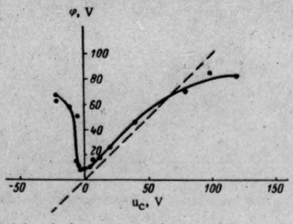

Fig. 2. Potential at the beam axis as a function of the potential of the electron-gun cathode.

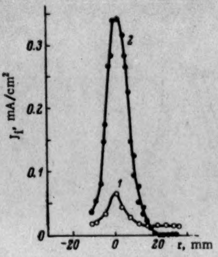

Fig. 4. Radial distributions of the current density of an ion beam which is not neutralized (1) and which is neutralized (2) by electrons. Ar$^+$, ε = 15 keV, $I_i \sim 0.5$ mA.

of the opposite sign is the potential associated with the net charge. The experiments show that the introduction of slow electrons into the ion beam by longitudinal injection through the ion source can reduce significantly the electric fields in the beam due to the ion space charge. The velocity of the injected electrons in this neutralization method is governed by the potential difference between the beam and the cathode of the electron gun, i.e., the average electron flow velocity is essentially a self-consistent parameter. Figure 2 illustrates the establishment of the self-consistent potential in the beam. Here, the ordinate shows the potential at the beam axis, while the abscissa shows the potential of the electron emitter with respect to the drift tube. In the absence of an ion beam electrons can enter the drift region only for negative values of u_c. When there is an ion beam the ion space charge makes it possible for electrons to move into the system even at a positive cathode potential. The ion space charge is neutralized at the level of the average beam potential $\varphi \gtrsim u_c$ (dashed line in Fig. 2). The average energy of the neutralizing electrons is then governed by the distance between the solid curve and the dashed line in Fig. 2. When $u_c < 0$ the neutralizing effect of the electrons falls off sharply with increasing electron energy, leading to the establishment of the relatively high potential of the unneutralized ion beam.

The neutralization of the positive space charge by slow electrons essentially eliminates the electric field along the path of the ions. Figure 3 shows the potential profiles along the axis of the system for unneutralized (1) and neutralized (2) ion beams. These measurements are carried out in the part of the drift tube immediately adjacent to the focusing system (curve 3 shows the measured potential profile of the single lens in the drift region in the absence of beams). The introduction of electrons into the ion beam essentially removes the electric field about the axis over the entire drift region – from the target, which bounds this region, to the focusing region. The resulting plasma consists of beam ions which are at a high energy and electrons whose energy is governed by the self-consistent residual potential. It should be noted that under typical experimental conditions the Debye shielding radius (0.1–0.2 cm) is much shorter than the transverse dimension of the plasma column (the effective diameter is ~1.5 cm).

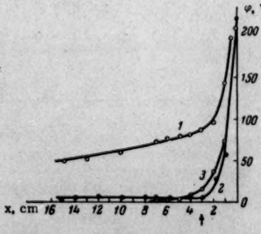

Fig. 3. Longitudinal potential profiles in the system. 1) Ion beam without neutralization, He$^+$, ε = 15 keV, $I_i \sim 1.5$ mA; 2) the same, with neutralization by electrons; 3) potential profile in the absence of ions and electrons. The arrow shows the edge of the last electrode of the focusing system.

The reduction in the positive potential in the beam due to the injection of electrons and the reduction in the associated radial electric field lead to a significant reduction of the spatial expansion of the ion beam. Figure 4 shows radial profiles of the ion-current density in the beam, obtained at a distance of 1 m from the source with (2) and without (1) the neutralizing electrons. The initial diameter and the electrical properties of the beam are the same in the two cases. We see that most of the beam current is distributed homogeneously in the entire cross section of the drift tube. The neutralized beam is concentrated in a narrow axial region.

The experiments show that in the case of longitudinal electron injection into the ion beam, where there is optimum neutralization of the space charge, there is also neutralization of the beam current in irradiation of an insulated target.

Accordingly, the introduction of electrons into the ion beam by longitudinal injection through the ion source can result in an effective neutralization of an ion beam moving in high vacuum. There is a reduction of the electric fields

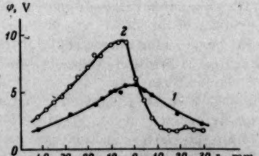

Fig. 5. Radial potential profiles in the beam in the absence (1) and presence (2) of a transverse magnetic field. He$^+$, ε = 16 keV, $I_i \sim 1$ mA.

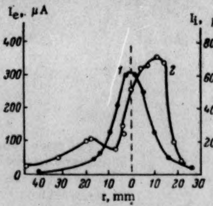

Fig. 6

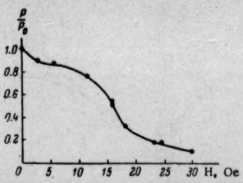

Fig. 7. Relative decrease in the beam power evolved at the target with increasing intensity of transverse magnetic field.

associated with the ion space charge and a corresponding decrease in the expansion of the ion beam in its motion. It is interesting to compare the self-consistent residual potential drop in the plasma produced in this manner with an estimate of this potential drop taking account of the thermal spread of the electron velocities.[2] The minimum potential drop in a beam with an ion current I_i, an ion velocity v_i, and the neutralizing-electron temperature is calculated to be

$$\Delta\varphi = \left(\frac{2I_i}{v_i}\frac{T_e}{e}\right)^{1/2}.$$

Under typical experimental conditions, i.e., at $I_{He+} = 1$ mA and E_i = keV, this value is a few volts, in order-of-magnitude agreement with the measured value of the potential drop in the beam.

3. EFFECT OF A TRANSVERSE MAGNETIC FIELD ON THE MOTION OF THE RESULTING BEAM

When ion–electron beams are used to process solids[7] magnetic fringing fields can exist near the object being processed. In this connection it is worthwhile to study the stability of such intense beams with respect to a transverse magnetic field, i.e., to determine how the motion of such beams is affected by such a field. We also note that an ion–electron plasma can serve as a model for continuous-operation study of the polarization which results from the influence of magnetic fields on the plasmas used for injecting fast particles into traps.[8]

Even in a relatively weak transverse magnetic field, as the neutralized ion beam propagates, the Lorentz force $F_\pm = e[v_\pm H]/c$ leads to charge separation and to the appearance of an electric field in the beam region. This polarization is demonstrated in Fig. 5, which shows the potential profile in the beam in the direction perpendicular to the external magnetic field (H = 6 Oe, curve 2). Curve 1 shows the potential profile in the absence of a magnetic field. The intensity of the polarization field agrees with the calculated value. Figure 6 shows the corresponding profiles of the ion (1) and electron (2) probe currents in the beam in the magnetic field; these profiles confirm the spatial separation of the charges of different sign. The slight additional peak in the electron profile (at the left in Fig. 6) is due to a reverse flow of electrons from the beam-irradiated target. Because of the polarization electric field, most of the fast ions in the beam move in the drift region without being deflected in the relatively weak magnetic field. The existence of a transverse magnetic field along the path of the neutralized ion beam hinders the motion of the injected electrons from the source to the target. In particular, at a certain field (~5 Oe in these experiments), the neutralization of the ion current at the insulated (floating) target is disrupted, so that this target is charged by the fast beam ions, and there is a corresponding reduction in the power evolved at the target. Figure 7 demonstrates the relative decrease in the beam power at the insulated target with increasing intensity of the transverse magnetic field in the drift region (the initial beam power is $P_0 \sim 15$ W). The region in which the ion motion is essentially unperturbed by the polarization field corresponds to magnetic fields H < 10-15 Oe.

CONCLUSION

We have reported here a method for producing a plasma by electron injection through the ion source. The apparatus is characterized by its small size and simplicity of operation as compared with other methods for producing ion–electron beams.[7,9]

The information found regarding the degree of neutralization of the ion–electron beam, in particular, the information found on the minimum potential drop in the beam, agrees with the model for a generated plasma incorporating the equality of the total ion and electron charges and incorporating the existence of an electron atmosphere outside the ion core.[2]

We have reported the first experimental study of the effect of a transverse magnetic field on the transport of the generated plasma, consisting of ions and electrons moving at approximately equal velocities.

Measurement of plasma electron temperature with a sinusoidal probe potential

B. I. Kanaev, V. V. Piterskii, and E. E. Yushmanov

(Submitted November 19, 1973; resubmitted March 11, 1974)
Zh. Tekh. Fiz., 44, 2302-2306 (November 1974)

A method for measuring the electron temperature which does not require the recording of the voltage–current characteristics is described. The method exploits the rectifying properties of the probe; these cause a shift of the floating potential of the probe when an rf voltage is applied to it. The output signal from the probe reflects the electron temperature directly, so that this temperature can be monitored continuously during one-shot processes. Another advantage of this method is its insensitivity to changes in plasma properties other than T_e. In most cases a magnetic field does not hinder measurements. The method has been used successfully in experiments on the confinement of hot plasmas in magnetic traps.

INTRODUCTION

In certain cases the classical Langmuir-probe method for measuring the plasma electron temperature from the slope of a semilogarithmic plot of the electron current collected by the probe is inconvenient. Let us assume, for example, that we are to follow the behavior of T_e during a transient one-shot process. The usual procedure might involve repeating the process many times in order to obtain a family of probe-current curves as a function of the time for various values of the probe potential. This family of curves would then be used to construct the voltage–current probe characteristics at various times: The electron components of the current are then found from the characteristics and plotted on a logarithmic scale; the slopes of the resulting lines yield the values of $T_e(t)$. This method obviously suffers from the disadvantage that both the measurements (involving repetitions of the process) and the subsequent calculations are laborious. A further disadvantage arises if the process in question is not perfectly reproducible from shot to shot, e.g., if systematic changes in properties such as the plasma density and potential or the component temperatures are subject to random fluctuations due to an instability, turbulence, etc. These fluctuations cause a "jitter" in the probe-current curves, which can make it impossible to plot the voltage–current characteristics. In any case, the result (if it is found) reflects only the average behavior of T_e over many repetitions, and the details of the individual processes are lost.

Ideally, we would like a method free of all these disadvantages. Specifically, this ideal method would a) make it possible to obtain all the information about the behavior of T_e during a single shot, b) be insensitive to changes in any of the plasma properties (the potential, the density, or T_i) other than T_e, and c) allow the information to be displayed in a form not requiring a complicated analysis, i.e., in terms of a quantity related to T_e in some simple manner.

Below we discuss a method which satisfies these requirements in many cases. It incorporates no concepts other than those of the Langmuir method, differing from the latter only in its use of rapid, automatic measurements of the characteristic constant $1/T_e$ of the exponential function describing the electron current collected by the probe.

THE MEASUREMENT PRINCIPLE

This method exploits the well-known rectifying properties of probe–plasma contacts which result from the nonlinearity of the voltage–current characteristic of the probe. As a result of this rectification process an alternating voltage fed to a probe which is floating (in terms of direct current) causes a shift of the average floating potential; this shift is related to T_e.

In particular, let us consider the circuit in Fig. 1. Let us assume for the moment that the plasma is in a steady state. We also assume that the output impedance of the oscillator and the isolation capacitor C is small in comparison with the resistance of the probe–plasma contact, so that all the rf voltage is fed to the probe and this voltage retains its sinusoidal shape. Since the probe is in a dc open circuit its potential is equal to the floating potential V_{fl} when the oscillator is off. When the oscillator is on how does the constant component of the probe potential respond?

It has been shown many times (see the review in ref. 1) that when a sinusoidal voltage of amplitude u is fed to a probe at some potential the average electron current collected by the probe increases by a factor $I_0(u/T_e)$, where $I_0(x)$ is the Bessel function of imaginary argument (and T_e is expressed in potential units). This statement holds if the probe characteristic has an exponential shape, as it does if the electrons have a Maxwell distribution and if the probe sheath is thin in comparison with the probe dimensions. This result means that when the oscillations are introduced the average characteristic simply shifts to the left by an amount $\Delta V = T_e \ln I_0(u/T_e)$ in the region in which this characteristic remains exponential. Obviously, the intersection of the characteristic with the abscissa, i.e., the floating potential, shifts by the same amount. The equation given above for ΔV has been verified experimentally,[2] with corrections made for the slope of the ion branch of the characteristic. It has also been suggested[2] that it might be possible to measure T_e on the basis of ΔV, although this possibility was not analyzed.

According to this equation, then, we can get information about T_e from the shift in the floating potential, ΔV. The most convenient case is that of moderate amplitudes of the superimposed alternating voltage, for which $u \leqslant T_e$. Expanding ΔV in a series

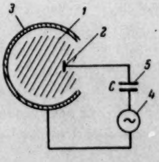

Fig. 1. "Oscillating-voltage" probe for measuring T_e. 1) Plasma; 2) probe; 3) reference electrode; 4) rf oscillator; 5) isolation capacitor.

$$\Delta V = -u\left[\frac{1}{4}\frac{u}{T_e} - \frac{1}{64}\left(\frac{u}{T_e}\right)^3 + \ldots\right],$$

we see that at moderate amplitudes we can assume $\Delta V = (-1/4)u^2/T_e$. At large amplitudes, $u \gg T_e$, on the other hand, we lose the relationship between ΔV and T_e because $\Delta V \to u$.

We note that measurements of ΔV to determine the electron temperature have the desirable features listed above: These measurements are not affected by plasma properties other than T_e, and the measured results are related to T_e in a simple manner, so that the ΔV signal can be read off in terms of T_e in the course of the experiments.

Furthermore, this method of determining T_e from the shift in the floating potential can also be used in the presence of a magnetic field: In the floating-potential region, i.e., at electron currents small in comparison with the saturation electron current, the characteristic is usually exponential.

MEASUREMENT METHOD

In order to measure $\Delta V(t)$ during a single rapid process we must evidently make a continuous comparison of the floating potentials with and without the rf signal. One of the major difficulties here is that the small signal $\Delta V(t)$ (which is much smaller than T_e) appears in a sum with the large signal $V_{fl}(t)$ (which is usually larger than T_e), so that we must find some highly accurate method for separating the two signals. One simple method for doing this is based on the use of two identical probes placed close together, one an "oscillating-voltage" (i.e., connected in the circuit of Fig. 1) and the other simply floating. The probes are connected to the inputs of a well-balanced differential amplifier; there should of course be high resistances in the input circuits to avoid disrupting the condition that the probes be floating in terms of direct current. The resulting differential signal is the signal $\Delta V(t)$.

However, the use of this method can be limited: At a low level of the signal $\Delta V(t)$ a difference may appear between the floating potentials of the two probes because of the unavoidable spatial separation. This difference is superimposed on the desired signal as a type of noise. It is possible that this noise may not be perfectly reproducible in shape and level from shot to shot, so that we would again be faced with the need for a statistical averaging and would lose our capability of studying each separate instance of the process in question.

In principle, this problem can be overcome by using a different method, involving only a single probe, which is fed an amplitude-modulated rf voltage with a modulation frequency much higher than the frequencies characteristic of the process under study. If the modulation is described by $u(t) = u_0 \sin \Omega t$ (a mixture of two high frequencies at the same amplitude), the signal $\Delta V(t)$ also oscillates sinusoidally at frequency $F = \Omega/\pi$. Using a resonant filter to extract this signal, we can eliminate the signal $V_{fl}(t)$.

Figure 2 shows the measurement circuit. The rf oscillator produces an alternating voltage at two frequencies. Comparison with the circuit in Fig. 1 shows that we have now added a measuring circuit consisting of the high resistance R and a filter passing frequency F and a circuit for measuring and monitoring the rf signal, which consists of elements C_1, R_1, and ρ (the characteristic impedance of the cable). The measured signal is sinusoidal at frequency F, and the peak-to-peak amplitude of the oscillations, $\Delta V(t)$, is related to the electron temperature by $\Delta V(t) = u_0^2/4T_e(t)$.

CHOICE OF PARAMETERS

In choosing the parameters for this circuit we must observe several quantitative conditions. An important role is played by the quantity R_{fl}, the dynamic resistance of the probe–plasma contact, when the probe potential is near the floating potential. If the probe current I is exponential we can write

$$R_{fl} \equiv \left(\frac{\partial I}{\partial V}\right)^{-1}_{V=V_{fl}} = \frac{T_e}{I_i},$$

where I_i is the saturation ion current. We first need some idea of the numerical value of R_{fl}.

As we mentioned above, to avoid superimposing the rf voltage on the probe we must use an rf oscillator and a capacitance C whose resultant impedance (including the impedance of the associated leads) is several times lower than R_{fl}. Another circuit parameter which affects R_{fl} is the resistance R in the measuring circuit. To satisfy the floating condition we require $R \gg R_{fl}$.

The choice of modulation frequency F is also governed significantly by R_{fl}. On the one hand, we cannot use a frequency F which is too high, since we must avoid superimposing the measured signal on the capacitance C_{tot} connected to the probe. This capacitance is governed primarily by the capacitance C and the parasitic capacitance between the probe and ground; it is also governed by the probe–plasma capacitance and by C_1. Since the output resistance of the equivalent generator of the measured signal is the same quantity, R_{fl}, the condition which must be met to avoid interference is $F \ll (2\pi R_{fl} C_{tot})^{-1}$. On the other hand, it is not desirable to use too small a value of F because the time resolution can be degraded (the resolving time is $\tau_{rslv} \approx Q/\pi F$, where Q is the quality factor of the filter) and because the interfering low-frequency signal $V_{fl}(t)$ would not be adequately filtered [the noise level is $\approx V_{fl}(2\pi F\tau Q)^{-1}$,

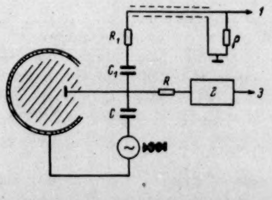

Fig. 2. Circuit for measurements with a modulated rf signal. 1) rf monitor; 2) filter; 3) measurement of $\Delta V(t)$.

where τ is the characteristic time for the changes in V_{fl}]. We must thus choose a value for F to satisfy all three of these conditions as well as possible. Finding such a value is easier, the smaller R_{fl}; in this connection we recall that R_{fl} is governed by the properties of the probe itself as well as by the plasma properties.

There is a lower limit on the carrier frequency f set by the obvious requirement $f \gg F$; generally speaking, the upper limit is fixed by the inertia of the plasma sheath near the probe, but this limit evidently lies near the electron plasma frequency, i.e., is usually quite remote. Thus the choice of f is governed primarily by practical considerations, e.g., the convenience in feeding the rf voltage from the oscillator to the probe, etc.

EXPERIMENTAL TESTS

We have used this method based on a modulated rf signal to monitor the electron temperature during the decay of a hot-ion hydrogen plasma in a mirror system. The decay, i.e., the loss of plasma from the trap occurs over a time scale of the order of 100-200 μsec; during the decay all the plasma properties — the density, the ion and electron temperatures, and the potential — undergo large changes. The local values of the density and the potential fluctuate because of the ion cyclotron instability characteristic of this confinement method. The plasma density at the beginning of decay is $\leqslant 10^{11}$ cm^{-3} near the probe; the ion and electron temperatures are about 100 and 5 eV, respectively. The magnetic field is 5 kOe.

We measure T_e at a carrier frequency of 10-15 MHz and at a modulation frequency of 100 kHz. The probe tip has an area of 5 mm^2. Figure 3 shows a typical $\Delta V(t)$ signal (oscillogram b). The behavior of the signal implies an increase in the electron temperature from 5 to ≈ 25 eV. This increase follows an intensification of the induced instability of the rf oscillations (oscillogram a), implying energy transfer from ions to electrons via the instability.

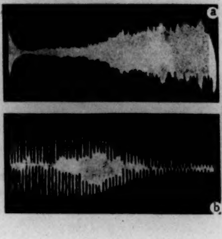

Fig. 3. a) Signal of the rf plasma noise due to the onset of instability; b) the signal $\Delta V(t)$, reflecting the increase in the electron temperature.

We have also studied the behavior of the electron temperature in this experiment, to the extent possible, by a method involving a recording of characteristics like those described earlier in this paper. As a further check we measure the energy spectrum of the plasma electrons escaping from the trap through the magnetic mirrors, by the cutoff method. The results found by both of these methods agree with the results found by the oscillating-voltage method.

(Submitted October 9, 1973)
Zh. Tekh. Fiz., 44, 2307-2310 (November 1974)

The calculated and experimental distributions of the cesium density are compared in the low-voltage arc of a planar cesium diode. The measurements are carried out by an interferometer method. The calculations are based on the measured distributions of the electron density and temperature in the arc. The calculated results agree with the experimental results. As the current is increased the atomic density in the arc decreases, because of heating of the ion–atom component and because of the reduction in the atomic pressure due to the increased electron–ion pressure. The heat carried to the electrodes by atoms is estimated. It is possible to determine the thermal conductivity of the cesium vapor by comparing the calculated and measured temperature distributions of the atoms.

Study of the distributions of the macroscopic properties of a hot-cathode gas discharge in cesium vapor is of considerable importance in determining the processes that occur in the discharge. These distributions have received much study over the years because of the practical application of thermionic converters. Accurate spectroscopic and probe methods are available for determining the electron density n and temperature T_e, but the density of neutral Cs atoms is usually determined indirectly and with large error. The use of interferometer methods – the hook method[1] and the superposition of interference patterns[2] – yields a direct determination of the atomic density and points to several conclusions regarding the interactions between the plasma components.

We describe here a study of the distribution of the cesium-atom density in the gap of a planar diode as a function of the current through the diode and the Cs vapor pressure. The atomic density determined experimentally by an interferometer method is compared with the calculated density. The calculations are based on the experimental distributions of the electron temperature and density over the gap.

The experimental apparatus contains a two-beam interferometer and a spectrograph. A planar cesium diode with molybdenum electrodes and an adjustable gap d is located in one arm of the interferometer. The interference fringes are localized in the central part of the diode gap by adjustment of the interferometer to permit a determination of the distribution of atoms over the gap. A spatial resolution of about 0.1 mm is achieved. The observations are carried out near the resonant absorption line of cesium, λ = 8521 Å. Some of the details are discussed in refs. 3 and 4.

The electron temperature T_e is determined from the recombination rate of the 6P continuum on the basis of the recombination cross section from ref. 5: $\sigma(v) = 3.74 \cdot 10^{-6} v^{-2} \cdot \mathrm{cm}^2$, where v is the electron velocity. The electron density n is determined from the Stark broadening of the lines of the fundamental series and the results of ref. 6. Typical experimental distributions of the electron density n(x) and temperature $T_e(x)$ are shown in Fig. 1. We note that the displacement of the interference pattern by the electron component of the plasma is negligible, being less than 10^{-2} of a fringe.

The increase in the electron density and temperature which occur as the diode current j is increased are accompanied by a heating of the atoms and a reduction of their neutral density n_a. The decrease in the atomic density due to increased current is indicated by $\gamma = n_{aa}/n_{afr}$, where n_{aa} is the atomic density in the arc, and n_{afr} is the atomic density in the free-run mode. The calculated and experimental values of $\gamma(x)$ are compared in Fig. 2 for various points of the gap. Figure 3 shows the quantity $1 - \gamma(d/2)$, calculated and measured at the center of the gap, as a function of the gap width d.

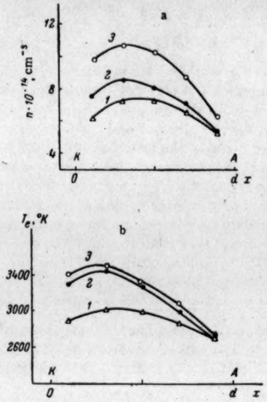

Fig. 1. a) Experimental electron density distributions; b) experimental electron temperature distributions over the gap for various arc currents. p = 7.1 torr, T_k = 1400°K, T_a = 750°K, d = 1.6 mm. j(A/cm²): 1) 10; 2) 15; 3) 20.

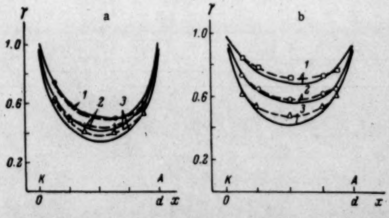

Fig. 2. Comparison of experimental and calculated values of $\gamma(x) = n_{aa}(x)/n_{afr}(x)$ for various arc currents. T_k = 1400°K, T_a = 750°K, d = 1.6 mm. a) p = 7.1 torr; b) 3 torr. 1) j = 10 A/cm²; 2) 15 A/cm²; 3) 20 A/cm². Solid curves–calculated; dashed–experimental.

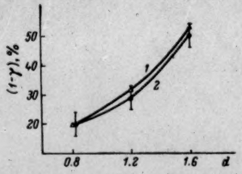

Fig. 3. Comparison of the calculated and experimental values of 1 − γ for various gap widths. j = 20 A/cm², p = 3 torr, T_k = 1400°K, T_a = 750°K. 1) Calculated; 2) experimental.

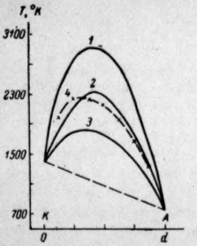

Fig. 4. Comparison of the values of T(x) calculated for various values of the thermal conductivity $\varkappa_a$ with the experimental values. $\varkappa_a$ (W/cm · deg): 1) $5 \cdot 10^{-7}\sqrt{T}$ (ref. 12); 2) $1.65 \cdot 10^{-6}\sqrt{T}$ (ref. 10); 3) $5 \cdot 10^{6}\sqrt{T}$ (ref. 11); 4) experimental results for j = 15 A/cm² and p = 7.1 torr.

The calculation of the atomic density $n_a(x)$ and temperature T(x) involves a numerical solution of the system of equations[7]

$$\frac{d}{dx}\left[(\varkappa_i+\tilde{\varkappa}_a)\frac{dT}{dx}\right]=\Delta Q_{ei}+\Delta Q_{ea}, \qquad (1)$$

$$p=n_a kT+nk(T_e+T). \qquad (2)$$

Here, $\varkappa_i = 3.9nk^2T(\tau_i/M)$ is the ion thermal conductivity, $\Delta Q_{ei} = (3m/M)(n/\tau_e)k(T_e - T)$ is the energy transferred from electrons to ions in collisions,[8] $\Delta Q_{ea} = (4m/M) \cdot (n\bar{v}_e/l_0)\,k(T_e - T)$ is the energy transferred from electrons to atoms in collisions $\tilde{\varkappa}_a = \varkappa_a[(nQ_{ai}/n_a Q_{aa}) + 1]^{-1}$ is the thermal conductivity of the atoms, with atom − ion collisions taken into account,[9] and $\varkappa_a$ is the thermal conductivity of cesium vapor.1) Equation (1) is solved under the boundary conditions T(o) = T_k, and T(d) = T_a, where T_k and T_a are the cathode and anode temperatures.

The calculated results, shown in Figs. 2 and 3, agree with the measured distributions of the atomic density in the gap, implying that the decrease in the atomic density in a low-voltage arc at higher currents is, in fact, due to the heating of the ion−atom component in the discharge and to the decrease in the atomic pressure, which itself is due to the increase in the electron−ion pressure $nk(T_e + T)$ (in a weakly ionized plasma, however, this latter factor is relatively unimportant).

By independently measuring n, T_e, and n_a and then determining T(x) from Eq. (1) we can, in principle, find

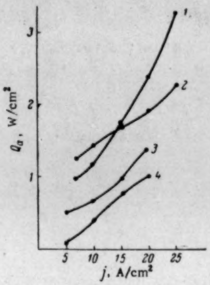

Fig. 5. Heat fluxes to the electrodes calculated from the measured distributions $T_e(x)$ and n(x) for various arc currents. 1,4) Heat flux to the cathode; 1) p = 7.1 torr; 4) 3 torr; 2, 3) heat flux to the anode; 2) 7.1 torr; 3) 3 torr. T_k = 1400°K, T_a = 750°K, d = 1.6 mm.

the thermal conductivity of the cesium vapor, $\varkappa_a$. We vary the quantity $\varkappa_a$ in (1) for best agreement between the calculated and experimental results. We use the values of $\varkappa_a$ from refs. 10-14 in comparing the calculated and experimental results. The best agreement is found when the results on $\varkappa_a$ from ref. 10 are used: $\varkappa_a = 1.65 \cdot 10^{-6}\sqrt{T}$ W/cm · deg (Fig. 4). Using this value of $\varkappa_a$ we find the results shown in Figs. 2 and 3. The intensified heating of ions and atoms which occurs as the current through the diode is increased is accompanied by an increase in the heat transfer from the heavy component to the electrodes. This heat flux can make an appreciable contribution to the total energy transfer from the plasma to the electrodes. The effect is illustrated in Fig. 5 by the functional dependence Q_a(j), where Q_a is the heat flux from atoms to the electrode.

---

1)A small term on the right-hand side of (1) describing the heating of ions in the electric field is neglected.

Free expansion of plasma jets

P. A. Demchenko, L. I. Krupnik, and E. S. Lyangner*

(Submitted December 29, 1972)
Zh. Tekh. Fiz., 44, 2311-2316 (November 1974)

An experimental study is reported of the free expansion in vacuum of plasma jets with densities $n \sim 10^{14}$ cm^{-3} and velocities $v \sim (0.5\text{-}1) \cdot 10^7$ cm/sec. The radial distribution of the density and the density distribution along the flow axis are studied. The electron temperature is measured. The results are compared with existing theoretical models for the expansion of plasmas and molecular fluxes. The possibility of finding the ion temperature is discussed.

INTRODUCTION

Several papers have been published on the expansion of plasmas in vacuum.[1-7] As a rule, the theoretical models deal with semiinfinite plasmas whose ions are initially at rest, for which the expansion occurs as a result of a finite electron temperature T_e.

Under actual conditions, however, the plasma is always bounded and the ion temperature is finite. Even if the ions are not in thermodynamic equilibrium there is always a finite ion velocity distribution.

In working with plasma jets generated by electrodynamic accelerators it is frequently necessary to calculate the density distributions in freely expanding jets. In particular, problems of this type arise in the transport of plasma jets, in the production of ion beams from plasmas in a determination of plasma properties,[8] and in other cases. Examination of the expansion mechanism and its sensitivity to a finite ion temperature thus becomes an important question.

In this work we study the expansion of moving plasma jets in vacuum in the absence of an external magnetic field. The experiments are carried out over ranges of initial densities n_0 and initial jet radii r_0 which satisfy the condition $r_0 \ll \lambda$, where $\lambda = 2E^2/\pi e^4 n_0 \ln\Lambda$ is the Coulomb mean free path.

EXPERIMENTAL PROCEDURE AND RESULTS

Figure 1 shows the experimental arrangement. A flow of hydrogen plasma is produced by conical electrode-type injector 1 with pulsed gas injection.[10,11] A plasma jet cut off sharply in the radial direction is isolated from the original flow, which fills the entire cross section of plasma guide 2, by conical limiter 3. The conical profile of the limiter is chosen to suppress the hydrodynamic effects which arise as the plasma strikes the barrier. We have studied the expansion of jets in vacuum chamber 5, 45 cm in diameter, varying the initial jet radius r_0 from 2.5 to 10 mm.

The radial distribution of the density is measured at various distances from the limiter by double probes.[12] For this purpose there are several probes, one of which (4) is moved along the axis of the moving jet; the others are moved in the radial direction, at several distances from the plane of the limiter. The double probes can also measure the electron temperature in the expanding plasma and the flow velocity.

The absolute densities of the charged and neutral particles are determined by probing the plasma with beams of fast hydrogen atoms and ions.[11,13]

Figure 2 shows the time evolution of the density at the axis, at a point 9 cm from the limiter; trace a is an oscillogram of the saturation ion current collected by the probe, while trace b is an oscillogram of the intensity of the diagnostic atomic beam.

We can explain this difference in the divergence behavior at a given electron temperature by assuming that the ion temperature does not remain constant along the jet. If the ions are not in thermodynamic equilibrium the radial dispersion in the ion velocity should be greater for the first density maximum than for the second. Since the plasma formation has finite dimensions along the axis of the jet, we should also observe a spreading along the longitudinal axis The experimental results show that for a given longitudinal dimension the longitudinal expansion is not important over the time interval studied here (or, correspondingly, over the distances traversed by the jets). We can therefore assume the expansion to be purely axisymmetric.

Let us compare the expansion of the plasma jet having the properties given above with the expansion of a jet of neutrals. For collisionless expansion into vacuum of an initially cylindrical cloud of neutrals of mass M and temperature T we can write the following equation for the functional dependence of the density of atoms at the axis on time t (ref. 14):

$$n = n_0\left(1 - e^{-\alpha r_0^2/t^2}\right),$$

where $\alpha = M/2kT$, r_0 is the initial cloud radius, and n_0 is the initial density. Generalizing this equation to the case of motion along the longitudinal axis at a velocity v_0, we

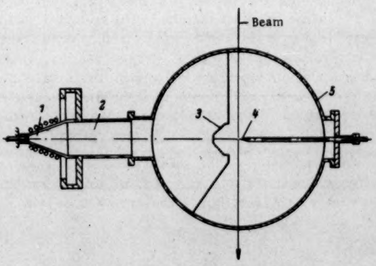

Fig. 1. The experimental arrangement.

find the density of atoms at the jet axis as a function of the distance which has been traversed, x:

$$n = n_0(1 - e^{-\beta/z^2}), \tag{1}$$

where $z = x/r_0$ and $\beta = Mv_0^2/2kT = E_0/kT$. Here E_0 is the energy associated with the directed motion of the particles. At large distances, $z \gg 1$, we can expand the exponential function in Eq. (1) in powers of z. We assume hydrogen atoms H_1^0 at an energy of 16 keV. It follows from the oscillograms shown here that the plasma jet is characterized by three regions of high density; these regions appear some 12-15 μsec apart. The directed velocities of the density maxima are $v_1 = 8.1 \cdot 10^6$, $v_2 = 5.2 \cdot 10^6$, and $v_3 = 3.3 \cdot 10^6$ cm/sec, respectively, and do not vary as the jet moves. The densities measured at the corresponding maxima at the jet axis at the position of the limiter are $(n_0)_1 = 1.5 \cdot 10^{14}$, $(n_0)_2 = 3.6 \cdot 10^{14}$, and $(n_0)_3 = 2.3 \cdot 10^{14}$ cm^{-3}. The electron temperature measured in the plane of the limiter is approximately the same for all three maxima at $T_e = 5$ eV.

The results on the jet divergence discussed below refer primarily to the first and the second density maxima, since important differences are found in the nature of their divergence.

Figure 3a shows the plasma density at the jet axis during the motion of the jet for the first (I) and second (II) density maxima. The distance along the motion axis is measured from the limiter and divided by the initial radius r_0 (radius of the aperture in the limiter). The densities are normalized to the density at the center of the aperture in the limiter, n_0.

The behavior of these curves remains the same as r_0 is changed from 2.5 to 10 mm. It follows from this figure that the divergence of the various parts of the jet are different; in particular, the part of the jet corresponding to the first density maximum expands more than the part of the jet corresponding to the second maximum.

While the plasma density at the axis of the jet varies by two orders of magnitude the electron temperature decreases from 5 to 3 eV, so that the density at the axis of the jet falls off in proportion to $1/z^2$, i.e., we have $n \approx n_0E_0/kTz^2$.

Accordingly, in the case of the jet of neutrals the functional dependence of $\ln(1 - n/n_0)$ on $1/z^2$ must be described by a straight line whose slope with respect to the $1/z^2$ axis is given by E_0/kT.

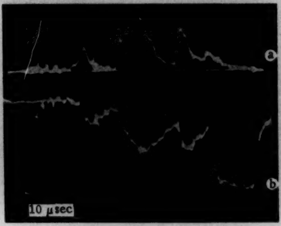

Fig. 2

Figure 3b shows the corresponding functional dependence for the plasma jet. We also observe a linear functional dependence in this case. From the slopes of the analogous lines and the known velocity of the directed motion of the particles we determine the values of the parameter kT for the three density maxima: $(kT)_1 = 5.3$, $(kT)_2 = 0.5$, and $(kT)_3 = 0.35$ eV.

It should be noted that we compare this parameter with the electron temperature only at the first maximum of the plasma flow; in subsequent regions it is an order of magnitude below the experimental value of the electron temperature. If we identify the parameter kT with the ion temperature we conclude that the expansion of the dense plasma jet in vacuum is governed solely by the initial spread in the ion velocity.

Having determined the ion temperature of the plasma jet in this manner we can calculate the radial distribution of the particle density at various distances from the limiter and compare the calculated curves with the experimental curves.

The curves in Fig. 4a correspond to the first (I) and second (II) density in the jet and are obtained for $x/r_0 = 9$. The solid curves show the calculated results; the points are experimental.

The theoretical curves are obtained through a generalization of the calculations of ref. 5 to the case of a moving jet. These curves are described by

$$\frac{n(\rho, z)}{n(0, z)} = \frac{2Ae^{-A\rho^2}}{1 - e^{-A}} \int_0^1 e^{-A\rho^2} I_0(2A\rho\tau)\tau d\tau,$$

where $\rho = r/r_0$; $z = x/r_0$; $A = (E_0/kT)/(x/r_0)^2$; and I_0 is the modified Bessel function. In this case we observe good agreement between the calculated and experimental results over a certain density range [$n(0, z) \sim 10^{14}$-10^{13} cm^{-3}]. Differences appear at radii for which the density

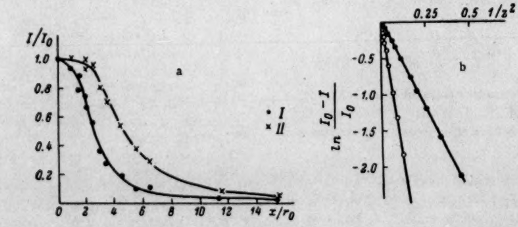

Fig. 3

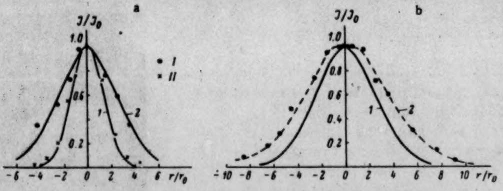

Fig. 4. Radial profile of the ion component in the plasma jet.

becomes significantly lower than the density at the axis, $n(\rho, z)/n(0, z) < 10^{-2}$.

Far from the limiter we observe an important difference between the divergence of the plasma jet and that of a flow of neutrals with similar properties. Figure 4b shows the radial profiles of the charged-particle density for the second maximum, obtained for $x/r_0 = 19$. The two curves show the calculated (1) and experimental (2) functional relations. In this case the divergence of the plasma jet is much more pronounced than that of the neutral flow for the same values of the parameter kT.

The electron pressure, which is only significant at the boundary of the jet for high densities (Fig. 4a), evidently has a significant effect on the nature of the plasma divergence in vacuum at lower plasma densities [$n(0, z) \sim 10^{12}$–10^{11} cm^{-3}; Fig. 4b].

The electron gas reaches a thermodynamic equilibrium over the characteristic times (the voltage–current characteristic implies a Maxwellian electron distribution).

An attempt to detect a concentric layer expanding at three times the ion sound velocity, $(kT_e/M_i)^{1/2}$, in accordance with the results of ref. 2, does not yield a definite result, perhaps because the probe measurements at the boundary of the jet are hindered by the intense fluctuations in the density. These fluctuations lead to a modulation of the probe current at 1-2 MHz.

CONCLUSION

These experiments are carried out in connection with the generally accepted model[16] for the free expansion of plasma in vacuum, according to which a thermal expansion due to an initial spread in the velocities (both ions and electrons) is superimposed on the macroscopic motion of the jet. We also assume that the thermal expansion in vacuum of plasma jets is similar to that of molecular beams, except that the sound velocity in the gas, which is characteristic of the expansion of beams, is associated with the acoustic velocity in the plasma:[17]

$$v_s = \sqrt{\frac{\gamma_i kT_i + \gamma_e kT_e}{M_i}},$$

where T_i and T_e are the ion and electron temperatures, γ_i and γ_e are the ratios of specific heats for the ion and electrons, M_i is the ion mass, and k is the Boltzmann constant.

Accordingly, the plasma expansion is characterized by the parameter $kT = k(T_i + T_e)$, which is a function of both the ion and electron temperatures. If neither component is in thermodynamic equilibrium we can treat this quantity as an average energy governed by the spread in particle velocities.

These experiments on the free expansion in vacuum of plasma jets carried out under approximately collisionless conditions at densities $0.5 \cdot 10^{15}$ cm^{-3} $\leq n_i \leq 1 \cdot 10^{12}$ cm^{-3} and a comparison of these results with those calculated for the case of free molecular expansion have revealed two important differences from the model described above.

The expansion of the plasma jet is governed primarily by the ion temperature, even when the electron temperature is an order of magnitude higher than the ion temperature.

The free expansion of plasma jets in vacuum is analogous to the expansion of a collisionless molecular flow (under the condition $\lambda \geq r_0$) up to the point at which the divergence of the jet causes the density to fall off by two orders of magnitude, $n/n_0 \geqslant 10^{-2}$. At a divergence $n/n_0 < 10^{-2}$ there is a significant difference between the experimental and calculated data.

In conclusion the authors thank B. A. Shevchuk for the computer calculations, and A. A. Kalmykov for useful discussion.

Laser-initiated vacuum discharge

V. P. Kovalenko, A. A. Makarevich,

V. A. Rodichkin, and A. M. Timonin

(Submitted August 15, 1973; resubmitted December 13, 1973)
Zh. Tekh. Fiz., 44, 2317-2321 (November 1974)

The amplitude and time characteristics of a vacuum discharge (initial pressure $p = 2 \cdot 10^{-6}$ torr) are studied in a two-electrode gap; the discharge is driven by the light pulse from a 15 MW ruby laser, which is focused on one of the electrodes. As the laser-produced plasma expands across the gap, a current flows due to the emission of charged particles from the plasma and changes caused in the strength and configuration of the electric field in the gap by the laser plasma. The maximum current across the gap and the time required for the current to reach its maximum value are functions of the gap voltage (U_0 = 5-50 kV) and the capacitance (C_0 = 1100-4400 pF).

Electrical discharges in vacuum are used for switching high pulsed currents, for producing plasmas, and for generating bursts of x radiation. One common method for initiating a vacuum discharge involves the use of the auxiliary spark produced between one of the main electrodes and the ignition electrode when an ignition-voltage pulse is fed to the latter electrode. Laser ignition seems promising as a method for initiating electrical discharges in general and vacuum discharges in particular. Guenther and Bettis[1] reported a study of laser-ignited arc switches with various dielectrics, including vacuum. The delay of the vacuum breakdown is of the order of 10^{-6} sec, while the rise time of the current ranges from 10^{-7} sec for a positive target electrode to $\sim 10^{-6}$ for a negative target electrode.

We report here a study of vacuum discharges initiated by laser radiation. We have obtained new data on the operation of laser-ignited vacuum arc switches. In particular, we have obtained breakdown delay times below 10^{-8}-10^{-7} sec. We observe a stepped switching of the current, a functional dependence of the current amplitude on the amount of energy, and certain other features.

1. EXPERIMENTAL CIRCUIT AND PROCEDURE

Figure 1 shows the schematic circuit of the apparatus used to study laser-ignited vacuum discharges.

The vacuum chamber, evacuated by a diffusion pump to a pressure of $p \sim 10^{-6}$ torr, holds the target M, the collector K, and the Faraday cup C. The distance between the target and the collector is 10 mm. Radiation from a ruby laser L at a power of 15 MW and a pulse length of ~20 nsec is focused on the target by lens FL, which has a focal length of 210 mm. The laser power and energy are monitored by a calorimeter Ca and an FÉK-15 photocell.

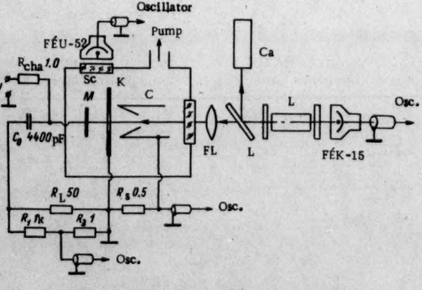

Fig. 1. Circuit used to study vacuum discharges.

The voltage from a high-voltage, low-inductance disk capacitor (C_0 = 1100-4400 pF) charged through charging resistance R_{cha} = 1 MΩ to a voltage of U_0 = 1-50 kV is applied across the discharge gap formed by the target and the collector. Connected in series with the capacitor is a load resistance R_L = 50 Ω, which limits the breakdown current.

The discharge current is measured by resistive divider $R_1 - R_2$ from the voltage drop across the load resistance. The current to the Faraday cup is measured by low-inductance shunt R_s = 0.5 Ω. In addition to measuring the current, we use an oscilloscope to study the x rays produced in the vacuum breakdown. The x radiation is detected by plastic scintillator Sc and an FÉU-52 photomultiplier.

All the oscilloscope measurements are carried out with S1-11 oscilloscopes, triggered by the signal from the photocell that detects the laser pulse.

2. EXPERIMENTAL RESULTS

Figure 2 shows an oscillogram of the voltage across the load resistance, recorded with a negative target electrode at a residual pressure of $p = 2 \cdot 10^{-6}$ torr. The current in the gap lags behind the beginning of the laser pulse by less than 12-15 nsec, regardless of the magnitude of the applied voltage, U_0 = 5-50 kV. During the first 50-60 nsec with a negative target the current across the gap remains essentially constant; then it increases to its maximum value in ~40 nsec. Thereafter it decays exponen-

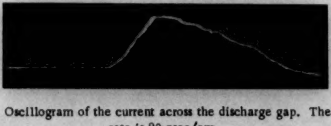

Fig. 2. Oscillogram of the current across the discharge gap. The sweep rate is 20 nsec/cm.

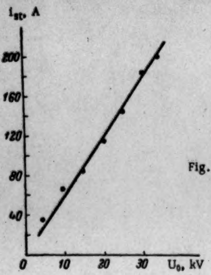

Fig. 3. Current step as a function of the applied voltage.

tially. The behavior of the current is similar when the target electrode is positive; in this case the lag time of the current is generally 2-3 nsec less and the current step has a clearly defined maximum. The size of the initial step is essentially the same for both polarities of the target electrode, being a linear function of the applied voltage (Fig. 3).

During the step a current pulse I_C is observed at the Faraday cup. With a negative target (see the data below) this current is more than an order of magnitude higher for the opposite polarity.

When the target is negative we observe an x-ray burst which is similar in shape and duration to the current pulse at the Faraday cup. Figure 4 shows an oscillogram of the current pulse at the Faraday cup. We see that the current at the Faraday cup increases smoothly, reaching a maximum at the end of the step; then it decays comparatively rapidly, vanishing when the current in the gap reaches its maximum.

The magnitude of the maximum current in the gap is a function of both the voltage applied to the gap and the discharge capacitance. Figure 5 illustrates the functional dependence of the gap current on the voltage for three capacitances. The time t_m between the beginning of the discharge and the current maximum is a function of the charge on the capacitor for a positive target.

U_0, kV	10	15	20	25	30	35	40
I_C, A	4.1	7.4	13.2	21.5	25.6	49.5	56

Figure 6 shows t_m as a function of the applied voltage for a capacitance of $C_0 = 4400$ pF.

Variation of the interelectrode distance d over the range 5-20 mm causes no significant change in the processes occurring in the discharge gap. Furthermore, we find that the gas pressure in the gap has no effect when $p \leqslant 2 \cdot 10^{-3}$ torr. At $p \geqslant 2 \cdot 10^{-3}$ torr the processes in the gap change: When the laser beam strikes the target a discharge occurs in the residual gas, and the current in the circuit varies as it does during the breakdown of the gas-filled gap.[2]

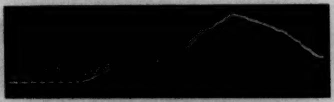

Fig. 4. Oscillogram of the current to the Faraday cup. The sweep rate is 10 nsec/cm.

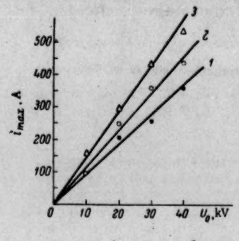

Fig. 5. Maximum current across the gap as a function of the applied voltage. C_0 (pF): 1) 1100; 2) 2200; 3) 4400.

Reducing the laser power leads to a reduction in the current and an increase in the length of the current pulse at the Faraday cup and of the x-ray burst. The integrated characteristics of these pulses (the charge and dose) remain approximately constant, regardless of the laser power.

3. DISCUSSION OF RESULTS

When a metal target is struck by focused laser radiation a laser plasma is formed and expands at a velocity $\sim 10^7$ cm/sec (ref. 3); this plasma apparently emits charged particles and changes the strength and configuration of the electric field in the gap. Accordingly, the current in the gap before breakdown (before the end of the step) must be governed by the current of the emitted charged particles, I_e, and the bias current I_c.

The emission current density is governed by the familiar "three-halves" law, which can be approximated in the following manner for the present case:

$$j_e = A\frac{\varepsilon_0}{9\pi}\sqrt{\frac{2e}{m}}\frac{U^{3/2}}{\left(d - \int\limits_0^t v\,dt\right)^2},$$

where A takes account of the gap form factor, ε_0 is the dielectric constant, e and m are the charge and mass of the particle, and v is the velocity of the emitting boundary of the plasma.

The current at the Faraday cup and estimates from Eq. (1) show that the emission component of the electron

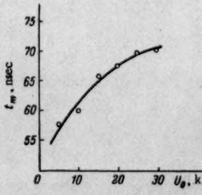

Fig. 6. Time required for the current to reach its maximum value as a function of the voltage on the capacitor.

current does not play an important role during the first ~20 nsec after the formation of the plasma (the time resolution of the measuring circuit is ~8 nsec). The emission component of the current of positive ions (with the target at positive polarity) can be neglected while the plasma expands to the opposite electrode. Accordingly, at least during the initial stage of the plasma expansion, the step in the voltage across the load can be caused only by the bias current (the inductance of the discharge circuit is less than 50 nH). This bias current is due to the change in configuration of the electric field in the gap under the influence of the laser plasma, the changes in the dielectric properties of the evacuated gap due to its filling by plasma and vapor, and the ejection into the gap of molten charged particles of macroscopic size.

Since the plasma velocity falls off during the expansion and while the plasma dimensions become comparable to the length of the gap, the bias current must fall off as a function of the time and the emission current must increase. As a result, with the target electrode at a negative polarity the total current across the gap remains essentially constant throughout the step. With the target at a positive polarity the emission component of the current is low, and the total current across the gap falls off toward the end of a step, then increasing to a maximum.

The functional dependence on the initial capacitor charge of the current and the time required to reach its maximum value is governed by two competing processes: On the one hand, the current increase after the step is due to a decrease in the resistance of the gap; on the other hand, the residual voltage on the capacitor at time t_m depends on the value of C_0. If we assume that the conductivity of the gap is a linear function of the charge which has flowed across the gap, we can write the following equation for t_m:

$$U_0 - I_m R_L - \frac{2}{C_0}\int_0^{t_m} i\,dt = 0, \tag{2}$$

where I_m is the maximum current.

Since the functional dependence of the current on the time is described by $i \sim t^n$ ($n > 0$) while the current increases, we can write the following relation for t_m:

$$t_m^{n+1} \sim n\left(1 - \frac{I_m R_L}{U_0}\right)\frac{C_0 U_0}{2}. \tag{3}$$

We see from (3) that the time required for the current to reach its maximum value is a function of the initial charge on the capacitor. The fact that this functional dependence is not observed when the target is at the negative polarity can be attributed to the fact that a large electron charge, which "conditions" the discharge channel, flows across the gap during the current step. Evidence for this conclusion comes, in particular, from the fact that the total charge which flows across the gap before the current maximum remains essentially constant as the radiation power is reduced.

Accordingly, we can conclude from these results that a laser-initiated vacuum discharge occurs as a result of the short-circuiting of the discharge gap by the expanding laser plasma. Before the gap is short-circuited the plasma is a source of an intense flux of accelerated charged particles, particularly electrons, which can be used to generate intense bursts of relatively soft x rays for nanosecond periods.

In conclusion the authors thank L. V. Dubovoi for critical comments and discussion.

Effects due to streamer shape

É. D. Lozanskii and D. B. Pontekorvo

Joint Institute for Nuclear Research, Dubna

(Submitted November 20, 1973; resubmitted March 18, 1974)
Zh. Tekh. Fiz., 44, 2322-2325 (November 1974)

A model of streamer development is proposed. The difference between the shape of the streamer surface and an ellipsoid of revolution is taken into account. Calculations based on the model agree with the experimental data.

The increasing number of papers devoted to experimental investigations of the development of discharges in streamer chambers makes it interesting to compare the existing theoretical results with the data of the latest experiments. A theory of streamer propagation is developed in refs. 1 and 2. The models discussed in these papers are represented mathematically in the form of a Laplace equation for the potential generated by the streamer in the surrounding space:

$$\Delta\Phi(\rho,\ z,\ t)=0. \tag{1}$$

Here, ρ and z are cylindrical coordinates, the z axis is in the direction of the applied field E_0, and t is the time. The potential of an ideally conducting sphere in a uniform field E_0 is taken to be the initial condition for Eq. (1):

$$\Phi(\rho,\ z,\ 0)=-E_0 z\left(1-\frac{r_0^3}{(z^2+\rho^2)^{3/2}}\right). \tag{2}$$

Here, r_0 is the initial radius of the avalanche, which is determined by electron diffusion and mobility at the point at which the avalanche changes into a streamer. The velocity of the equipotential surface $\Phi = 0$ is determined by the electron velocity in the resulting field near this surface, i.e.,

$$v=|k\nabla\Phi|, \tag{3}$$

where k is the electron mobility.

It is shown in ref. 2 that near the ends of a streamer its surface is essentially the same as the surface of an ellipsoid of revolution; accordingly the true shape of the streamer, i.e., the equipotential $\Phi = 0$ is replaced by an ellipsoid of revolution.

To compare theory with experiment, however, requires that the theory developed in refs. 1 and 2 be refined It follows from (2) that when z = 0 the field is equal to zero; thus, all the points of this plane on the streamer surface remain fixed. It is easy to see that this leads to the formation of a "neck" and, thus, to a difference between the streamer shape and an ellipsoid of revolution.

Model of streamer propagation with the effect of the "neck" taken into account. The effect of the neck on streamer development can be considered if the following function is taken as the solution of Eq. (1):

$$\Phi=-E_0 z\left[1+\frac{p r_0^3}{(z^2+\rho^2)^{3/2}}-(1+p)\frac{\ln\frac{\sqrt{(f-z)^2+\rho^2}+f-z}{\sqrt{(f+z)^2+\rho^2}-f-z}+\frac{\sqrt{(f-z)^2+\rho^2}-\sqrt{(f+z)^2+\rho^2}}{z}}{\ln\frac{\sqrt{f^2+r_0^2}+f}{\sqrt{f^2+r_0^2}-f}-\frac{2f}{\sqrt{f^2+r_0^2}}}\right]. \tag{4}$$

Here,

$$p=\frac{\ln\frac{\sqrt{r_0^2+f^2}+f}{\sqrt{r_0^2+f^2}-f}-\ln\frac{a+f}{a-f}-\frac{2f}{\sqrt{r_0^2+f^2}}-\frac{2f}{a}}{\ln\frac{a+f}{a-f}-\frac{2f}{a}-\frac{r_0^3}{a^3}\left(\ln\frac{\sqrt{r_0^2+f^2}+f}{\sqrt{r_0^2+f^2}-f}-\frac{2f}{\sqrt{r_0^2+f^2}}\right)}. \tag{5}$$

The selection of Φ in the form of (4) is due to the following considerations. If we set p = 0, the rest of expression (4) gives the equipotential $\Phi = 0$ in the form of the surface of an ellipsoid of revolution with f as the distance between foci and major semiaxis a. If we set $a = r_0$, which is valid at the initial time, it then follows from (5) that p = −1 and (4) then gives the equipotential $\Phi = 0$ in the form of a sphere of radius r_0. Finally, when z = 0, $\rho = r_0$ the resulting field is

$$E=\sqrt{E_z^2+E_\rho^2}=\sqrt{\left(\frac{\partial\Phi}{\partial z}\right)^2+\left(\frac{\partial\Phi}{\partial\rho}\right)^2}=0, \tag{6}$$

which ensures that a neck is formed. The following two relations, which are independent of the model, are given in ref. 2 for the radius of curvature R of the streamer surface near its ends:

$$R=\frac{2\Phi'}{\Phi''}, \tag{7}$$

$$\frac{dR}{da}=2\left(\frac{\Phi'\Phi'''}{\Phi''^2}-2\right), \tag{8}$$

where Φ', Φ'', and Φ''' are values corresponding to the first, second, and third derivatives of the potential with respect to z at the point $z = a$, $\rho = 0$, i.e., at the end of the streamer. Finding the values of these derivatives from (4) and substituting into (7) and (8), we obtain (more detailed calculations are given in ref. 3)

$$R=-\frac{a^2-f^2}{a}\frac{1-\frac{r_0^3}{a^3}-\frac{3}{2}\frac{r_0^3(a^2-f^2)}{a^2f^3}A}{1-\frac{r_0^3}{a^3}-\frac{3}{2}\frac{r_0^3(a^2-f^2)^2}{a^4f^3}A}, \tag{9}$$

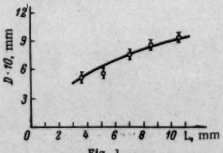

Fig. 1

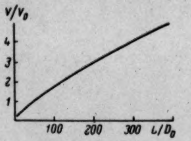

Fig. 2

$$\frac{dR}{da} = -6\frac{(a^2-f^2)r_0^3 f\left(1-\frac{r_0^3}{a^3}\right)A}{\left[1-\frac{r_0^3}{a^3}-\frac{3}{2}\frac{(a^2-f^2)^2 r_0^3}{a^4 f^3}A\right]^2 a^6}, \tag{10}$$

where

$$A = \ln\frac{\sqrt{f^2+r_0^2}+f}{\sqrt{f^2+r_0^2}-f} - \frac{2f}{\sqrt{f^2+r_0^2}} - \ln\frac{a+f}{a-f} + \frac{2f}{a}.$$

For $f \ll r_0$, i.e., $a \to r_0$, from (10) we find

$$\frac{dR}{da} \sim \left(1-\frac{r_0^3}{a^3}\right),$$

i.e., it is close to zero. As a increases dR/da goes to zero rapidly. Consequently, one can assume in the first approximation that as the streamer develops dR/da remains equal to zero, i.e., R = const; thus, as follows from (9) and (10),

$$|R| = r_0. \tag{11}$$

Using (9) to express f in terms of a and r_0 and substituting this value into the expression for $\Phi'(a)$ we find the relation $v = |k\Phi'|$. Since the streamer velocity is

Using (9) to express f in terms of a and r_0 and substituting this value into the expression for Φ' we find the relation $\Phi'(a)$. Since the streamer velocity is $v = |k\Phi'|$ we can find the dependence of the streamer velocity on its length.

It is also interesting to consider what shape the streamer surface will assume during its development. For this purpose the value of f obtained from (9) is substituted into (5). Then the function obtained, $p(a)$, is substituted into (4); for a definite value of a, after equating (4) to zero, we obtain the relation $z(\rho)$, i.e., the equation of the surface.

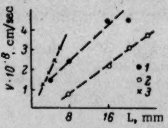

Fig. 3. Streamer propagation velocity as a function of length for different fields.

By selecting the maximum value of ρ for each a and considering this value to be the effective half-width of the streamer, we can also find the dependence of the half-width of the streamer on its length.

Figure 1 gives the maximum width of the streamer as a function of its length L, where $L = 2a$. The experimental results (points) obtained by Davidenko et al.[4] are also given in Fig. 1. In Fig. 2, the streamer propagation velocity is given as a function of length in the dimensionless parameters V/V_0 and L/D_0, where $D_0 = 2r_0$ and $V_0 = kE_0$. The calculations are performed on a CDC-1604A computer. Figure 3 gives the experimental results of Davidenko et al.[5] (1 – 16, 2 – 10.4 kV/cm) and Rudenko and Smetanin[6] (3 – 16.7 kV/cm).

It can be seen from Figs. 1-3 that good qualitative agreement exists between the theory and the experimental data. A quantitative comparison with experiment is difficult at the present time because of the absence of reliable data on the value of r_0, which is only known in order-of-magnitude terms.

In conclusion, the authors thank O. B. Firsov, M. M. Kulyukin, I. V. Falomkin, and Yu. A. Shcherbakov for useful discussion.

Electrical breakdown of vacuum gaps under superhigh voltage pulses

I. I. Kalyatskii, G. M. Kassirov, and G. V. Smirnov
S. M. Kirov Tomsk Polytechnical Institute

(Submitted November 12, 1973; resubmitted April 2, 1974)
Zh. Tekh. Fiz., 44, 2326-2328 (November 1974)

Experimental results are reported for electrical breakdown of centimeter vacuum gaps under superhigh voltage pulses. At distances up to 15 cm the breakdown field across the cathode is virtually constant, and the processes leading to the breakdown occur in short time intervals. In the microsecond time range the breakdown voltage is independent of the pressure and species of the residual gas.

The inadequate data on electrical breakdown of large vacuum gaps and the remarkable differences in the breakdown properties at superhigh voltages[1-4] have stimulated experimental investigations into voltages higher than 1 mV. For this purpose we have constructed a vacuum apparatus with a maximum pulsed working voltage of 2 mV. In the first stage of the investigation we study the electrical strength of the vacuum insulation in large gaps subjected to voltage pulses as a function of electrode separation and residual gas pressure. The experiments are performed in a steel vacuum chamber with superhigh voltage pulses provided by a GIN-3MV generator with a capacitance of 7200 pF. The voltage and current pulses are recorded on a dual beam OK-17M oscilloscope, and all the experiments employ aluminum electrodes. The cathode is a sphere 150 mm in diameter. The anode is a disk 200 mm in diameter. The working vacuum in the apparatus is $1\text{-}2\cdot 10^{-5}$ torr. The electrode separation is varied by means of a Wilson seal and is measured to within 0.05 mm.

Before the dependence of the breakdown voltage on the gap width is measured the electrodes are subjected to repeated preliminary breakdowns, which result in an increase and stabilization of the breakdown voltage. To estimate the effect of the resistance of the discharge circuit on the gap aging process, aging curves are plotted for three sharply differing resistances of the discharge circuit (Fig. 1). It can be seen from this figure that at all three resistances the breakdown voltage increases with the number of preliminary discharges. Since the width of the leading edge of the voltage pulse, and thus the time that the voltage acts on the vacuum gap, increases as the resistance of the discharge gap increases, the breakdown voltage is higher for small resistances than for large resistances. Since the resistance does not have a significant effect on the aging process, all the subsequent experiments are carried out for the smallest resistance, and the leading edge of the voltage pulse is then 0.5 μsec. The breakdown voltage is measured after 200-300 preliminary pulses. The curve is plotted from 20 oscilloscope traces of the breakdown for each electrode separation. The curve is plotted three times – for a change in the separation from a maximum to a minimum and vice versa.

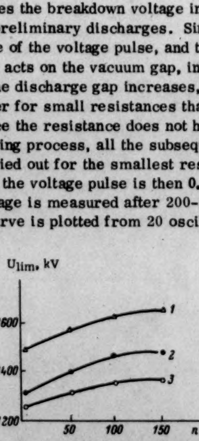

Fig. 1. Aging curves of vacuum gaps 90 mm wide with aluminum electrodes. 1) 50 Ω; 2) 4 kΩ; 3) 30 kΩ.

The curve in Fig. 2 shows the effect of electrode separation on breakdown voltage for breakdown at the leading edge of the voltage pulse. As can be seen from this figure, the breakdown voltage increases more slowly than the electrode separation. However, as a result of the increase in field inhomogeneity due to the increase in the electrode separation, the field voltage across the cathode, calculated from the well-known equation for a sphere-plane system:

$$E_{\text{lim}} = 0.9\frac{U_{\text{lim}}}{d}\left(\frac{r+d}{r}\right),$$

where E_{lim} is the field at the cathode, U_{lim} is the breakdown voltage, r is the radius of the sphere, and d is the electrode separation, varies by a small amount from 408 kV/cm for a 10 mm gap to 361 kV/cm for a 150 mm gap, i.e., it is virtually constant. Analytically the curve of breakdown voltage vs electrode separation is described by

$$U_{\text{lim}} = 400d^{0.61},$$

where U_{lim} is the breakdown voltage (kV), and d is the electrode separation (cm).

To estimate the possible coefficients of the pulse for a breakdown of large gaps the breakdown voltage is measured in 100 μsec pulses. This breakdown voltage is conventionally taken to be "static." The pulse coefficient for an 8 cm gap is of the order of 3.

Our experiments on the breakdown of centimeter vacuum gaps for different residual gas pressures indicate that the well-defined dependence of the breakdown voltage on the pressure for a constant voltage does not occur for a pulsed voltage in the microsecond range. The corresponding experimental results for 40 and 90 mm gaps are shown in Fig. 3 (curves 1 and 2). The dependence of breakdown voltage on the gas species is also absent. It should be noted that as for small gaps with pressures of 10^{-3}-10^{-2} torr the spread of breakdown voltages increases. Evidently, the processes leading to an increase in the

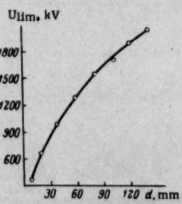

Fig. 2. Breakdown voltage as a function of gap width.

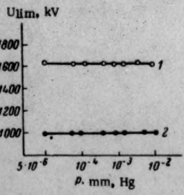

Fig. 3. Dependence of breakdown voltage on residual gas pressure in gaps of different width. 1) 90 mm; 2) 40 mm.

electrical strength of vacuum insulation of large gaps under static voltages at pressures of 10^{-3}-10^{-4} torr do not occur for pulsed voltages.

Thus, our investigation of the breakdown voltage of centimeter vacuum gaps under microsecond pulses leads to the following conclusions:

1. Under vacuum breakdown of centimeter gaps the breakdown field remains virtually unchanged as the gap width increases.

2. The well known dependence of the breakdown voltage of centimeter gaps on gas pressure for a constant voltage does not operate for microsecond pulses.

3. A reduction in the width of the pulse acting on an 8 cm vacuum gap from 100 to 0.5 μsec leads to a threefold increase in the breakdown voltage.

Volt–ampere characteristic of the low-voltage arc.
I. Recombination model

P. P. Shcherbinin

(Submitted March 26, 1973; resubmitted October 12, 1973)
Zh. Tekh. Fiz., 44, 2329-2339 (November 1974)

The parameter dependence of the volt–ampere characteristic is given with recombination and Coulomb scattering included; the derived expressions can be used for rapid analysis. The dependence of the characteristic on gap width is given as an illustration.

Baksht, Moizhes, and others (e.g., refs. 1, 2) have given a general theory of ionization and recombination processes in the plasma in a thermionic converter (TC) and have given solutions of the transfer equations. A number of other workers have studied qualitatively the specific effects on the volt–ampere characteristic due to specific phenomena. For example, volume ionization is considered in ref. 3, surface and volume ionization in ref. 4, volume ionization and Coulomb scattering in ref. 5, the Schottky effect in ref. 6, and the possibility of formation of a virtual cathode in refs. 5-7. In the present paper we analyze a model which takes account of surface and volume ionization, recombination, Coulomb scattering, and the Schottky effect. These are the most important physical phenomena that occur in the gap.

The only basic phenomenon that is not allowed for is the finite thermal conductivity of the electrons. At low pressures,[8] and at high voltages and high pressures,[9] the electron temperature can be assumed to be constant. In other cases the electron temperature can vary by some tens of percent along the gap.[1] If the electron temperature is not constant the generation rate is a function of the coordinate. As a result, in the model with $T_e(x)$ = const = T_e (T_e being understood as the mean electron temperature over the gap) the theoretical density profile will differ qualitatively from the experimental profile. But since the volt–ampere characteristic is defined by the integrated characteristic of the plasma[8,10] we expect that the model density profile will only introduce quantitative differences.

PLOTTING THE VOLT–AMPERE CHARACTERISTIC

To plot the characteristic we must obtain expressions for the potential jump $\varphi_{1,2}$ near the electrodes and the potential drop in the plasma $\delta\varphi$, which determine the voltage V across the gap (the subscript 1 refers to the cathode, 2 to the anode, $\varphi_1 > 0$, $\varphi_2 < 0$):

$$V = \varphi_1 + \delta\varphi + \varphi_2. \tag{1}$$

The jumps near the electrode can be determined from the boundary conditions for the particle and energy fluxes (we take these conditions in elementary form: $1/2$ for ions, $1/4$ for electrons[11]). But the number of unknown parameters in the boundary conditions ($\varphi_{1,2}$, $\delta\varphi$, $n_{1,2}$, the plasma density, V, $J_{1,2}$, the electron flux $J_{i\,1,2}$, the ion flux, and $Q_{1,2}$, the total energy flux of the electrons) is 12, while the number of boundary conditions is six. To close the system of equations we must find a link between the plasma parameters at the cathode and the anode, i.e., we must solve the system describing the plasma in the TC gap.

This system has the following form[5,12] ($0 \le x \le d$):

$$\frac{eJ_e}{\mu_{ea}} + \frac{e(J_e - J_i)}{\mu_{ei}} = -\Theta_e n' + en\varphi', \tag{2}$$

$$-\frac{eJ_i}{\mu_{ia}} - \frac{e(J_i - J_e)}{\mu_{ei}} = \Theta_i n' + en\varphi', \tag{3}$$

$$J'_e = J'_i = \alpha n\left(1 - \frac{n^2}{n_p^2}\right), \tag{4}$$

$$-Q' = (E_i + e\varphi)\, J'_e. \tag{5}$$

Here, E_i is the ionization energy; n_p is the plasma equilibrium density; $\Theta_{e,i} = kT_{e,i}$; the coefficients $\mu_{ea} = a_0/n_a$, $\mu_{ia} = c_0/n_a$, $\mu_{ei} = b_0/n$ are defined in refs. 5, 12, and 13; is n_a is the neutral density. Equation (4), as can be seen from ref. 14, is a qualitatively accurate description of the ionization and recombination process in the plasma; $\alpha = v_e n_a \sigma$; we use the expression given in ref. 14 for σ.

From (2), (3) we obtain [$\Lambda = \mu_{ia}/\mu_{ea}$, $D_a = (1 + \lambda)D_i$, $\lambda = \theta_e/\theta_a$, $\theta_i = \theta_a$].

$$J_i = -\Lambda J_e - D_a n' \tag{6}$$

and the equation for determining the density

$$n'' + \gamma^2 n\left(1 - \frac{n^2}{n_p^2}\right) = 0, \quad \gamma^2 = \frac{1 + \Lambda}{D_a}\alpha. \tag{7}$$

The fact that n_a depends on x is not taken into account, since $n \ll n_a$ at thermodynamic equilibrium; and as the discharge develops further the plasma density is determined by the expression $n \simeq n_p$.

From (7) we find

$$n'^2 = \frac{\gamma^2}{2n_p^2}(n_3^2 - n^2)(2n_p^2 - n_3^2 - n^2), \tag{8}$$

where n_3 is the maximum density in the gap; $n_3 < n_p$, and it follows from (8) that n(x) can reach the value n_p only in an infinitely long gap (for $n_{1,2} \neq n_p$).

The plasma density is ($z = n/n_3$, $y = n/n_p$, sn(x) is the elliptic sine[15])

$$z(x) = \operatorname{sn}(F\gamma x + \beta), \quad F = \sqrt{1 + \frac{y_3^2}{2}}. \tag{9}$$

Here, y_3 and β are integration constants and are determined from the boundary conditions for Eq. (7):

$$z_1 = \operatorname{sn}\beta, \tag{10}$$

$$z_2 = \operatorname{sn}(F\gamma d + \beta). \tag{11}$$

The resultant density profile makes it possible to determine the relationship between the plasma parameters between the cathode and the anode. Substituting (8) into (6), we obtain

$$J_{i2} - J_{i1} = J_{e2} - J_{e1} = \frac{D_a\gamma n_3}{\sqrt{2}\,(1 + \Lambda)}(K_1 + K_2),$$

$$K_{1,2} = [(1 - z_{1,2}^2)(2 - y_3^2 - y_{1,2}^2)]^{1/2}. \tag{12}$$

From (6), (8), and the boundary conditions for the ion flux we obtain a system of three equations for the three unknowns $n_{1,2,3}$ ($\psi_{1,2} = |e\varphi_{1,2}|/\Theta_e$; eJ_C is the Saha current):

$$z_1 = 2\frac{J_C e^{-\lambda\psi_1} + \Lambda J_{e1}}{n_3 v_i} + aK_1, \tag{13}$$

$$z_2 = -2\Lambda\frac{J_{e2}}{n_3 v_i} + aK_2, \tag{14}$$

$$F^{-1}(z,\ k) = \sqrt{(1 - z^2)(1 - k^2 z^2)},\quad k^2 = \frac{y_3^2}{2 - y_3^2},\quad a = \frac{\sqrt{2}\gamma D_a}{v_i},$$

$$F\gamma d = \int\limits_{z_1}^{1} dz F(z,\ k) + \int\limits_{z_2}^{1} F(z,\ k). \tag{15}$$

From (2), using (8), we can determine the voltage drop in the gap $\delta\psi = e\delta\varphi/\Theta_e$; F_R is the Richardson current (A/cm^2), D is the gap length (cm); $t_i = T_i/(10^3\,°K)$; eJ_R is the Richardson current; Λ_E is the Coulomb logarithm,

$$\delta\psi = \delta\psi_1 + \delta\psi_2 + \ln\frac{z_2}{z_1}, \tag{16}$$

$$\delta\psi_1 = \frac{J_{e2}}{D_e n_3 \gamma F}\ln F_1,\quad F_1 = \frac{\sqrt{1 - z_2^2 k^2} + \sqrt{1 - z_2^2}}{\sqrt{1 - z_1^2 k^2} - \sqrt{1 - z_1^2}}\frac{z_1}{z_2}, \tag{17}$$

$$\delta\psi_2 = c_5\frac{J_e - J_i}{J_R},\quad c_5 = \frac{edJ_R}{b_0\Theta_e} \simeq \frac{2.5\Lambda_e F_R D}{(\lambda t_i)^{3/2}}. \tag{18}$$

Here, $\delta\psi_1$ results from electron scattering on atoms (ohmic resistance of the plasma), while $\delta\psi_2$ results from scattering on ions (Coulomb scattering); $D_{e,i} = l_{e,i} v_{e,i}/3$; $l_e = 3l_i$. In integrating the term with J_e in (2), the quantity J_e is removed from the integral sign for $J_e = J_{e2}$; thus the expression for $\delta\psi_1$ is too high.

From (5) and the boundary conditions[11] for Q we obtain an equation which determines the energy balance in the gap ($U = eV/\Theta_e$),

$$J_{e2}U = 2\left(1 - \frac{1}{\lambda}\right)J_{em} + \left(\frac{S_3}{\lambda} + \bar{\psi} + 2\right)(J_{e2} - J_{e1}), \tag{19}$$

$$\psi_1 = \ln\frac{n_1 v_e}{4}\frac{1}{J_{em} - J_{e1}},\quad \psi_2 = \ln\frac{n_2 v_e}{4J_{e2}}, \tag{20}$$

$$V = \frac{\Theta_e}{e}\left(\ln\frac{J_{e2}}{J_{em} - J_{e1}} + \delta\psi_1 + \delta\psi_2\right). \tag{21}$$

Here, $\bar{\psi} \simeq \psi_1$ is the value of $e\varphi/\Theta_e$ at some median point of the gap; $s_3 = E_i/\Theta_i$; the term equal to two in (19) appears because J_{e2} differs from J_{e1} in $Q_{1,2}$; J_{em} is the electron emission flux.

$$J_{i2} - J_{i1} = \frac{n_1 + n_2}{2}v_i - J_C e^{-\lambda\psi_1}; \tag{22}$$

and setting $\bar{\psi} - \psi_1 - \delta\psi \simeq 0$, we find that (19) is replaced by

$$J_{e1}U = 2\left(1 - \frac{1}{\lambda}\right)J_{em} + \left(\frac{s_3}{\lambda} + 2 + \psi_2\right)\left(n_1 + n_2 - \frac{2}{v_i}J_C e^{-\lambda\psi_1}\right)\frac{v_i}{2}. \tag{23}$$

The boundary conditions for $Q_{1,2}$ used in deriving (23) are derived under the assumption that the beam of emission electrons is thermalized immediately at the cathode; this occurs at both low[8] and high[9] pressures.

We should note that the right side of (23) has the same form for any plasma density profile. Without volume ionization the losses due to this phenomenon are small and $n_1 + n_2 - 2J_C e^{-\lambda\psi_1}/v_i \to 0$. Equations (12) and (23) make it possible to determine V as a function of the total current $e(J_e - J_i) = eJ$. As can be seen from (12)-(23), Coulomb scattering only introduces additional losses – the term[5] $\delta\psi_2$ in V.

Above we have taken account of divergence of the electron current. The corresponding corrections in the expression for γ^2 and $J_{1,2,3}$ are of order λ [therefore J_{e2} can be replaced by J_{e1} in (14)]. Allowing for the fact that $J_e' \neq 0$ only in ψ_2 introduces a major contribution: From (22) for $n_{1,2}/2 \gg J_C e^{-\lambda\psi_1}/v_i$, $n_1 \sim n_2 \gg J_{em}/v_e$ we obtain $J_{e2} \simeq n_1 v_i$ and

$$\psi_2 \to \ln\frac{v_e}{4v_i},\quad n \to \infty, \tag{24}$$

whereas for $J_{e2} = J_{e1} < J_{em}$, $n_1 \simeq n_2$, bounded J_{em}, and $n_1 \to \infty$ (the model in ref. 4) we have $\psi_2 \to \infty$. From (13) and (14) we obtain

$$\frac{n_1 + n_2}{2}v_i = J_C e^{-\lambda\psi_1} + \frac{D_a\gamma n_3}{\sqrt{2}}(K_1 + K_2). \tag{25}$$

The left side of (25) is the ion flux leaving the gap, while the right side is the sum of ion fluxes arriving at the gap and generated in the gap. Analysis shows that balance of the ion fluxes [the left and right sides are equal in (25)] does not occur for any arbitrarily specified value of Θ_e. For example, in the absence of recombination Θ_e cannot be greater than the quantity Θ_{e0} defined by the equation [a consequence[3-5,16] of (25), where $s = \sin\gamma d$, $c = \cos\gamma d$]

$$\frac{n_1 + n_2}{2}v_i = (1 - c)\gamma D_a\frac{n_1 + n_2}{s} + J_C e^{-\lambda\psi_1} \tag{26}$$

for $J_C = 0$. If $\Theta_e > \Theta_{e0}$, more ions are generated in the gap than go to the electrodes. Recombination limits the regeneration rates and therefore we expect that Eqs. (13)-(15) will also have solutions for $\Theta_e > \Theta_{e0}$.

To take account of the Schottky effect, we need only add the expression[16,17] for J_{em} to the above equations.

VOLT–AMPERE CHARACTERISTIC WITHOUT RECOMBINATION

The case in which the Schottky effect is small and there is no Coulomb interaction and $J_e' = 0$ is considered in ref. 4 (the boundary conditions for ions are taken with $1/4$ in ref. 4), it is shown that surface ionization leads to Θ_e being a function of J [this conclusion can be readily obtained from (26)]. However, near $J_e \simeq J_{em}$ ($J_e > 0.5\,J_{em}$) $\Theta_e \simeq$ const, while[16] $n_1 \simeq n_2$. The same is valid (as can readily be shown) for the case under consideration (Schottky effect and Coulomb scattering $J_e' \neq 0$). When $d//l_i \gg 1$, Eq. (26) for Θ_{e0}, which can conveniently be written in the form $M = 0$ [$M = c + B - 1$, $B = sv_i/(2D_a\gamma)$], reduces to the expression[3,5] $\gamma d = \pi = \varepsilon_1$, $\varepsilon_1 = 4D_a\gamma/v_i$.

The plasma density at the maximum n_3 is related to $n_{1,2}$ by an expression that is a consequence[4] of (15),

$$sn_3 = \sqrt{n_1^2 + n_2^2 - 2n_1 n_2 c}. \tag{27}$$

In the $M = 0$ approximation we obtain $z_1^2 = 2a^2/(1 + a^2) =$ const, and from (27) for $d/l_i \gg 0$ we find ($n_1 = n_2$).

$$n_1 = \frac{1}{2}\varepsilon_1 n_3. \tag{28}$$

For small current $J_e \nless 0.5\,J_{em}$, if we disregard the possibility of formation of a virtual cathode[5-7] and surface ionization,[4] the voltage begins to increase with decreasing current. Allowance for surface ionization and the possibility of a virtual cathode markedly narrows (in terms of parameter values) the region of formation of the drooping part of the volt–ampere characteristic.[4,7] For $J \gtrsim 0.5\, J_{em}$ the voltage increases monotonically with the current, while $n(x) \to \infty$.

ALLOWANCE FOR RECOMBINATION

The size of the electrode region L in which the plasma is not in equilibrium is defined by an expression obtained in refs. 1 and 2 (p is the pressure in mm Hg),

$$\frac{L}{d} \equiv \frac{1}{\gamma d} = \frac{1}{pD} 10^{-5+\frac{8.1}{\lambda l_i}}.$$

In the model without recombination, taking M = 0 for $d \simeq l_i$ we obtain L > d; for $d \gg l_i$ $\gamma d \simeq \pi$. Here, γ increases with Θ_e, equilibrium is established at the center of the gap, and the nonequilibrium regions are restricted to the electrode regions.

Let us first consider the case in which the recombination is small: $y_3 \ll 1$. From (8) we obtain

$$F\gamma x = \int_{z_1}^{z} dz' F(z', k). \tag{29}$$

We expand the integrand in powers of $k^2 \ll 1$; retaining the first two term we obtain [the upper sign for $0 < x < x_3$, the lower for $x_3 < x < d$, $n(x_3) = n_3$]

$$z(x) = \sin\left[\gamma_1 x + \beta \pm \frac{k^2}{4+k^2}\left(z\sqrt{1-z^2} \mp z_1\sqrt{1-z_1^2}\right)\right],$$

$$\gamma_1 = \gamma \frac{F}{\varepsilon_5}, \quad \varepsilon_5 = 1 + \frac{k^2}{4}. \tag{30}$$

The third term in brackets in (30) is of order (y_3^2) and can be neglected. Then $z(x) = \sin(\gamma x + \beta)$, and all the results of ref. 4 hold provided that we replace γ by γ_1. Here, Eq. (27) will be a transcendental equation in n_3.

When $z_{1,2} \ll 1$, (30) is a fairly good approximation all the way to $k^2 \le 0.95$ [this follows from comparing the exact value of (15) (with $z_{1,2} = 0$)] and its expansion in powers of k^2]. This result follows because the contribution to recombination is determined by an integral of $J_e' \sim 1 - n^2/n_p^2$.

Let us investigate the case $1-k^2 \ll 1$ ($k^2 > 0.95$), $z_{1,2} \in [0, 1)$ further. We assume that the terms with $J_{e1,2}$, J_C in (13) and (14) can be omitted because they are small (developed arc). In this case $y_1 = y_2$, and we obtain the following expression for y_1 from (13) (which can also be used for $k^2 < 0.95$, $y_1 = y_2$)

$$y_1^2 = 1 + \frac{1}{2a^2} - \sqrt{\left(1 + \frac{1}{2a^2}\right)^2 - y_3^2(2 - y_3^2)}. \tag{31}$$

We make the following estimates, using the fact that $\int_0^z dz' F(z', k) < \int_0^{z_1} dz' F(z', 1) \equiv \ln[(1 + z_1)/(1 - z_1)]/2$:

$$\int_{z_1}^{1} dz' F(z', k) + \int_{z_2}^{1} dz' F(z', k)$$

$$\leqslant \int_0^1 dz' F(z', k) - \ln b, \quad b^2 = \frac{(1+z_1)(1+z_2)}{(1-z_1)(1-z_2)}. \tag{32}$$

When $z_{1,2} \ll 1$ the second term in (32) is small ($b \simeq 1 + 2z_1$), and (15) is replaced by K(k), an elliptic integral of the second kind:

$$F\gamma d = 2K(k). \tag{33}$$

We note that Eqs. (31) and (32) have a solution for all $\lambda \in [1, \infty)$; in the case in question, therefore, ion balance does not impose constraints upon the growth of λ. When $1-k \ll 1$ we have[18] $k(j) \simeq \ln(4/\sqrt{1-k^2})$. This expression for K(k) can be used for all $k \in [0, 1)$; when $k^2 \to 1$ it coincides with the exact expression, and when k = 0 it differs by less than 15%. From (15) and (32) we obtain

$$\gamma d = \frac{1}{F} \ln \frac{16}{(1-k^2)\, b}. \tag{34}$$

Thus Eqs. (31) and (34) determine the quantities $y_{1,3}$. For $k^2 > 0.95$, y_3 is almost equal to unity, and only in (17) is this difference substantial ($\delta\psi_1$ diverges if we formally set $z_1 = z_2$, $k^2 = 1$). Expanding F_1 in (17) in the neighborhood of $z_1 = 0$ ($a^2 \gg 1$, see (31); $F_1 \simeq 4/[(1-k^2) z_1^2]$), and then in the neighborhood of $z_1^2 = 1$ ($a^2 \gg 1$, $z_1 = 1 - 1/a$), and using (34), we obtain an approximation for $\delta\psi_1$:

$$\delta\psi_1 = \frac{J_{e2}(d + d_1)}{D_e n_3}, \quad d_1 = \frac{1}{\gamma F} \ln \frac{b}{(4 + 2a) z_1^2}, \tag{35}$$

which, for $a^2 \ll 1$ and $a^2 \gg 1$ [and also as $k^2 \to 0$, γd being determined from (34) in this case], goes over the exact expressions.

Equations (31) and (34) together with (21) and (23) [the term with J_C being dropped in (23)] describe the volt–ampere characteristics; they hold for all $k \in [0.1)$. If Θ_e is taken as a parameter the numerical solution of these equations presents no problems. Indeed, if Θ_e is known the equations separate into Eqs. (31) and (34) in $y_{1,3}$ and Eqs. (21) and (23) in V and J_{e1}. Finding $y_{1,3}$ and substituting V from (21) into (23) we can obtain a simple expression for J_{e1}.

As z_1 approaches unity, we obtain $z_1^2 = 1 - 1/a$, $b = 2a$ from (31) (for $y_3 = 1$), and d_1 vanishes ($2a \gg 4$):

$$\delta\psi_1 = \frac{J_{e2} d}{D_e n_3}. \tag{36}$$

Equation (36) can also be obtained directly from (2) when $n(x) \equiv n_3$.

When $y_{1,2,3} \simeq 1$ the plasma in the gap is in equilibrium, and therefore the relationship between the plasma densities at the cathode and anode is trivial, since $n_1 = n_2 = n_3 = n_p$, and the need for considering (13)-(15) is obviated. It is also easy to obtain (36). This case is equivalent to the total equilibrium model in ref. 1.

SIMPLIFIED EXPRESSIONS FOR THE VOLT–AMPERE CHARACTERISTIC

When surface ionization is unimportant we can obtain simple expressions (where we assume that $J_{e1} = J_{e2} = J$, the difference between J_{e1} and J_{e2} being small). In this region, Eqs. (21) and (23), which describe the basic processes in the plasma, assume the following form [$n_1 = n_2$, $b = (1 + z_1)/(1 - z_1)$]:

$$V = \frac{\Theta_e}{e}\left[\ln \frac{J}{J_{em} - J} + \frac{J(d + d_1)}{D_e n_3} + \delta\psi_2\right], \tag{37}$$

$$VJ=\frac{\Theta_e}{e}[a_5J_{\text{em}}+a_3v_in_1],\quad a_3=\frac{\varepsilon_3}{\lambda}+2,\ a_5=2\left(1-\frac{1}{\lambda}\right). \tag{38}$$

To close (37) and (38), it remains only to give the relationship between the density at the maximum n_3 and the density at the electrode n_1, and to find Θ_e; this is done by using (31) and (34) (for arbitrary $y_{1,3}$).

Let us first consider the case $k^2 \ll 1$. Replacing γ by γ_1 in $M(\lambda)$ and in (27), we obtain

$$\gamma_1 d \simeq \pi,\quad \gamma d=\frac{\varepsilon_5\pi}{F}, \tag{39}$$

$$n_1 \simeq \frac{F}{\varepsilon_5}\frac{\varepsilon_1}{2}n_3 \equiv \frac{2\pi D_a}{v_i d}n_3, \tag{40}$$

where Eq. (39) is the analog of (13), and (14), while Eq. (40) is the analog of (15). Expression (39) implies that Θ_e varies slightly with increasing y_3 (by about 0.1 Θ_e for $J_3 = 1$), while (40) indicates that the ratio n_1/n_3 does not change and is the same as (28) (there is no recombination).

We obtain expressions for $\delta\psi_1$ by setting k = 0 (17) and replacing γ by γ_1. If we obtain an expression for $\delta\psi_1$ from (35) we should not retain the term with k^2 in F and use (40); if the term with k^2 is kept in F we obtain the expression $z_1 = z_{1a} + z_{11}k^2$ from (31) in place of (40) (the subscript *a* indicates that the value is defined without recombination). From (37), (38), and (40) we obtain the expression $[b \simeq 1,\ 4+2a \simeq 4,\ d+d_1 \simeq d_0 \equiv 2d\ln[\nu_i d/(\pi D_a)]/\pi]$

$$V=\frac{\Theta_e}{e}\left[\ln\frac{J}{J_{\text{em}}-J}+a_2\left(\frac{eV}{\Theta_e}-\frac{a_5J_{\text{em}}}{J}\right)^{-1}+\delta\psi_2\right],\quad a_2=\frac{2a_3d_0D_a\pi}{dD_e}, \tag{41}$$

which is the same in form (if we omit $\delta\psi_2$) as the volt–ampere characteristic without recombination,[16] but now $\Theta_e \neq$ const. The next approximation can be obtained by allowing for z_{1a} in z_1. When $z_1 \ll 1$ the approximation holds all the way to $k^2 \leq 0.95$; it then follows that recombination has virtually no effect on the characteristic in its initial stage of development ($z_3 \to 1$). If, however, z_1 is not small, if $z_3 \simeq 1$ there will be substantial recombination over the entire gap and we must use a more exact approximation for the characteristic.

From (38) and (41) we find $n_1 = n_1(J)$, and hence $n_3(i = J/J_R)$:

$$n_1=\frac{10^{13}}{2.9}\lambda\sqrt{t_i}\varepsilon_2F_R,$$

$$\varepsilon_2=\sqrt{4i^2a_2+(a_1+i\delta\psi_2)^2}+a_1+i\delta\psi_2, \tag{42}$$

$$a_1=i\ln\frac{J}{J_{\text{em}}-J}-2\left(1-\frac{1}{\lambda}\right)\frac{J_{\text{em}}}{J_R}.$$

Setting $\Theta_e = \Theta_{e0}$ and comparing the results with $n_p(\Theta_{e0})$, we can readily determine how close $n_{1,3}$ is to the equilibrium value for a given J.

When $k^2 > 0.95$ the approximation above is no longer effective. Since $y_3 \simeq 1$, when $k^2 > 0.95$, by setting $y_3 = 1$, we replace (34) by

$$n_3=n_p\equiv\left(n_aN_ee^{-\frac{E_i}{\Theta_e}}\right)^{1/2}, \tag{43}$$

(N_e is the density of electron states), which makes it possible to express γ, a quantity which depends exponentially on Θ_e, in terms of n_3, $[\gamma \sim \sigma^{1/2} \sim e^{-E_0/2\Theta_e}$, $E_0 = 3.21$ eV, (ref. 14), $\omega_1 = E_0/E_i]$:

$$n_3^2=n_aN_e\left(\frac{\gamma}{\gamma_2}\right)^{2/\omega_1},\quad \gamma_2=\gamma e^{\frac{E_0}{2\Theta_e}}. \tag{44}$$

As a result, only an algebraic dependence of the terms on Θ_e remains in all equations except for (43). Since Θ_e varies slowly, Eq. (43) can be omitted, in a first approximation by setting $\Theta_e = \Theta_{e0}$ in the remaining one.

As already noted, however, the solution of the complete system of equations does not present difficulties when Θ_e is taken as a parameter, the more so because when $y_3 = 1$ (43) and $[a = n_3^{\omega_1}/A$, $A = v_i(n_a N_e)^{\omega_1/2}/\sqrt{2}D_a\gamma_2$, $x = 1/a]$:

$$z_1=\sqrt{1+\frac{x^2}{4}}-\frac{x}{2}, \tag{45}$$

this being a consequence of (31) for $y_3 = 1$, determines $n_{1,3}$ directly.

It follows from the above expressions that the effect of recombination of $\delta\psi_1$ is marked if $\delta\psi_1 \gg \delta\psi_{1a}$:

$$\frac{1}{n_3}\left(1+\frac{d_1}{d}\right)\gg\frac{1}{n_{3a}}\frac{2}{\pi}\ln\frac{1}{z_{1a}}, \tag{46}$$

where n_{3a} is determined from (28) and (42). The quantity d_1 characterizes the degree of recombination. When $z_1 \simeq z_{1a}$ recombination is important only in the center of the gap ($y_3 \to 1$, γ of order π/d, and $d + d_1 \simeq d_0$). When $z_1 \gg z_{1a}$ recombination is important over the entire gap, and $d_1 \gg d$, when $a \ll 1$, we obtain from (45):

$$z_1=a(\gamma)\ll 1. \tag{47}$$

We note that (47) is the same as (40) to within 4/5 ($k^2 = 1$). From (47) we find ($\omega = E_i/(E_0 + E_i)$).

$$n_3=(An_1)^{\omega}, \tag{48}$$

and the volt–ampere characteristic is defined by the following equation ($b \simeq 1$, $4 + 2a \simeq 4$, $z_1 = n_1^{1-\omega}/A^{\omega}$):

$$V=\frac{\Theta_e}{e}\left\{\ln\frac{J}{J_{\text{em}}-J}+\frac{J}{D_e(An_1)^{\omega}}\left[d+\frac{4D_a(An_1)^{\omega}}{n_1v_i}\ln\frac{A^{\omega}}{n_1^{1-\omega}}+\delta\psi_2\right]\right\}. \tag{49}$$

When d_1 is small and can be omitted, we can readily determine n_3 from (37). Finding $n_1 = n_1(n_3)$ from (45) and substituting it into (38) with n_3 from (37), we obtain

$$UJ=a_5J_{\text{em}}+a_3v_in_3\left[\sqrt{1+\frac{A^2}{4}\frac{1}{n_3^{2\omega_1}}}-\frac{A}{2}\frac{1}{n_3^{\omega_1}}\right]. \tag{50}$$

The quantity ω is close to 1/2. Using this fact and setting $E_0 = E_i$, we find from (45)

$$n_3=\sqrt{An_1+n_1^2}. \tag{51}$$

In the limiting case $y_1 \simeq 1$

$$n_1=n_3=n_p(\Theta_e), \tag{52}$$

and (37) assumes the form

$$V=\frac{\Theta_e}{e}\left[\ln\frac{J}{J_{\text{em}}-J}+a_{21}\left(\frac{eV}{\Theta_e}-\frac{a_5J_{\text{em}}}{J}\right)^{-1}+\delta\psi_2\right],\quad a_{21}=\frac{a_3v_id}{D_e}, \tag{53}$$

which differs from the volt–ampere characteristic (41) without recombination by the coefficient a_{21} (which defines the relation between n_3 and n_1), this being larger than a_2 by roughly a factor of d/l_i. Equation (53) together with (38) and n_1 from (52) define the volt–ampere characteristic. These expressions imply expression (42) for the density, in which a_2 should be replaced by a_{21}.

In view of our approximations, when $y_3 \rightarrow 0$ Eq. (31) does not lead to the equation $M = 0$ for Θ_{e0}, but to the equation $\gamma d = \ln [16(1-z_1)/(1+z_1)]$, where z_1 is determined from (34) and is the same as its exact limiting value $z_1^2 = 2a^2/(1+2a^2)$. The quantity $\Theta_e = \Theta_{e1}$, which is a solution of these two equations, differs very little from Θ_{e0}; thus, when $d/l_1 = 2, 10, 100$ we obtain $\Theta_{e1} = 1.866, 1.657, 1.278$ and $\Theta_{e0} = 1.849, 1.699, 1.297$, respectively. Thus, approximation (31) is a qualitatively correct description of the way in which Θ_e changes with increasing y_3 and yields quantitative values that are close to the exact values.

Equations (43)-(53) for the characteristic (in which Θ_e should obviously be compared to Θ_{e1} and not Θ_{e0}) have a solution for all $J \in (0, J_{em})$, small currents corresponding to $\Theta_e < \Theta_{e1}$. We note that the solutions of (43)-(53) become meaningless for $\Theta_e \simeq \Theta_{e1}$ (and the more so for $\Theta_e < \Theta_{e1}$), and Eqs. (31) and (34) must be used instead. To describe the region of the characteristic with $\Theta_e < \Theta_{e1}$ we must take account of surface ionization [Eqs. (13) and (14)].

Figure 1 shows the volt–ampere characteristic in various approximations ($J_{em} = J_R$, $p = 4$ mm Hg, $J_R = 20$ A/cm², $d = 0.05$ cm, $T_k = 1800$°K). Curve 1 is plotted without recombination and Coulomb scattering [Eqs. (28), (37), (38), $\Theta_e = \Theta_{e1}$]; curve 2 from (37), (38), (43), (51) with $\delta\psi_2 = 0$ (without Coulomb scattering); curve 3 from (38), (49) with $\Theta_e = \Theta_{e1}$, $\delta\psi_2 = 0$; and curve 4 from (38), (43), (48), (49), $\delta\psi = 0$. Calculations using (37), (38), (44), (45), $\delta\psi_2 = 0$ coincide with this curve; $\Theta_e > \Theta_{e1}$ at all points of curve 4. Curve 9 is computed from (31), (34), (37), (38), $\delta\psi_2 = 0$; for this curve we also give the following functions: 10) $\lambda = \lambda(J)$, 11) $y_1 - y_1(J)$, 12) $y_3 = y_3(J)$. The shift in curve 9 relative to curve 4 toward curve 1 is due to the fact that y_3 is different from unity. Thus approximations with $\Theta_e(J) =$ const and (51) are unsatisfactory.

The voltage drop resulting from Coulomb scattering can be either much less than or much greater than $\delta\psi_1$. The case $\delta\psi_2 \gg \delta\psi_1$ is illustrated by curve 5 in Fig. 1, which is constructed from (31), (34), (37), (38) allowing for $\delta\psi_2$, and curves 6) $\lambda = \lambda(J)$, 7) $y_1 = y_2(J)$, 8) $y_3 = y_3(J)$. As indicated by (42), Coulomb scattering (for the same current value) leads to an increase in recombination (an increase in λ, y_1, y_3), and this is confirmed by curves 6-8 and 10-12.

Reference 19 gives equations analogous to (9), (13), and (14); in place of y_1 the author introduces d_e, the extrapolated length, this being equivalent to the use of inhomogeneous boundary conditions. The inequality $\Delta d_e/d \ll 1$ is the same as $y_1 = a \ll 1$; unlike this purpose here, however, the object in ref. 19 is to determine the optimum parameters.

QUALITATIVE FEATURES OF VOLT–AMPERE CHARACTERISTICS

Equations (37) and (38) are conveniently written in a form that is invariant to recombination. Let us follow the development of the plasma (increase in density and temperature) in the gap. From (37) we have that $V \rightarrow \infty$ as $J \rightarrow J_{em}$, which results in an unbounded increase in the left side of (38); the right side (for bonded J_{em}) can increase if n_1 and λ increase. In going to the arc mode, at first the applied energy JV (if we take the contact potential difference as the external source) is spent in heating the plasma from $\Theta_e \simeq \Theta_l$ to $\Theta_e \simeq \Theta_{e0}$; the term $a_5 J_{em}$ in (38) increases, and the term with n_1 is small,[4] since volume ionization is weak as a result of the low electron temperature.[4] When a temperature $\Theta_e \simeq \Theta_{e0}$ is reached, intensive volume ionization begins, the applied energy is spent in creating the plasma in the gap [n_1 in (38) increases, while $a_5 J_{em}$ is small], and the electron temperature remains virtually the same. As n_3 approaches $n_p(\Theta_{e0})$, recombination starts to come into play, and the increase in the plasma density is retarded. The applied energy is spent more on further heating of the plasma. Now Θ_e again begins to increase and equilibrium obtains.

The parameter pd in (31) and (34) is involved only in (34) and has almost no influence on z_1 for $y_3 \simeq 1$, as can be seen from (31). The degree of ionization, on the other hand, depends on p. At low pressures and with increasing Θ_e, therefore, the density n_p approaches n_a even for $z_1 \ll 1$ and the degree of ionization approaches unity at the center of the gap.

Since recombination increases Θ_e and retards the growth of n_3, it follows from (37) that the characteristic shifts to the right when recombination is allowed for. In the $\Theta_e(J_e) =$ const approximation it is easy to show that dJ/dV decreases when recombination is allowed for. As a result, the increase in the characteristic is more shallow, and the point of transition to the segment with $dJ/dV < 0$ (if it exists) occurs farther down (curves 1, 5, and 9 in Fig. 1).

Recombination alters the function $V = V(d)$, $J =$ const. Recombination is weak for small d, and from $\gamma d = \pi$ we obtain

$$\lambda \simeq \lambda_0 = \frac{E_0}{2} \frac{1}{\ln(100 b_2 l_i/d)}, \quad b_3 = \left(\frac{1.5\sqrt{\lambda}}{1+\lambda}\right)^{1/3}. \tag{54}$$

The decrease in Θ_e with increasing d here is the result of the same factors as the decrease in Θ_e in a positive glow-discharge column[20] with increasing tube radius. Thus, as is seem from (37), the characteristic shifts to the left ($V \sim \Theta_e$), and $d + d_1 \simeq d_0$

Recombination is more important for large d, and

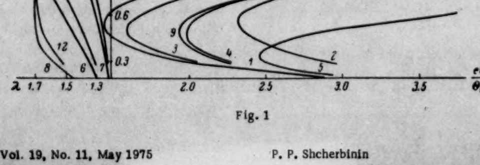

Fig. 1

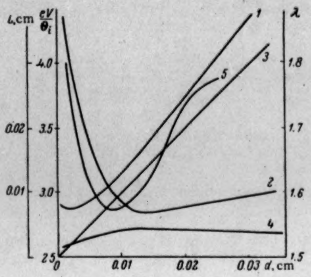

Fig. 2

near equilibrium we have $d_1 \ll d$, $n_1 \simeq n_3$. A strong dependence on d appears in $\delta\psi_1$, and this causes the characteristic to shift to the right ($d_1 \ll d$). For $\delta\psi_2 \gg \delta\psi_1$, Coulomb scattering leads to a similar result. Near equilibrium, we can use (42) in place of (54) for λ, with a_{21} instead of a_2; this implies that for the case of equilibrium, λ increases with d. Thus with increasing d the electron temperature first drops, and then begins to increase (curve 2 in Fig. 2).

Curve 1 in Fig. 2 shows V = V (d) as found for the parameters indicated in ref. 21, and $J/J_R = 0.8$ from (31), (34), (37), (38); the basic contribution to $\delta\psi$ in this case comes from $\delta\psi_2$. Curve 5 shows the experimental V = V (d) dependence (ref. 21, Fig. 3); curves 1 and 5 are combined with respect to voltage). Curves 2) λ = λ (d), 3) L = d, 4) L = L(d) illustrate the process of formation of a positive column in the gap (regions with a plasma in equilibrium[14,21,22]). In Fig. 2 we have p = 4 mm Hg, J_R = 20 A/cm², T_k = 1800°K.

CONCLUSIONS

1. The model we have considered with infinite electron thermal conductivity [$T_e(x)$ = const] makes it possible to establish the effects of the various physical phenomena, such as recombination and Coulomb scattering on the volt–ampere characteristic. But certain model-related results appear here, namely the symmetric distribution of the plasma density n(x) and the absence of a region in which recombination predominates [everywhere we have $n(x) < n_p$; in the model with $T_e(x)$ = const we have $n(x) > n_p(x)$ near the anode[14]].

2. Recombination and Coulomb scattering shift the characteristic to the right.

3. Coulomb scattering results in an increase in recombination.

4. Electron temperature increases with current, the value being determined, by surface ionization (and radiation),[4] in the transition to the arc mode and by recombination and Coulomb scattering in the arc mode.

5. The appearance of an optimum voltage as the gap is increased[21] results from the development of recombination and Coulomb scattering.

6. Expressions have been obtained that make it possible to determine $T_e(J)$ and the contribution from recombination and Coulomb scattering to the characteristic in various approximations. The most satisfactory results are provided by expressions (31), (34), (37), and (38), which hold with good accuracy for an arbitrary degree of recombination.

Gasdynamic model of the spark discharge

Yu. K. Bobrov

Kiev Polytechnic Institute

(Submitted March 30, 1972; resubmitted April 8, 1974)

Zh. Tekh. Fiz., 44, 2340-2347 (November 1974)

Spectroscopic investigations of the temperature and density characteristics of the plasma in a pulsed arc in air are described. Concepts of gasdynamic processes during detonation and deflagration of the fuel gases together with the physical conditions at the boundary of the discharge are used to interpret the experimental data. The boundary of the spark channel is treated as the front of a cylindrical ionization wave, whose velocity is determined by radiant heating of the cold gas.

Studies of spark discharges in gases[1-15] have provided the basic theoretical mode for the electrical and physical processes which occur in gas discharge gaps. It has been experimentally established that shock waves are initiated by the discharge in free gaseous atmospheres. These serve as a basis for the development of a gasdynamic theory of the spark.[8,9] The mechanism by which the high-temperature spark channel expands can be described by a model with nonequilibrium[12] or equilibrium[13,15] thermal waves. A series of self-similar solutions for the motion of the gas in expansion of a cylindrical piston[8,9,12] indicates agreement between experiment and theory for the temperature and expansion velocity of the spark channel. Continuity of the gas velocity and pressure at the channel boundary is taken as the boundary condition for these solutions. Under certain experimental conditions[13,14] a pressure jump is observed at the boundary of the channel; this has an important role in the gasdynamics of the spark discharge. The present work discusses the basic results of earlier investigations of the physical properties in a pulsed arc channel in air.[13,14] In the analysis of these results we use concepts from an earlier theory of detonation and deflagration of fuel gases.[16-18] As Raizer[19] has shown in a series of papers, some processes in the propagation of electrical and optical discharges can be regarded as direct analogs of the detonation and deflagration regimes of fuel gases.

In refs. 13 and 14 spectroscopic investigations of the temperature and density characteristics of a pulsed arc channel in air are performed in a discharge gap up to 50 cm long with discharge currents of 10 to 50 kA and a current rise time τ_M = 13-22 μsec. By mirror scanning of the stigmatic image of the pulsed arc channel in the plane of the input slit of an ISP-51 spectrograph (focal length f = 270 mm), with an exposure time of t_e = 1 μsec, spectrograms of the emission from the discharge channel are obtained at various values of the discharge current. The spectrograms yield the spatial and temporal characteristics of the channel. The experimental apparatus and technique for determining the temperature and density of the electrons are described in detail in refs. 10, 13, and 14.

The temperature is determined from the relative intensities of the nitrogen lines N II 504.5 nm, N II 517.9 nm, N II 549.5 nm, and N II 553.5 nm, which have previously been used for this purpose in ref. 7. This temperature coincides with that of the heavy particles in the plasma. The electron–ion relaxation time, τ_{ei}, for the plasma in the discharge channel with electron temperature $T_e = 4 \cdot 10^4$ °K, ion density $N_i \sim 10^{17}$ cm^{-3}, charge $z_i \approx 2$, and atomic weight A = 16 (oxygen) is[20]

$$\tau_{ei} = \frac{250 A T_e^{3/2}}{N_i z_i^2 \ln \lambda} \sim 10^{-7} \text{ sec}$$

($\ln \lambda = 5$ is the Coulomb logarithm), which is two orders of magnitude smaller than the characteristic time for the discharge current, $\tau_p = 10^{-5}$ sec.

The electron density is determined from the half-widths of Stark profiles (Hα, Hβ) of hydrogen fed into the discharge gap as a small impurity; the nitrogen lines (N II 453 nm, N II 442.7 nm) are also used. The parameters for Stark broadening of these lines are given in ref. 21. The absolute values of the electron density obtained from broadening of the nitrogen and Hβ lines are in satisfactory agreement. The time dependence of the electron density in the discharge channel is constructed from the data on broadening of nitrogen lines since these are available for the entire time interval of interest. The intensities and half-widths of the spectral lines are determined from the contours of the corresponding spectral lines obtained after conversion of the observed intensities into local values for an optically thin cylindrical radiator (Abel inversion).[21]

Some of the resulting radial and temporal properties of the pulsed arc channel in air are shown in Figs. 1 and 2. A characteristic of the radial temperature profile is the flat central part and the sharp decrease in temperature at the boundary of the channel (Fig. 1). The channel boundary is defined by the emission of nitrogen lines whose excitation temperature is high. In the time interval studied here (Fig. 2) the temperature on axis decreases monotonically from $T = 4.5 \cdot 10^4$ °K (t = 1 μsec) to $T = 3 \cdot 10^4$ °K (t = 18 μsec). According to line-broadening data on Hα from the sheath surrounding the channel, the electron density is continuous at the channel boundary (Fig. 1). An increase in the electron density with time is observed as

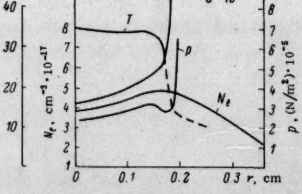

Fig. 1. Radial distributions of electron density (N_e), relative density ($\delta = \rho/\rho_H$), kinetic pressure (p), and temperature (T) of the air in a spark channel with a discharge gap of length 50 cm at t = 5 μsec with a current amplitude I_M = 13 kA and a current rise time to maximum of τ_M = 19 μsec. $\rho_H = 1.29 \cdot 10^{-3}$ g/cm³ is the normal pressure of air.

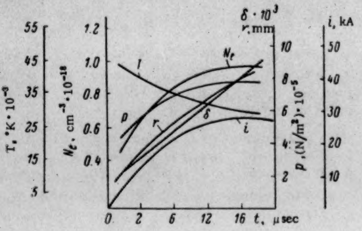

Fig. 2. Time variation of temperature (T), relative density (δ), kinetic pressure (p) of the air, and electron density (N_e) in a spark channel with a discharge gap of length 50 cm and current i. r is the radius of the spark channel.

current varies from zero to its maximum value and the temperature decreases (Fig. 2).

The rate of the relatively slow process of establishment of equilibrium ionization in the plasma can be estimated from the relaxation times for ionization of atoms from the ground state by electron impact (τ_e) and by photoionization (τ_ν). According to ref. 20, $\tau_e = (\alpha_e N_a)^{-1}$, where N_a is the density of atoms, and α_e is the rate constant for electron impact ionization, given by $\alpha_e = \sigma_e \bar{v}_e (I/T_e + 2) \exp(-I/T_e)$. Here, $\sigma_e = CT_e$ is the mean value of the effective cross section for ionization by electron impact (the constant $C \sim 10^{-17}$ cm^2/eV), I is the ionization potential of the atom, T_e is the electron temperature, and $\bar{v}_e = 6.71 \cdot 10^7 T_e^{1/2}$ is the mean thermal velocity of the electrons. From interferometer measurements,[5] we find $N_a \sim 10^{16}$ cm^{-3} in the spark channel, which for I = 14.6 eV (nitrogen) and $T_e = 4$ eV gives $\sigma_e \approx 4 \cdot 10^{17}$ cm^2, $\bar{v}_e = 1.34 \cdot 10^8$ cm/sec, $\alpha_e = 1.05 \cdot 10^{-10}$ cm^3/sec, and $\tau_e = 10^{-6}$ sec. The photoionization relaxation time τ_ν is given by $\tau_\nu (N_e)/\alpha_\nu N_a$, with $\alpha_\nu = 8.68 \cdot 10^6$ sec^{-1}, which for the same conditions, an equilibrium electron density $(N_e) \sim 10^{17}$ cm^{-3}, and an effective photoionization cross section $\sigma_\nu = 7.5 \cdot 10^{-18}$ cm^2, gives $\alpha_\nu = 8.68 \cdot 10^6$ sec^{-1} and $\tau_\nu \approx 10^{-6}$ sec. Thus, the time required to establish ionization equilibrium in this discharge channel is an order of magnitude less than the characteristic time for changes in the discharge current ($\tau_e \sim \tau_\nu < \tau_p$) and the experimentally measured[14] electron densities are nearly in equilibrium. Thus, the measured electron temperature and density can be used in determining the density and kinetic pressure of the gas in the channel from calculations of the equilibrium composition of an air plasma. In addition to providing estimates of the absolute values of the density and kinetic pressure of the gas, this approach demonstrates the tendency of these quantities to change in time and at the boundary of the channel. Thus, in moving from the channel to the sheath [whose temperature is tentatively equal to the temperature of maximum excitation of the Hα line ($T_0 = 1.5 \cdot 10^4$ °K) and whose particle density $N_a \sim 10^{18}$ cm^{-3}], the electron density measured in the sheath can be less than the equilibrium value since $\tau_{e,\nu} \sim 10^{-5}$ sec. In this case the possibility remains of explaining the direction of change in the density and gas pressure at the channel boundary, in addition to a jump in gas density,[5] there is a pressure jump from a lower value of the pressure in the channel (while the gas density in the channel increases in time). The possible existence of this kind of pressure jump and of this time dependence for the gas and electron densities must be explained on the basis of the general propositions of gasdynamics and appropriate numerical estimates.

We now consider possible reasons for the experimentally observed expansion of the spark channel in time. Expansion of the discharge at a boundary with cold air layers is possible if the electrical conductivity attained in these boundary layers is high during heating and ionization (comparable with the electrical conductivity of the plasma in the channel). From theoretical and experimental data,[22] the electrical conductivity σ of an air plasma increases sharply with temperature for $T = 0.4$–$1.2 \cdot 10^4$ °K and reaches some sort of saturation for $T_I \ge 1.5 \cdot 10^4$ °K, for which it is possible to use the approximation $\sigma(T_I) \approx \sigma(T)$. Up to the ionization temperature[19] T_I, heating the layers of air adjacent to the spark channel will cause propagation of the current zone with the release of Joule heat into the layer and heating of the gas up to the channel temperature. Regardless of the specific mechanism for initial heating of the air up to T_I, the subsequent heating is due to the Joule heating by the discharge current, since the effectiveness of the initial heating mechanism is reduced sharply. It is evident that the rate of expansion of the channel must be considered on the basis of the initial mechanism for heating of the gas to T_I; however, the magnitude of the Joule energy in the channel can affect this process.

Shock heating of the gas at maximum front velocities of $D_s = 2$–5 km/sec yields low temperatures at the front, $T_s = 2$–$7 \cdot 10^3$ °K $< T_I$. Thus the boundary of the spark channel, which moves at the indicated velocities, cannot be a shock front. This is certainly the case for the subsequent stages, in which the expansion velocity of the spark channel is smaller than the sound speed in the sheath surrounding the channel, where the gas temperature is between 1 and $1.5 \cdot 10^4$ °K.

The heating of the air to T_I can be due to the absorption of radiation from the channel itself as in the propagation of equilibrium and nonequilibrium thermal waves.[20] The release of Joule energy in the channel during expansion leads to conditions differing from those usually considered for thermal waves produced by the instantaneous release of energy at an initial time.

In the initial stages of the discharge, when the shock front has not yet separated from the channel and the latter is expanding into a region of cold and motionless air, the plasma density in the channel is determined by the density of the air swept up by it. The plasma radiates approximately as a blackbody at temperatures T = 4–5 eV as indicated by the high continuum levels in the emission in the earliest states. It is known that cold air at normal density completely absorbs radiation at $\lambda = 186$ nm or less in molecular levels. For a channel temperature T of 4–5 eV the maximum spectral density of the radiated energy occurs at $\lambda_M = 62$–50 nm. That is, the radiation from the channel is absorbed, for the most part, by the cold layers of air at the channel boundary, heating them. Depending on how much the gas has been heated, the mechanism by which light is absorbed changes, so that after complete molecular dissociation the basic absorption mechanism is the absorption of photons by atoms in the ground state or in low excited states. Absorption of photons is also the principal mechanism for heating the air in the subsequent stages of the spark, when the shock front has separated from the channel boundary. In this case the channel is in the rear of the shock wave, the density of gas in the channel is small, and the emission is characteristic of an optically thin medium. The width of the radiative heating zone in both cases may be estimated from the absorption coefficient $\varkappa_\nu = 1/l_\nu \sim 1/\Delta r$ for photons with an energy, $h\nu$, equal to the ionization energy, I, of air[20]

$$\varkappa_\nu = 0.96 \cdot 10^{-7} \frac{N z^{*2}}{T^2} \frac{2x_1}{x^3} \text{ cm}^{-1},$$

where $x_1 = I/kT$, $x = h\nu/kT$, and $z^* \approx 4$ is the effective charge of the "atomic residue" according to Unsöld. For sheath conditions $T = 1.2 \cdot 10^4$°K, $N_0 = 5 \cdot 10^{18}$ cm^{-3}, and $x_1 = x = 10$ we obtain a value for the photon mean free path $l_\nu = 1/\varkappa_\nu = 0.59 \cdot 10^{-2}$ cm. This value of l_ν is approximately two orders of magnitude smaller than the radius of the spark channel, so that the channel boundary can be regarded as a thin absorbing and ionizing layer. The heated layer is optically dense in the initial stages and transparent in the subsequent stages.

The electron thermal conductivity can play a significant role in the region of large temperature gradients at the channel boundary. The thickness of the electron relaxation layer in the channel sheath is determined by the magnitude of the electron mean free path $l_e = \tau_{ei} \bar{v}_e = 0.67 \cdot 10^{-2}$ cm ($\tau_{ei} = 10^{-10}$ sec, $\bar{v}_e = 6.7 \cdot 10^7$ cm/sec). Thus, the electron thermal flux is absorbed at the channel boundary in a layer of thickness $\Delta r \sim l_\nu \sim l_e \sim 0.6 \cdot 10^{-2}$ cm. That is, there is simultaneous radiative and thermal conduction heating of a single layer of gas at the channel boundary.

Under these conditions the heating zone is displaced to new layers of cold gas. This situation can be regarded as wave motion of a thin heating and ionization front, or an ionization wave.

The speed of the front of the ionization wave can be estimated from energy balance. A cylindrical channel of unit length and radius r at time t radiates energy

$$Q_\Sigma = \int S d\Sigma = \sigma_0 T^4 2\pi r dt,$$

$$Q_V = \int J dV = \frac{4\sigma_0 T^4}{l_1} \pi r^2 dt$$

in time dt. Here, Q_Σ is the energy of the blackbody emission of the spark channel in the initial stages of its development; $S = \sigma_0 T^4$ is the radiation flux from the side surface, $\Sigma = 2\pi r$, of the channel, emitted as from a blackbody with a plane radial temperature profile at T; Q_V is the energy of the transparent volume radiation from the spark channel in subsequent stages of its development; $J = 4\sigma_0 T^4/l_1$ is the integrated emissivity per unit volume of the channel for transparent radiation with a Planck mean free path l_1; and $\sigma_0 = 5.67 \cdot 10^{-12}$ J/cm^2 · sec · (deg K)^4 is the Stefan–Boltzmann constant. The electron thermal conduction energy is given by

$$Q_e = \int S_e d\Sigma = -\varkappa_e \frac{dT}{dr} 2\pi r dt,$$

where the effective coefficient of electron thermal conductivity is[20] $\varkappa_e = \xi\, 1.93 \cdot 10^{-5} T^{5/2}/(z \ln \lambda) \approx 4 \cdot 10^5$ erg/sec · cm · (deg K) for channel conditions $T = 4–5 \cdot 10^4$ °K, $Z = 2$, $\ln \lambda = 5\xi (Z = 2) = 1.5$.

The internal energy of a gas layer heated to a temperature T_I is given by $Q_n = 2\pi r dr N\varepsilon(T_I)$, where $\varepsilon = 8.3(T/10^4)^{1.5\delta^{-0.12}}$ eV/atm is the specific internal energy of air at temperature T and relative density $\delta = N/N_L$ (where $N_L = 2.69 \cdot 10^{19}$ cm^{-3} is the Loschmidt number).

In the initial stage of expansion of the spark channel into the region of cold motionless air the equality $Q_\Sigma + Q_e = Q_I$ must hold; therefore

$$D_{\Sigma,e} = \frac{dr}{dt} = \frac{\sigma_0 T^4 - \chi_e \frac{dT}{dr}}{N\varepsilon(T_I)}.$$

The rate of expansion of the spark channel in the initial stages $D_{\Sigma,e}$ for $T = (4–5) \cdot 10^4$ °K, $N = 2N_L = 5.38 \cdot 10^{19}$ cm^{-3}, $T_I = 1.5 \cdot 10^4$°K, $\varepsilon(T_I) = 15$ eV/atm, and $-\varkappa_e dT/dr \sim \varkappa_e T/\Delta r = (1.3–1.7) \cdot 10^{12}$ erg/sec · cm^2, is given by $D_{\Sigma,e} = 1.14–2.77$ km/sec, for which the role of electron thermal conductivity in this regime is negligibly small. These values of $D_{\Sigma,e}$ correspond to the experimentally observed rates of expansion of a spark channel.[1–6]

At later times, the equality $Q_V + Q_e = Q_I - Q_0$ holds within the hot sheath at temperature T_0. It is then possible to estimate the velocity of propagation of the ionization wave for nonequilibrium emission from the channel by

$$D_{V,e} = \frac{dr}{dt} = \frac{\frac{2r}{l_1}\sigma_0 T^4 - \varkappa_e \frac{dT}{dr}}{N_0[\varepsilon(T_I) - \varepsilon(T_0)]}.$$

In the completely ionized gas of the spark channel absorption of light is due to bound–free and free–free transitions and the Planck mean free path of the radiation is given by[20]

$$l_1 = \frac{1.1 \cdot 10^{23} T^{7/2}}{N^2 \bar{m} (\bar{m} + 1)^2 \bar{x}_1} \text{ cm}.$$

For the channel conditions (Figs. 1 and 2) given by temperature $T = 3.5 \cdot 10^4$°K, ion density $N = 5 \cdot 10^{17}$ cm^{-3}, mean ion charge $\bar{m} = 1.9$, and relative ionization potential $\bar{x}_1 = \bar{I}/kT = 9.3$, this equation yields $l_1 = 200$ cm. Taking $T_0 = 1.2 \cdot 10^4$°K, $[\varepsilon(T_I) - \varepsilon(T_0)] = 3$ eV/atm, $N_0 = 5 \cdot 10^{18}$ cm^{-3}, and $\varkappa_e dT/dr \sim \varkappa_e (T - T_0)/\Delta r = 7.68 \cdot 10^{11}$ erg/sec · cm^2, for example, at time t = 5 μsec, r = 0.4 cm (Fig. 2), we obtain $D_{V,e} = D_V + D_e = 100 + 320 = 420$ m/sec. Here the significance of the electron thermal conductivity is already shown, as it contributes the basic portion, $D_e/D_{V,e} = 76\%$, of the ionization wavefront velocity. From Fig. 2, at t = 5 μsec we have dr/dt = 474 m/sec, which is close to the value obtained here, $D_{V,e} = 420$ m/sec. It should be noted that the mass velocity of the gas in the channel and the sheath is nearly zero since the speed of sound in the channel c and in the sheath c_0 greatly exceed the expansion velocity. Under these conditions all the gasdynamic parameters of the channel and sheath rapidly reach equilibrium. The mass velocity is zero since it is zero at the axis of the channel by symmetry considerations.

The energies of the absorbed radiation, q_V, of the electron thermal conductivity, q_e, and of the Joule heating, q_h, due to the longitudinal discharge current i are released in the front of the ionization wave. For the present example at t = 5 μsec (Fig. 2), these energies are given by

$$q_V = \sigma_0 T^4 \frac{2r}{l_1} \frac{1}{D_{V,e}} = 0.58 \ \mathrm{J/cm^3},$$

$$q_e = \varkappa_e \frac{T - T_0}{\Delta r} \frac{1}{D_{V,e}} = 1.83 \ \mathrm{J/cm^3},$$

$$q_h = \left(\frac{i}{\pi r^2}\right)^2 \eta \frac{\Delta r}{D_{V,e}} = 2.54 \ \mathrm{J/cm^3},$$

where[22] $\eta = 0.02 \ \Omega \cdot \mathrm{cm}$ at $T_1 = 1.5 \cdot 10^4$ °K. The total energy q_{0V} dissipated in the front is equal to $q_{0V} = q_V + q_e + q_h = 4.95 \ \mathrm{J/cm^3}$. A calculation of the energy per unit mass of a heated layer with a mean density $\sim 0.01 \rho_H = 1.3 \cdot 10^{-5} \ \mathrm{g/cm^3}$ gives $q_0 = 3.81 \cdot 10^5$ J/g. When the ionization wave front is propagating, gas particles from the sheath pass through the front into the channel region as they are heated and the energy q_0 must be taken into account in the equation of energy conservation at the front. The usual equations of mass, momentum, and energy conservation for the front of an ionization wave can be written in the form

$$\rho_0 u_0 = \rho u, \quad p_0 + \rho_0 u_0^2 = p + \rho u^2, \quad i_0^* + \frac{u_0^2}{2} + q_0 = i^* + \frac{u^2}{2},$$

$$\rho = \frac{1}{V}, \quad i^* = \varepsilon + pV.$$

In the general case these equations do not assume any particular physical mechanism by which energy is released in the discontinuity. They are used to analyze the detonation and deflagration regimes of fuel gases;[16–18] to a certain degree, the similar features of these regimes and the gasdynamic processes in the spark discharge must be determined by them. The difference lies in the fact that, first, the chemical reaction of combustion occurs only in a thin reaction layer and energy is not released in the region of burned-up gas, and, second, the chemical energy is a constant for a given fuel gas. In the case of a spark, the Joule energy continues to be released in the heated gas even after the ionization wave front passes it. Hence, the amount of energy released in the channel varies in time.

In the coordinate system fixed in the motionless gas in the channel and in the sheath ahead of the front, we have

$$D = V_0 \sqrt{\frac{p - p_0}{V_0 - V}}, \quad \frac{pV}{\gamma - 1} - \frac{p_0 V_0}{\gamma_0 - 1} - q_0 = \frac{p + p_0}{2}(V_0 - V),$$

Since $\gamma p/V = (p - p_0)/(V_0 - V)$ along the tangent to the Hugoniot adiabatic we obtain conditions for the transition of the gas particles to the Jouguet point from an initial state (0) in the sheath:[18]

$$p - p_0 = \frac{\rho_0 D^2}{\gamma + 1}\left(1 - \frac{\gamma}{\gamma_0} \frac{c_0^2}{D^2}\right),$$

$$V_0 - V = \frac{V_0}{\gamma + 1}\left(1 - \frac{\gamma}{\gamma_0} \frac{c_0^2}{D^2}\right),$$

$$\frac{D}{c_0} = \sqrt{\frac{\gamma^2 - 1}{2} \frac{q_0}{c_0^2} + 1} \pm \sqrt{\frac{\gamma^2 - 1}{2} \frac{q_0}{c_0^2}}.$$

From the last of these equations with a negative sign (corresponding to propagation of a slow ionization front at subsonic speed), written with the adiabatic index $\gamma = \gamma_0$, with $c_0 = 3$ km/sec, $\gamma = 1.2$, and $q_0 = 3.81 \cdot 10^5$ J/g we have $D \approx 450$ m/sec. The pressure difference and ratio of the specific volumes of gas on both sides of the discontinuity (for $\rho_0 = 1.3 \cdot 10^{-4} \ \mathrm{g/cm^3}$) are $p - p_0 \approx -5.2$ bar, and $V/V_0 = 20.7$.

Thus, with the use of the mechanism proposed here, including the values of the parameters, the experimentally observed radial profiles of pressure and gas density in the discharge channel (Fig. 1) are reasonable. The front of the slow ionization wave is similar to a deflagration front with its associated pressure drop. As is known,[16] in this case the ionization front (boundary of the spark channel) can be regarded as a moving permeable piston. The channel boundary emits pressure waves in the sheath by means of which energy is transferred from the channel into the shock-wave region. This explains how the shock front is accelerated as the expansion velocity of the spark channel increases. The velocity of the gas at the slow ionization front is directed toward the front. The wave front encounters gas at a higher pressure, which leads to an increase in the gas pressure in the spark channel. Due to the growth in gas density with time the electron density in the channel increases (Fig. 2) although the temperature and degree of ionization of the plasma decrease.

Therefore, the ideas developed here on the mechanism for expansion of a spark channel as the propagation of an ionization wave, taking account of the Joule energy and considering the boundary conditions at the channel boundary to be analogous to those at a combustion front in fuel gases, provide a good explanation of the experimental results.

The author thanks A. A. Rukhadze, I. S. Marshak, and A. F. Aleksandrov for discussion and Yu. P. Raizer for helpful comments.

Development of an inhibited glow discharge

Yu. A. Bystrov, S. A. Ivanov, and Yu. F. Radchenko

V. I. Ulyanov-Lenin Electrotechnical Institute, Leningrad

(Submitted December 10, 1973)
Zh. Tekh. Fiz., 44, 2348-2351 (November 1974)

The effect of the anode material on the development time of an inhibited glow discharge is investigated. It is shown that the dependence of the formation time on the nature of the anode material is due to ultrasoft x rays produced by fast-electron bombardment of the anode.

The nature of electron emission from the cathode in a glow discharge, in particular in an anomalous glow discharge, has been discussed. Some authors attribute the existence of anomalous discharges to the increased contribution by charge exchange to ion motion which produces fast atoms and molecules capable of increasing the coefficient[1] γ. Others consider the increase in electron emission from the cathode as due to enhancement of the ion flux from the region of negative glow[2,3] and the subsequent "potential" or "kinetic" ejection of ions. In each case, one mechanism or the other will predominate depending on the specific conditions. In particular, some authors[4,5] consider the basic mechanism for anomalous glow discharges to be photoemission induced by photons emitted by the discharge.

In considering the contribution of the photoeffect to confinement of the discharge, usually only ultraviolet radiation from the cathode dark space and the negative glow are considered.[6] This approach is valid for anomalous and normal glow discharges when the electrode separation is larger than the length of the normal cathode drop. In an inhibited glow discharge the negative glow is partially or completely absent and the anode is in the region of the cathode potential drop. Therefore, ion and ultraviolet fluxes incident on the cathode from the negative glow are negligible in this case.

But the fact that the primary electrons strike the anode at high velocities in an inhibited discharge indicates the existence of another mechanism for electron emission from the cathode. We refer to photoemission induced by ultraviolet and x radiation resulting from electron bombardment of the anode at energies of tens and hundreds of electron volts, which occurs in an inhibited glow discharge.[7]

Soft x-ray bremsstrahlung arises with a continuous spectrum that overlaps the vacuum ultraviolet when electrons of the above energies are retarded at the surface of the anode. Furthermore, characteristic x-ray radiation can be exicited in the atoms of the anode material. Since the quantum yield of different metals attains large values in the vacuum ultraviolet[8,9] and has a relatively large value at the edge of the x-ray region,[10] in spite of the low intensity of the radiation from the anode, fairly high photoemission from the cathode can be expected for an inhibited glow discharge. The ignition time of the discharge, in particular the development time t_d, is determined by secondary processes at the cathode. Since the x-ray photoemission current of metals has a complex dependence on the nature of the anode material,[11,12] t_d depends on the nature of the anode material for an inhibited glow discharge. Therefore, by measuring the length of the formation stage of discharges in tubes with anodes of different materials and comparing it to the x-ray photoemissivity of a cathode with the same material as the anode, the above assumptions can be checked. In other words, a definite relationship must exist between the curves $t_d = f(z)$ and $I_{ph} = F(z)$, where t_d is the development time of the discharge, z is the atomic number of the anode material, and I_{ph} is the x-ray photocurrent from the cathode. Smaller t_d values correspond to larger photocurrent densities. The curve $I_{ph} = F(z)$ can be obtained from an independent experiment, for example using the technique described in ref. 12.

Special investigations are required to explain the nature of the dependence of t_d on z. For example, it is important to ensure that after the anode is replaced all the other experimental conditions are the same. The voltage applied to the gap is of special importance. On the one hand, it should be high enough to increase the x-radiation intensity and exclude the statistical delay time of the discharge; on the other, it should not be so strong that the development time is reduced and the experimental error increased.

The existing methods of estimating the contribution of the photoeffect consist of measuring the photocurrent from a target which is usually fabricated from the same material as the cathode. In some cases; this involves placing extended electrodes in the gap and subjecting them to an applied transverse field; in others, the discharge gap is

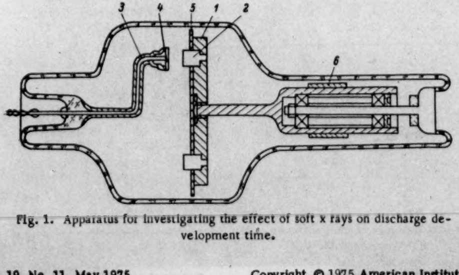

Fig. 1. Apparatus for investigating the effect of soft x rays on discharge development time.

separated from the target by a vacuum barrier, for example of lithium fluoride,[13,14] that transmits ultraviolet radiation. Theoretically, such methods do not permit ultrasoft x rays to be detected in the discharge.

The apparatus in Fig. 1, which is used to investigate the effect of ultrasoft x rays on the formation time t_d of an inhibited discharge, allows the anode to be replaced without destroying the vacuum or the gap geometry. The electrode of the device rotates on ball bearings, and on the holder 1 are mounted anodes 2 of different materials: graphite, titanium, molybdenum, and tungsten. The nickel cathode 4 is displaced with respect to the axis of rotation of the anode assembly and is 5 mm from the anode. The anodes are replaced by rotating the holder with a permanent magnet 6. To avoid arcing of the discharge along the "long path" the inputs of the cathode mount are covered with a special vacuum cement 3, and the holder surface is covered by a mica sheet 5. The apparatus is filled with spectrally pure neon and argon to a pressure of 0.1-1.0 torr. Thus, in tubes with this design almost completely identical test conditions are maintained after the anode is replaced.

The discharge tube is connected to a pulsed generator which supplies 50-100 μsec square current pulses with a leading edge of not more than 20 nsec. To decrease the statistical delay time the output voltage of the generator is maintained at 30-40% above the discharge initiation voltage.

The formation time t_d is measured as the period from the instant the anode current appears to the instant that the leading edge of the current pulse is formed. The shape and amplitude of the current pulse are measured using a noninductive coaxial shunt. The discharge voltage is measured simultaneously.

Figure 2 shows the dependence of the formation time t_d/t_a of the discharge in the gas gap with a nickel cathode on the atomic number z of the anode material for different gap voltages and it also shows the dependence of the x-ray photocurrent I_{ph}/I_a of a nickel cathode[11] on z.

Comparison of the curves $t_d/I_a = f(z)$ and $I_{ph}/I_a = F(z)$ indicates that there is a close relationship between them: Smaller formation times correspond to larger x-ray photocurrents from the cathode.

Actually, the formation time determined from the Schade method,[15] but including the effect on its duration of γ_ν processes due to soft x rays from the anode, is

$$t_d = \frac{\tau_i \mu}{\mu + \gamma_\nu \exp(\alpha d) - 1} \ln \frac{1 + \frac{i(t_d)}{i_0}[\mu + \gamma_\nu \exp(\alpha d) - 1]}{\mu}. \quad (1)$$

Here, $\mu = \gamma_p[\exp(\alpha d) - 1]$; γ_p is the coefficient of secondary emission due to ion bombardment; τ_i is the ion transit time; $i(t_d) = (E_a - U_a)/R_v$; α is the electron-impact ionization coefficient; γ'_ν is a coefficient characterizing photoemission due to ultrasoft x rays; $\gamma_\nu = \gamma'_\nu G\beta$ is a reduced coefficient characterizing the photoemission; G is a geometrical factor; β characterizes the radiation output for one electron interacting with the anode.

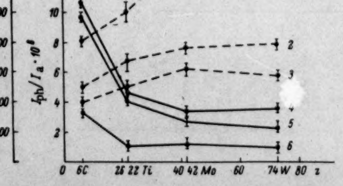

Fig. 2. Curves $t_d/I_a = f(z)$ and $I_{ph}/I_a = F(z)$. Solid lines are for the formation time, and the dashed lines are for the photocurrent. Cathode material is Ni. 1, 4) $U_a = 300$; 2) 200; 3) 100; 5) 320; 6) 340 V.

It can be seen that if ultrasoft x rays are absent from the discharge, this equation has the form of the well known Schade equation[15] obtained with only γ_p processes taken into account. In this case the duration of the formation stage is a maximum.

With other conditions equal, γ_ν is determined only by the anode material. The lack of data in the literature on β which characterizes the radiation output for the interaction between one electron and the anode makes a quantitative analysis of the equation difficult. Even a purely qualitative analysis, however, indicates the possibility of decreasing t_d by selecting the appropriate anode material.

It follows from the experimental curves $t_d/I_a = f(z)$ given above that the relative formation time t_d/I_a for a tungsten anode (z = 74) is four to five times smaller than for a graphite anode (z = 6). However, the relative photocurrent for a tungsten target is 1.5-2 times larger than for a graphite target. Thus, one can conclude that under certain conditions, and especially in an inhibited discharge, ultrasoft x rays can have a considerable effect.

Ultrasoft x rays not only affect the formation time t_d but also the statistical delay time of initiation of an inhibited discharge; this effect can be even stronger since in this stage the predischarge current is a purely electron current. The presence of x rays can considerably accelerate the appearance of a "successful" electron in the discharge gap. A final solution of this problem will be possible only after a careful experimental investigation.

Resistance and inductance of a gas arc

S. I. Barannik, S. B. Vasserman, and A. N. Lukin

Institute of Nuclear Physics, Siberian Branch, Academy of Sciences of the USSR, Novosibirsk

(Submitted May 30, 1973; resubmitted April 2, 1974)
Zh. Tekh. Fiz., 44, 2352-2359 (November 1974)

The resistance and inductance of arc channels (40 cm long) in air, SF_6, and mixtures of SF_6 with nitrogen have been measured at pressures up to 12 atm and at voltages up to 5 MV. The discharge is ignited by a trigatron. The experimental procedure and results are reported. The results are used to calculate the constants in the functional dependences obtained from the Braginskii theory. These functional dependences relate the radius of the arc channel and its resistance to the arc current as a function of the time. The electrical properties of the arc channel are studied in connection with the development of sources for high-power pulses of relativistic electron beams in the nanosecond range; in these the characteristics of the high-voltage switch influence the properties of the electron beam (the shape and length of a current pulse, the maximum energy and energy spectrum of the electrons, and the total energy per pulse).

EXPERIMENTAL PROCEDURE AND RESULTS

The experiments are carried out with an RIUS-5 source of relativistic electron beams in the nanosecond range.[1] The arc channel is part of the discharge circuit of the source, which also includes the high-voltage electrode (conductor), the electrode of the accelerating tube with the cathode, and an evacuated accelerating gap.

On the basis of the geometric dimensions of the elements and of the system and the experimental rates of change of the currents and voltages we can treat the discharge circuit as a lumped-parameter circuit. The equivalent circuit is shown in Fig. 1 and is described by

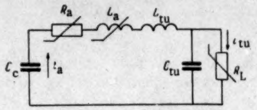

Fig. 1. Discharge circuit.

$$U_c = \left[R_a(t) + \frac{dL_a(t)}{dt}\right] i_a + L(t)\frac{di_a}{dt} + U_{tu}, \tag{1}$$

$$i_a = C_{tu}\frac{dU_{tu}}{dt} + i_{tu}, \tag{2}$$

$$U_c = U_{c0} - \frac{1}{C_c}\int_0^t i_a(\tau)\,d\tau, \tag{3}$$

$$L(t) = L_a(t) + L_{tu}, \tag{4}$$

$$i_{tu} = \frac{U_{tu}}{R_L}, \tag{5}$$

where i_a is the current in the arc channel, i_{tu} is the current in the load (the tube), U_{tu} is the voltage on the tube electrode, U_c is the voltage on the conductor, C_c is the capacitance between the conductor and the vessel, $L_a(t)$ is the inductance of the arc channel, $R_a(t)$ is the resis-

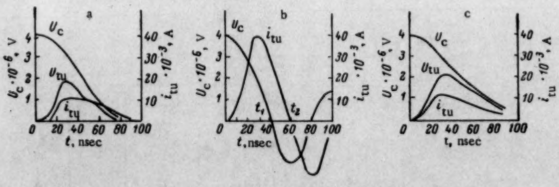

Fig. 3. Characteristic current and voltage oscillograms. a) Working regime; b) short-circuited regime; c) regime of a constant load resistance.

tance of the arc channel, L_{tu} is the inductance of the tube cathode, C_{tu} is the capacitance between the tube electrode and ground, and R_a is the load resistance of the source.

Figure 2a shows the construction of the part of the source that forms the discharge circuit. Using the oscillograms of the conductor and tube voltages and of the tube current along with Eqs. (1)-(5), we can determine R_a and L_a at certain times, and we can determine the average values of these properties over selected time intervals. Analyzing the current and voltage oscillograms, we can find the arc resistance as a function of the time. The voltages on the conductor and tube are measured by capacitive pickups, while the tube current is measured by a Rogowski loop;[2] the signals are displayed on an OK-19M oscilloscope. Figure 2 shows the pickups. We studied three regimes: a) the working regime of the accelerator (in general, with $R_L \neq$ const; Fig. 2a); b) the regime in which the accelerating gap is short-circuited ($R_L = 0$; Fig. 2b); and c) a regime in which the accelerating tube is replaced by its water equivalent (R_L = const; Fig. 2c). In the latter case we vary the concentration of KCl in water, using a vinyl plastic tube.

Figure 3 shows typical oscillograms for all three regimes. The arc resistance at time t_1 ($di_a/dt = 0$) is, according to Eq. (1),

$$R_a + \frac{dL_a}{dt} = \frac{U_c - U_{tu}}{i_a}.$$

Since the discharge current is not measured directly in regimes "a" and "b" it is determined from the curve for the voltage [$i_a = C_c(dU_c/dt)$] and compared with (2). We see from the experimental data below that dL_a/dt does not exceed 5% of R_a and it is neglected in the calculations.

More information on the arc resistance is obtained in experiments in the short-circuit regime ($R_a = 0$). From energy conservation we can evaluate the equivalent resistance of the arc channel, R_a, during the first, second, etc., current half-cycles in the following manner: The difference between the energies stored in capacitance C_c at zero times and t_2 is determined by the energy loss in the arc channel (i.e., the energy dissipated in R_a) for the first (1) current half-cycle:

$$W_{R_a I} = \frac{C_c U_{ca}^2}{2} - \frac{C_c U_{c1}^2}{2} = \int_0^{t_2} i_a^2 R_a \, dt.$$

Then we can define a resistance which is equivalent in terms of the loss over the time interval under consideration:

$$R_{a\,\mathrm{equ}} = \frac{W_{R_a I}}{\int_0^{t_2} i_a^2 \, dt}.$$

Similarly, we can find the equivalent (in terms of loss) arc resistance during the second half-period. The inductance of the arc channel is determined from the oscillation period in the experiments in the short-circuit regime. From the equation

$$\frac{T}{2} = \frac{\pi}{\sqrt{\frac{1}{L_{\mathrm{equ}} C_c} - \frac{R_{a\,\mathrm{equ}}^2}{4 L_{\mathrm{equ}}^2}}}$$

and the known values of T/2, C_c and $R_{a\,\mathrm{equ}}$, we can calculate the equivalent circuit inductance $L_{\mathrm{equ}} = L_{a\,\mathrm{equ}} + L_{tu}$ over the half-period under consideration. The instantaneous values of the inductance at points for which $i_a = 0$ (the short-circuit regime) are found from Eq. (1):

$$L(t_2) = \frac{U_c}{\frac{di_a}{dt}}.$$

The values of R_a and L_a at certain times and the equivalent values over a half-period $R_{a\,\mathrm{equ}}$ and $L_{a\,\mathrm{equ}}$, obtained in the experiments in the short-circuit regime, are shown in Table 1. Table 2 shows the values of R_a obtained in the working regime and in the regime with R_L = const. All the experiments in these regimes are carried out at a gas pressure of 12 atm; the voltages and currents are

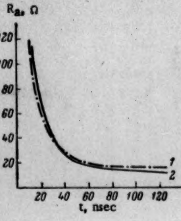

Fig. 4. Arc resistance as a function of the time in one regime. 1) Result of an analysis of the oscillograms; 2) calculated from Eq. (10).

measured within 10%. In all experiments the discharge gap is 40 cm long. The capacitance of the conductor is 220 pF, and the inductance of the tube electrode in the short-circuited regime is 0.58 μH. The values of U_{C0} obtained from the various experiments lie in the range 0.4-0.9 of the self-breakdown voltage of the gas-filled gap.

Because of the small difference between the values of $L_{a\,equ}$ in the first and second half-periods in the short-circuit regime, which can be attributed to the weak functional dependence of the inductance on the channel diameter, we can neglect the functional dependence of the inductance on the time in many calculations. Assuming L_a = const, we can find the functional dependence of the arc resistance on the time by a graphical solution of Eq. (1) based on the current and voltage oscillograms. Figure 4 shows the results calculated for the $R_L = 0$ case in a 1 : 1 mixture of SF_6 and N_2 at a pressure of 12 atm and at U_{C0} = 2.5 MV. Similar curves can be constructed for the other experiments.

DISCUSSION OF RESULTS

The Braginskii theory[3] is apparently the most complete of the known theories for the arc channel. Integrating the basic differential equation for the model of the channel adopted in this theory

$$2\pi^2\rho_0 a_a^3 \dot{a}_a^3 \xi = \frac{i_a^2}{\sigma}$$

we find the functional dependence of the channel radius on the time, which involves the time t_0 at which the channel is formed:

$$a_a(t) = \left[\left(\frac{4}{\rho_0\pi^2}\right)^{1/3} \int_{t_0}^{t} \left(\frac{i_a^2(\tau)}{\sigma\xi}\right)^{1/3} d\tau + a_a^2(t_0)\right]^{1/2}, \qquad (6)$$

where ρ_0 is the density of the gas in which the discharge occurs, σ is the electrical conductivity of the plasma in the channel,

$$\xi = K_e\left[1 + (\gamma - 1)^{-1}\frac{1}{2\dot{a}_a^2}\frac{d^2 a_a^2}{dt^2}\right], \qquad (7)$$

$K_e = 2/(\gamma + 1)$ is the expansion coefficient, and γ is the effective ratio of specific heats.[4]

In applying this theory to the geometric and electrical properties of the arc channel we are assuming that the channel is a straight cylinder and that the temperature, pressure, and density of the gas in the channel are constant over a cross section. We did not record the geometric characteristics of the channel in our experiments, but data from the literature for long channels (see, e.g., ref. 5) show that under conditions like ours an arc channel is usually neither homogeneous nor straight. However, in the experiments described here, involving the use of the RIUS-5 apparatus, the current and voltage oscillograms obtained under identical conditions are essentially the same for many of the measurements. For our purposes we can then assume that the electrical properties of the arc channel are stable, so that it is legitimate to replace the actual channel geometry by an equivalent geometry.

In order to use the Braginskii theory we must ensure that the condition $P_m/P_g \ll 1$ is satisfied, where P_m and P_g are the magnetic pressure on the channel and the gas-kinetic pressure in the channel, respectively.

According to ref. 6, we have

$$\frac{P_m}{P_g} = 1.4\left(\frac{\rho_A}{\rho_0}\right)\left(\frac{i_a}{\dot{a}_a a_a}\right)^2. \qquad (8)$$

Here, ρ_v is the density of air at normal conditions. To evaluate the ratio P_m/P_g for the regime with the maximum current i_a, i.e., for the experiments in the short-circuit regime, we can use the values U_{C0} = 4 MV, $i_a(t_1)$ = 40 kA, $\rho_v/\rho_0 \approx 0.08$, $a_a(t_1) \approx 4 \cdot 10^{-2}$ cm, and $\dot{a}_a(t_1) \approx 10^6$ cm/sec [a_a and $\dot{a}_a$ are obtained from Eq. (9)]. As a result we find $P_m/P_g \approx 0.1$.

As shown in the Appendix, at the plasma temperatures prevailing in the arc channel the quantities σ and ξ [(7)] which appear in Eq. (6) can be assumed to be independent of the time and can be taken through the integral sign.

The literature reveals no data on the initial radius of the arc channel [$a_a(t_0)$] in long gaps, so we replace Eq. (6) for $a_a(t)$ by an approximate equation, from which $a_a(t_0)$ is omitted:

$$a_a(t) \approx K_1\rho_0^{-1/6}\left[\int_{t_0}^{t} i_a^{1/3}(\tau)\, d\tau\right], \qquad (9)$$

where $K_1 \approx (4/\pi^2\sigma\xi)^{1/6}$. This quantity is determined experimentally for each gas and for each pressure from the value of L_a at time t_2 (Table 3).

In evaluating the integral in Eq. (9), we choose t_0 to be the time at which the current pulse begins on the oscillogram. It is apparently possible to determine more rigorously the time at which the channel formation ends,[7,8] but this procedure is of no particular interest since no changes occur in systems of this type which are significant from the standpoint of energy transfer over the time required for the formation of the channel. Below we replace t_0 in the equations by t = 0.

Because of our assumptions and the method used to determine the coefficient K_1 from the value of the inductance, which is related logarithmically to the channel radius, the error involved in the determination of a_a from (9) is very large. However, for our purposes – to calcu-

*The last row of this table shows the coefficients obtained through an analysis of the data in ref. 6 for an air-filled gap 0.8 cm long.

late the inductance of the arc channel (except in the initial period) – this circumstance is unimportant.

The resistance of the arc channel is

$$R_a(t)=\frac{l_a}{\sigma\pi a_a^2}\approx\frac{K_2\rho_0^{1/3}}{\int\limits_0^t i^{2/3}(\tau)\,d\tau}, \tag{10}$$

where l_a is the length of the discharge gap, and Q_2 is a coefficient which is determined experimentally for each type of gas and each pressure from the resistance of the arc channel at time t_1 (Table 3). The coefficients K_2 and K_1 are related by $K_2 = 1/\sigma\pi K_1^2$.

Figure 4 shows the functional dependence $R_a(t)$ calculated from Eq. (10). Comparison with the curve constructed from the oscillograms reveals completely satisfactory agreement; the discrepancy between the curves in the early stages occurs apparently because Eq. (9) gives an underestimate of the channel radius in these stages. To estimate the initial channel radius from Eq. (6), which would lead to coincidence of the two curves at time[1] $t_0 \approx$ 10 nsec (with coincidence at time t_1 also), we assume that at time t_0 the plasma conductivity reaches a quasistable value of about 200 $\Omega^{-1}\cdot cm^{-1}$ (Appendix); we find $a_a(t_0) \approx$ 0.25 mm. This result is consistent with the known results. The quantity $a_a(t_0)$ has been measured previously[8] for short air-filled gaps (pd = 600 torr · cm) and found to be 0.1-0.12 mm for those particular conditions.

We see from Table 3 that the coefficients K_1 and K_2 are essentially independent of the nature and pressure of the gas. The apparent explanation is that the electrical conductivities of different highly ionized gases are essentially the same at identical electron temperatures.[9] The curves in Fig. 6 (see the Appendix) offer further support for this conclusion.

Accordingly, in calculating the electrical properties of high-voltage, gas-filled arc switches we can use the approximate functional dependences of the radius and resistance of the arc channel on the time given above, with average values of the common constants for the cases considered (Table 3):

$$a_a(t)\approx 4.8\rho_0^{-1/6}\left[\int\limits_0^t i_a^{2/3}(\tau)\,d\tau\right]^{1/2}\ \text{cm}, \tag{11}$$

$$R_a(t)\approx l_a\frac{7\cdot 10^{-5}\rho_0^{1/3}}{\int\limits_0^t i_a^{2/3}(\tau)\,d\tau}\ \Omega, \tag{12}$$

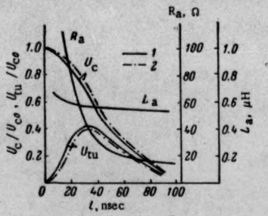

Fig. 5. Calculated (1) and experimental (2) curves for the voltage on the high-voltage electrode and the tube in the regime with R_L = 120 Ω. The calculated $R_a(t)$ and $L_a(t)$ curves are also shown.

where ρ_0 is the gas density in the arc switch (grams per cubic centimeter), l_a is the length of the discharge gap (centimeters), i_a is in amperes, and t is in seconds.

Using Eqs. (11) and (12) we can compare different types of switches (differing in the nature and pressure of the gas). In particular, we see that for a given gas the resistance of the arc channel falls off with increasing pressure according to $\sim 1/P^{2/3}$ ($l_a \sim 1/p$). We also see that the use of multichannel switches, which significantly reduce the inductance (or characteristic impedance) of a commutator, leads to a relatively slight reduction in the resistance (for a given current). With N channels we would have $R_a(N) = (1/N^{2/3})R_a$ (1).

The use of these equations facilitates calculations of the amplitudes and lengths of current and voltage pulses in nanosecond-range sources of relativistic electron beams involving gas-filled arc switches. Our calculations for the regime with R_L = const leads to good agreement with the experiment results (Fig. 5).

APPENDIX

Analysis[3,10] of Eq. (7) for the parameter ξ has shown it can be assumed to be independent of the time. This conclusion follows from the established fact[10-13] that the expansion of the visible part of the channel during the stage of intense energy evolution in the channel can be described approximately by the power law $a_a \approx At^n$ (where A and n are constants). Substituting the latter relation into (7), we find

$$\xi=\frac{2}{\gamma+1}\left[1+\frac{2n-1}{n(\gamma-1)}\right]. \tag{A.1}$$

At temperatures $10^4 < T < 3\cdot 10^4$°K and at relative gas densities $10^{-4} < \rho/\rho_0 < 10$, the value of γ for air is found to be 1.22 in ref. 4.

The effective value of the ratio of specific heats for SF_6 can be determined from the experimental values of the enthalpy of an SF_6 plasma, obtained in ref. 11 at temperatures from 10,000 to 45,000°K and at unperturbed-gas pressures from 1 to 16 atm. Over this temperature range and over the range of relative gas densities $10^{-3} < \rho/\rho_0 < 10^0$, the value is γ = 1.17. On the basis of the slight difference between γ for air and SF_6 we would expect that the values of the parameter ξ for these gases would also differ only slightly.

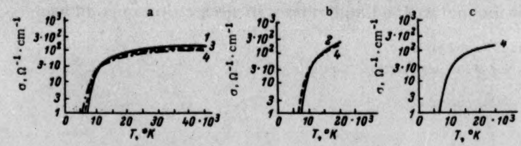

Fig. 6. Pressure (atm): 1) 16; 2) 10; 3) 4; 4) 1.

The values of the conductivity σ are calculated in refs. 11, 14, and 15 for SF_6, air, and nitrogen plasmas as a function of the temperature for various pressures of the unperturbed gases; the results are shown in Fig. 6, a–c, respectively. We see that the conductivity is a weak function of the pressure and that the values of σ are approximately the same for the different gases. At $T \geqslant 2$ eV the conductivity changes only slightly and can be assumed essentially constant. According to the data of ref. 16, the plasma temperature in the channel lies in the range 3.6–5.3 eV for a relatively low rate of energy evolution in the channel but for a total energy per unit length which is approximately equal to that in our experiments. The value of σ is also assumed to be constant over the first current half-period in ref. 6. According to the arguments of ref. 7, a rapid change in the value of σ in the channel ($T < 2$ eV) occurs during channel formation.

---

1) According to ref. 8, the time t_0 is the time at which the derivative of the current in the channel reaches its maximum value.

Electrical explosion of the metastable liquid phases of zinc, cadmium, and lead

M. M. Martynyuk and I. Karimkhodzhaev

Patrice Lumumba Friendship of Nations University, Moscow

(Submitted June 1, 1973)
Zh. Tekh. Fiz., 44, 2360-2366 (November 1974)

The relative resistances of Zn, Cd, and Pb are measured by a pulsed oscilloscope method as functions of molar enthalpy in the electrical explosion of conductors caused by current pulses 15-25 μsec. The enthalpy of the liquid phase at the initial point of the explosion for all three metals is much higher than its value at the normal boiling point because the liquid becomes metastable. This behavior shows that the electrical explosion of a conductor is accompanied by an explosive transition of the metastable liquid-metal phase into a stable state. The critical parameters of Zn, Cd, and Pb are evaluated from the experimental data on the basis of the theory developed previously by Martynyuk for exploding wires.

Martynyuk[1] used the thermodynamics and kinetics of evaporation and boiling to show that the initial point of the electrical explosion of a conductor, T_3 (T is the temperature), for a specified duration of the heating of the liquid phase, τ, must lie in the neighborhood of the cusp point T_c, which is the thermodynamic-stability boundary of the liquid phase in the case of a continuous change.[2] These points are approximately equal ($T_3 \approx T_c$) only if τ satisfies the conditions

$$\tau_1 > \tau \gg \tau_2, \tag{1}$$

where τ_1 is the maximum period of liquid-phase heating over which the effect of heterogeneous vapor nuclei and the effect of MHD instabilities of the liquid sample can be neglected; τ_2 is the time required for the establishment of steady-state homogeneous formation of vapor nuclei in a superheated liquid metal (according to theoretical estimates, $\tau_2 = 10^{-7}$-10^{-8} sec). Accordingly, when (1) holds the point T_3 has a definite thermodynamic meaning, and a determination of this point can yield valuable information about the high-temperature properties of the metal in question.

Working on the basis of arguments of this type regarding the nature of exploding wires, we have carried out oscilloscope measurements of the electrical resistance and enthalpy of the liquid phases of Zn, Cd, and Pb in the states preceding explosion. The basic purpose of this study is to demonstrate experimentally the possibility of superheating a liquid metal above its boiling point under pulsed-heating conditions and to evaluate the temperature T_3 at the initial point of the explosion. We choose these particle metals because the literature reveals data on the resistivity[3,4] and the enthalpy[5] of Zn and Cd up to temperatures exceeding the normal boiling point T_{nb}, so that we were able to compare the results obtained in pulsed and ordinary measurements. The same comparison is possible for Pb, which has a relatively low value of T_{nb}.

1. EXPERIMENTAL PROCEDURE AND RESULTS

For a current pulse 200-400 μsec long the destruction of the sample begins immediately after melting, after a weak penetration into the liquid region.[6] For our experiments we assemble a pulsed apparatus with which we are able to reduce the pulse length by a factor of more than 10. The apparatus is described in ref. 7. The apparatus operates on the basis of an aperiodic discharge of a pulsed capacitor (200 μF) charged to 3 kV; it discharges through a wire sample held on the axis of a cylindrical copper chamber. The discharge is initiated by arc switching (with a trigatron). A nondistorting cylindrical current shunt[6] with a constantan resistance of (5-20) · 10^{-3} Ω is used to detect the current. A capacitive–resistive voltage divider is used to record the voltage oscillograms. This divider has several advantages[8] over simple resistive or simple capacitive dividers; it is capable of maintaining a constant division factor above 10 MHz and also transmits voltage pulses with rise times shorter than 0.1 μsec without any significant distortion.

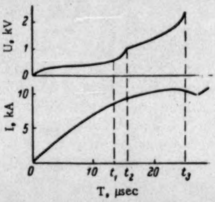

Fig. 1. Current and voltage oscillograms for lead, obtained in explosion in air.

Using the oscillograms of the current I and the voltage U and the equations of ref. 6, we calculate the resistance of the metal R/R_0 as a function of its molar enthalpy $H = H_T - H_{298}$ (R_0 is the initial resistance of the sample at 298°K) on a Minsk-22 computer. The rms error in the determination of R/R_0 is ± 5% (six experiments) and the corresponding error in the determination of H is ± 7%. The details of the oscilloscope study, the calibration, and the analysis of the oscillograms are given in ref. 6, along with a description of the effects of various factors on the results of the pulsed measurements of R/R_0 and H.

The Zn samples are 99.98% pure, the Cd samples are 99.99% pure, and the Pb samples are 99.999% pure; the diameter of the wire samples is 0.5 mm in the case of Zn and Cd or 0.86 mm in the case of Pb, and the samples are about 62 mm long. The wires are exploded in air, and additional experiments are carried out in water for the case of Zn and Cd. Figure 1 shows current and voltage oscillograms for Pb; the oscillograms for Zn and Cd are similar. On the voltage oscillogram we observe the beginning t_1 and end t_2 of the melting of the sample as well as the beginning of the explosion t_3; beyond this point the beam moves so rapidly that it leaves essentially no trace on the film.

Figure 2, a-c, shows $(R/R_0)(H)$ curves averaged over the data of six experiments for each metal. On these curves we see the points corresponding to the beginning

TABLE 1. Relative Resistance and Enthalpy of Zn, Cd, and Pb at the Beginning (R_1/R_0, H_1) and End (R_2/R_0, H_2) of Melting as Well as at the Beginning of the Electrical Explosion (R_3/R_0, H_3)

Metal	t, μsec		ρ_0, μΩ·cm	$\frac{R_1}{R_0}$	$\frac{R_2}{R_0}$	$\frac{R_3}{R_0}$	$H = H_t - H_{298}$, kJ/mole

				2.26 [3]	4.37 [3]		8.5 [5]	13.2 [5]	

Note: Here ρ_0 and R_0 are referred to 298°K; t_3 is the time required for heating to the beginning of the explosion; τ is the time over which the liquid phase is heated. For each metal the data in the first row correspond to explosions in air, the data in the second row correspond to explosions in water, and the data in the third row are for slow heating as given in the literature.

1 and end 2 of melting and the beginning of the electrical explosion, 3; here, nb is the normal boiling point of the metal.[5] Table 1 shows the values of R/R_0 and H obtained for these points.

Comparison of these results with the slow-heating results in the literature[3-5] shows the following:

1) The values of R_1/R_0, H_1, H_2, and $H_2 - H_1$ for Zn, Cd, and Pb agree with the results in the literature within the experimental errors.[1)]

2) The shape of the $(R/R_0)(H)$ curves for liquid Zn and Cd agrees with the shape of the $(R/R_0)(T)$ curves obtained in ref. 4. After melting the value of R/R_0 for Cd remains constant over a broad temperature range; that for Zn falls off with increasing T. At high temperatures, the value of R/R_0 begins to increase for liquid Zn and Cd. The increase in R/R_0 for liquid Zn and Cd is observed in our experiments at temperatures higher than in ref. 4.

3) The value of R_2/R_0 for Pb agrees with the data of ref. 3, but in the case of Zn and Cd it is lower than the data of refs. 3 and 4 by about 25%, larger than the experimental errors of the present measurements. We attribute this discrepancy in R_2/R_0 to the magnetic pressure caused by the pinch effect. The value of this pressure[6] averaged over the cross section for the Zn and Cd samples is less than 220 bar; for the Pb samples it is less than 80 bar.

4) For all three metals the enthalpy at the beginning of the electrical explosion, H_3, is much higher than the enthalpy of the liquid phase at the normal boiling point T_{nb}, H_{nb} (ref. 5); if the heating rate is high enough the liquid phase exists over a larger range (Fig. 2, a–c). This increase can be described by the ratio $\gamma = (H_3 - H_2)/(H_{nb} - H_2)$. For explosions in air the values of γ for Zn, Cd, and Pb are 3.4, 3.6, and 2.2, respectively. (According to ref. 5, the values of H_{nb} for Zn, Cd, and Pb are 33.6, 27.6, and 54.6 kJ/mole, respectively.) In the explosions of Zn and Cd in water we observed slight increases in H_2 and H_3 (Fig. 2, a and b).

2. DISCUSSION OF RESULTS

Let us consider the factors which could lead to values of H_3 higher than H_{nb} under these experimental conditions. The difference between these values cannot be attributed to thermal loss resulting from heat transfer between the sample and the surrounding air or between the sample and the massive copper clamps; solution of the corresponding heat-conduction equations[6] and a consideration of the radiation of the metal show that this loss is less than 0.5% of H. In our experiments the sample cannot be ruptured before time t_3, and the associated appearance of local arcs, whose maintenance requires additional expenditure of heat, cannot occur. Any changes of this type would be reflected on the voltage oscillogram by a sharp increase in the resistance of the sample. It can also be argued that H_3 is larger than H_{nb} because the boiling temperature of the liquid metal is raised by the pressure exerted on the surface of the conductor during the pulsed heating, but the

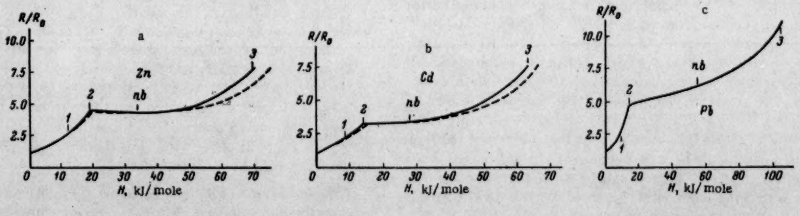

Fig. 2. Relative electrical resistance of zinc (a), cadmium (b), and lead (c) as a function of the molar enthalpy in pulsed heating. Solid curves show heating in air; dashed curves, in water.

conclusions reached below show that this is not the case.

The boiling of a thin film near the surface of a sample of radius r_0 cannot be affected by the magnetic pressure p_m, since this pressure is nonvanishing only in the interior of the sample; as $r \rightarrow r_0$, we would have $p_m \rightarrow 0$ (ref. 6). Vapor nuclei can form in a surface film;[2] the average magnetic pressure for Zn and Cd is less than 4.5 bar, and that for Pb is less than 1.5 bar, so that there can be only a slight displacement of the boiling point of the metal. The pressure due to the inertial forces during the radial thermal expansion of the sample would have a similar effect. Simple calculations show that p_{in} is much lower than p_m.

When a liquid sample is subject to pulsed heating in atmospheric air the surface of the sample is subject to the atmospheric pressure p_{at} as well as the pressure produced by the reaction of the flow of metal vapor evaporated from the metal surface; at any temperature T this latter pressure is $(2\alpha/\pi)p_b$, where p_b is the saturation vapor pressure at this temperature and α is the evaporation coefficient.[1] For a clean metal surface we have $\alpha = 1$, but for the contaminated surfaces of our experiments we have $\alpha \ll 1$ (ref. 9), so that this pressure can be neglected. Accordingly, the pulsed heating of a thin metal film near the surface of the sample in the experiments in air can be assumed to be approximately isobaric when $p = p_{at}$.

It has been shown[1] that at $p < p_k$ (where p_k is the critical pressure) a rapid heating of a liquid metal must be accompanied by a superheating of this metal above the boiling point, so that we can assume that the time t_3 determined on the voltage oscillogram and the corresponding value H_3 refer to the explosive boiling of a thin film of superheated liquid metal lying near the surface of the sample as the cusp point (T_c, H_c) is approached at $p_c \approx 1$ atm. An objection can be raised against this conclusion, however: A constrictive MHD instability can arise in a liquid sample during Joule heating (in ref. 10 the time constant for this instability is shown to be about 0.1 μsec for Pb). In this case the explosive boiling of the metal does not begin throughout the entire volume of the sample, but only at points at which the cusp point has been previously reached. It is understandable that the instabilities lead to a situation in which the value of H_3 determined from the oscillograms is lower than H_c, since H_3 is obtained by averaging over the entire volume of the sample. However, the large values of γ found in these experiments indicate that if it occurs at all the constrictive instability develops as the metal approaches T_c.

Evidence that the beginning of the electrical explosion, H_3, is near the cusp point, and not near the phase-equilibrium curve, comes from experiments involving explosions of Zn and Cd in water: The values found for H_3 in these experiments are not much higher than the value obtained for explosions in air (Fig. 2, a and b). In the state preceding the electrical explosion of the sample in water a thin sheath of water vapor forms around the sample and exerts a considerable pressure on the surface of the liquid metal; however, this pressure does not significantly displace the point H_3. This result is consistent with the conclusion that the cusp point T_c, in contrast with the boiling point, is a slight function of the pressure p_c (refs. 1, 2). As the voltage on the capacitor is changed by 20-30% the value of H_3 for these metals remains essentially constant.

TABLE 2. Melting Temperature T_2 and Specific Heat C_2 of the Liquid Phase near T_2, Normal Boiling Point T_{nb}, the Temperature at the Beginning of the Electrical Explosion T_3, and the Critical Parameters T_k and P_k for Zinc, Cadmium, and Lead

Metal	T_2[5], °K	C_2[5], J/(mole·°K)	T_{nb}[5], °K	T_3, °K	T_k, °K	P_k, atm
Zn	692.7	31.38	1184	2333	2590	740
Cd	594.0	29.71	1040	2230	2480	980
Pb	600.6	30.63	2016	3570	3970	160

That the MHD instabilities have no appreciable effect on the value of H_3 found for Cd has been confirmed in subsequent experiments involving the electrical explosion of this metal in a plastic medium (Teflon) under a pressure p up to 6 kbar at a current pulse length of about 100 μsec. At $p > 1$ kbar the instability is completely suppressed and H_3 is a weak function of p; the function $H_3(p)$ is approximately linear. Extrapolation of this functional dependence to $p = 0$ yields $H_3 = 64$ kJ/mole, in good agreement with the values shown in Table 1 for the experiments in air.

A calculation of the cusp point in the coordinates p−T for Cs on the basis of the Furth equation[1] has shown that this point is described accurately by

$$\frac{p_c}{p_k} = \frac{10T_c}{T_k} - 9 \tag{2}$$

(here the subscript "c" refers to the cusp point, while the subscript "k" refers to the critical parameters); this equation agrees with the equation of the cusp point for several organic liquids determined experimentally by various methods, including a pulsed-heating method.[2] On the basis of this agreement we can assume that thermodynamic similarity holds satisfactorily for the cusp points of liquids differing in their physical properties. Assuming that $p_c = p_{at} \ll p_k$ for our experiments in air, we find from (2) that

$$T_k = \frac{10T_c}{9} \approx \frac{10T_3}{9}. \tag{3}$$

We can evaluate T_3 from the specific heat of the liquid metal, C_2, near the melting point T_2 and from the data obtained on H_2 and H_3. Then we can write the critical temperature as

$$T_k = \frac{10}{9}\left[T_2 + \frac{H_3 - H_2}{C_2}\right]. \tag{4}$$

Some justification for equating C_2 in (4) to the average value of C_p over the range from T_2 to T_3 comes from the circumstance that for liquid metals the value of C_p generally falls off initially and then increases with increasing T; as we approach T_c we evidentally have $C_p > C_2$. The values of T_3 and T_k calculated from (4) on the basis of the values of H_2 and H_3 obtained for explosions in air are shown in Table 2, along with the values of T_2, C_2, and T_{nb} taken from ref. 5 for these metals.

These values of T_k are apparently slightly underestimated, for two reasons: First, because of the possible onset of MHD instabilities H_3 can be slightly lower than H_c at $p = 1$ atm. Second, since the internal layers of the metal in a sample are compressed by the magnetic pressure, we should not substitute in Eq. (4) the value of C_2 which is generally measured in vacuum, but a slightly lower value (as the value of p increases for liquids, the value of C_p is known to decrease). However, this factor cannot presently be taken into account in the absence of data on the influence of p on C_p for Zn, Cd, and Pb in the liquid state. We can nevertheless assume that this effect does not exceed the error in the determination of H_3 in our experiments.

We can use these values of T_k to evaluate the critical pressure p_k for Zn, Cd, and Pb by extrapolating data (given in ref. 5 for pressures up to p = 1 atm) on the functional dependence of the saturation vapor pressure of these metals on the temperature. We plot this functional dependence in the coordinates log p vs 1/T and extrapolate linearly to $T = T_k$. Table 2 shows the values found in this manner for p_k for Zn, Cd, and Pb; for all three metals the values are much higher than the corresponding maximum values of the magnetic pressure at the axis of the sample. This circumstance again demonstrates that a superheated, metastable, liquid-metal phase existed under our experimental conditions. When this method for determining p_k is applied to Cs and Hg the values are approximately equal to those found in direct measurements.[11]

After the beginning of the electrical explosion the supply of energy to the conductor is essentially cut off because of the rapid increase in the resistance of the conductor. As the cusp point is approached this increase is due to the rapid growth of fluctuations in the superheated liquid metal, which lead to a localization of conduction electrons and to the conversion of the metal into a nonmetal.[1] The free energy of the superheated liquid-metal phase near the cusp point is much higher than the energy of its saturated vapor, so that the conversion of this liquid into vapor is of an explosive nature (a phase explosion) and occurs due to the excess enthalpy of the superheated liquid metal, $H_3 - H_{nb}$, which can be called the "energy release" during a phase explosion. For experiments in air (Table 1) the values of $H_3 - H_{nb}$ for Zn, Cd, and Pb are, respectively, 0.55, 0.31, and 0.24 kJ/g or, per unit of the original volume, 3.9, 2.7, and 2.7 kJ/cm^3. If the final state of the two-phase system which arises after the explosion without external supply of energy is associated with the normal boiling point of the metal, we conclude that the ratio $x = (H_3 - H_{nb})/\lambda$ (where λ is the heat of vaporization at this point) is equal to the fraction of evaporated metal. For explosions in air, according to the values found for H_3, we have x = 0.31 for Zn, 0.35 for Cd, and 0.31 for Pb.

---

1) Martynyuk and Gerrero[6] show that at a heating rate of about 10^6 deg K/sec the points H_1 and H_2 lie about 40°K above the normal melting point in the case of Pb; this result has been confirmed in subsequent experiments by Martynyuk and Tsapkov. There was also apparently a superheating of the solid phase of Pb in these experiments, but this superheating does not exceed the error in the determination of H.

Resistance and enthalpy of refractory exploding wires

M. M. Martynyuk, I. Karimkhodzhaev, and V. I. Tsapkov
Patrice Lumumba Friendship of Nations University, Moscow

(Submitted June 7, 1973)
Zh. Tekh. Fiz., 44, 2367-2373 (November 1974)

A pulsed oscilloscope method has been used to measure the relative electrical resistance R/R_0 as a function of the enthalpy H for Zr, Hf, Nb, Mo, W, and Pt as the wire samples are heated by current pulses with t_3 = 400-500 and 30-35 μsec. In the prolonged heating the samples are ruptured immediately after melting; with a briefer heating, there is a deeper penetration into the liquid-state region, up to temperatures far above the normal boiling point of the metal. The values of R/R_0 and H for the solid and liquid phases of these metals are measred at the boiling point and at the temperature corresponding to the beginning of the electrical explosion, T_3; in pulsed heating in water at t_3 = 30-35 μsec, the values of R/R_0 for Zr, Hf, Nb, and Mo remain essentially constant in the liquid-state region up to T_3. The temperature T_3, which is identified as being approximately equal to the critical temperature, is evaluated. In pulsed heating in air there is a dip in the value of R/R_0 for the liquid state of all these metals; this behavior is attributed to discharge shunting the sample.

The electrical resistance R/R_0 (where R_0 is the resistance of the sample at T = 298°K) and the enthalpy $H = H_T - H_{298}$ of the refractory d-transition metals have not been studied adequately at high temperatures.[1,2] For many of these metals the value of H has been measured only up to $T < T_{me}$ (where T_{me} is the melting point), and the heat of melting is not known; the information which has been reported requires verification. There is little information available about the physical properties of the d-transition metals in the liquid state. This situation results from the difficulty of carrying out high-temperature studies of metal properties by classical methods, which generally involve slow heating.

We report here measurements of R/R_0 and H for Zr, Hf, Nb, Mo, W, and Pt by a method involving the heating of a wire sample by a powerful current pulse and simultaneous oscilloscope study of the current and voltage in the sample; the R/R_0 (H) functional dependences are calculated from the oscillograms.[3] When a liquid metal is subjected to pulsed heating at a sufficiently high rate the metal undergoes a transition to its metastable state; then there is an explosive transition to the gaseous state[4,5] (an electrical explosion), so that we measure R/R_0 and H not only in the regions of the stable states of these metals, but also in the states preceding their electrical explosion. Measurements of this type are extremely important for studying the nature of this phenomenon.

1. EXPERIMENTAL PROCEDURE AND RESULTS

The measurements are carried out on two types of pulsed experimental devices. In arrangement No. 1, current pulses of 0.7-4 kA, approximately rectangular, are produced by an artificial line with a characteristic impedance of 0.4 Ω. This line is charged to 3 kV. The voltage across the sample does not exceed 350 V. The current pulses are detected by a nondistorting cylindrical shunt of constantan foil as suggested by Park.[6] Otherwise, the apparatus is the same as in ref. 3. The rms error in the measurements, averaged over the data of six experiments, is ± 2% for R/R_0 and ± 3% for H.

Arrangement No. 2 uses the aperiodic discharge of a capacitor charged to a voltage of 3 kV; the circuit is described in ref. 5. In this case the length of the pulses before the beginning of the electrical explosion, t_3, is 30-35 μsec; the samples are heated in the liquid state for τ = 10-15 μsec; and the maximum current reaches 10 kA. The rms error in the determination of R/R_0 with this arrangement is ±5%, and that for H is ±7%.

The samples are made from 99.76% pure Zr, 99.0% pure Hf, 99.94% pure Nb, 99.96% pure Mo, 99.9% pure W, and 99.93% pure Pt. The diameter of the Hf samples is 0.74 mm, and that for the other metals is about 0.5 mm; the samples range in length from 33 to 84 mm. The experiments with arrangement No. 1 are carried out only in air, while those with arrangement No. 2 are carried out in both air and water, since the shunting discharge is observed to have a significant effect on the experimental results for the experiments in air at high temperatures.

Figure 1 illustrates the results with oscillograms of the current I and the voltage U for the case W; Fig. 2,

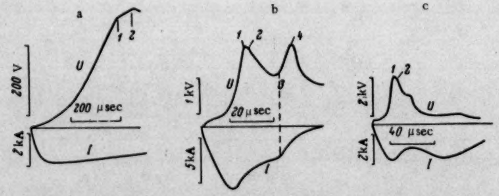

Fig. 1. Oscillograms of the current I through the sample and the voltage U for W samples. a) Arrangement No. 1 in air; b) arrangement No. 2 in water; c) the same, in air. 1) Beginning of melting; 2) end of melting; 3) beginning of electrical explosion; 4) "peak" in the voltage across the sample.

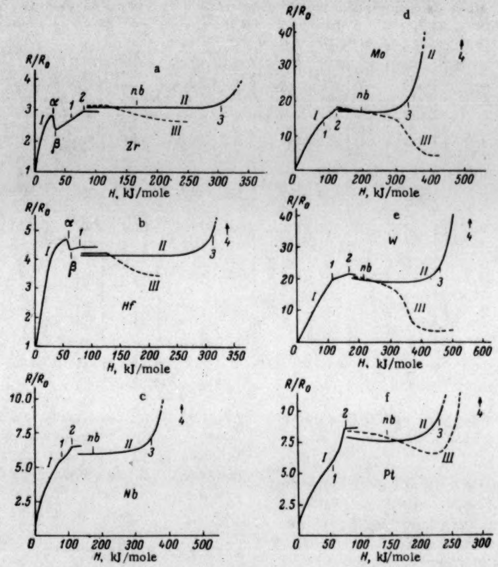

Fig. 2. Relative resistance of Zr, Hf, Nb, Mo, W, and Pt as a function of the enthalpy. I) Arrangement No. 1 in air; II) arrangement No. 2 in water; III) the same, in air. 1) Beginning of melting; 2) end of melting; 3) beginning of electrical explosion; 4) "peak" in the voltage across the sample. The beginning α and end β of the polymorphic transitions are indicated for Zr and Hf.

a-f, shows the functional dependence (R/R_0) (H) calculated from the oscillograms for the various metals studied. On the voltage oscillograms and the (R/R_0) (H) curves we mark the points of slope change, corresponding to the beginning (t_1, R_1/R_0, H_1) and end (t_2, R_2/R_0, H_2) of the melting of the sample. For Zr and Hf in the solid state we also mark the beginning (t_α, R_α/R_0, H_α) and end (t_β, R_β/R_0, H_β) of the polymorphic $\alpha-\beta$ transition, which is accompanied by a conversion of the hcp crystal structure into a bcc structure.

In the experiments with arrangement No. 1 the samples are ruptured immediately after melting; the beginning of rupture is identified with the rapid change on the oscillogram of U. In the experiments with arrangement No. 2 in water we determine the beginning of the electrical explosion, t_3; beyond this point the current falls off sharply, and the voltage across the sample increases to its "peak" value at t_4 (Fig. 1). On the (R/R_0) (H) curves (curves II in Fig. 2, a-f), after the beginning of the explosion (R_3/R_0, H_3) we observe a rapid increase in R/R_0. The values of H_3 at this point, in contrast with the values H_4 at the voltage peak, are reproducible well from experiment to experiment for a given metal. We believe that the explosive destruction of the sample begins at t_3, but the oscillograms are continuous up to t_4 because of the discharge through the explosion products.

In the experiments carried out with arrangement No. 2 in air we observe a decrease in R/R_0 in the liquid-state region (Fig. 2, a-f), apparently due to the development of a surface discharge shunting the liquid sample. In this case the points t_3 and t_4 are not found from the oscillograms (Fig. 1).

Each of the curves shown in Fig. 2, a-f, is obtained by averaging the experimental data for six experiments; computer analysis of the oscillograms for each curve yields 250-300 points. The results found with arrangement No. 2 are shown in Fig. 2, a-f, only for the liquid-state region (curves II and III). In the case of pulse heating in water for Zr, Hf, Nb, and Mo (curves II in Fig. 2, a-e), there are no changes of any kind in the value of R/R_0 during the heating over a broad temperature range in the liquid state. For the solid state and for the melting region we show the experimental data obtained with arrangement No. 1 (curves I); these data are more accurate than those obtained with arrangement No. 2. The results found with the two experimental arrangements agree within the error corresponding to arrangement No. 2 over the ranges where the experiments overlap.

Within the experimental error we observe a tendency toward a decrease in the resistance of the liquid metal in the results found with arrangement No. 2 (curves I and II in Fig. 2, b-f); this decrease can be attributed to the higher magnetic pressure in the experiments carried out with this arrangement. The value of this pressure, averaged over

TABLE 1. Relative Resistance and Enthalpy of the Solid Phase (R_1/R_0, H_1) and Liquid Phase (R_2/R_0, H_2) of Zr, Hf, Nb, Mo, W, and Pt at the Melting Point and in the Liquid Phase at the Beginning of the Electrical Explosion (R_3/R_0, H_3)

Metal	μΩ·cm	$\frac{R_1}{R_0}$	$\frac{R_2}{R_0}$	$\frac{R_2}{R_1}$	$\frac{R_3}{R_0}$	H, kJ/mole			
						H_1	H_2	H_2-H_1	H_3
Zr	47.9	2.69	2.95	1.10	3.35	60.0	81.5	21.5 21.2 [8]	310
Hf	35.3	4.42	4.42	1.00	4.99	78.0	—	—	312
Nb	15.8	5.50	6.50	1.18	7.20	76.0 72.8 [1]	109.0	33.0	348
Mo	5.54	14.5	17.5	1.21 1.18 [10]	20.5	85.0 85.0 [1]	123.0	38.0 36.6 [9]	336

Note: Here ρ_0 is the resistivity at T = 298°K. The upper row for each metal shows the data of the present work.

the cross-section of the sample,[3] is no higher than 40 bar for arrangement No. 1 and no higher than 250 bar for arrangement No. 2.

Table 1 shows the values of R/R_0 and H found for the beginning (R_1/R_0, H_1) and end (R_2/R_0, H_2) of melting with arrangement No. 1, along with the values (R_3/R_0, H_3) corresponding to the beginning of the electrical explosion, obtained from the experiments in water with arrangement No. 2. The values R_1/R_0, H_1 and H_2 for Zr, Mo, and Pt agree with the results of experiments carried out by ordinary methods,[1,2,7-9] so that we have grounds for assuming that under these experimental conditions no significant shift of the melting point of these metals is observed and that the values obtained for these quantities are approximately equal to the equilibrium values. Our data on R_2/R_1 for Pt, Mo, and W and on the heat of melting H_2-H_1 for W agree with the results of pulsed measurements carried out by Lebedev et al.;[10] for Pt and Mo the values of H_2-H_1 from ref. 10 are slightly higher than our values.

Comparison of H_3 with the enthalpy H_{nb} corresponding to the normal boiling point of the liquid metal, T_{nb}, which is estimated in ref. 1, shows that $H_3 > H_{nb}$ for all the metals studied, i.e., for a prolonged heating of the liquid phase, for 10-15 μsec, corresponding to a heating rate of $5 \cdot 10^8$ deg/sec, we observe a significant elongation of the enthalpy range corresponding to the existence of the liquid phase (Fig. 2, a-f).

In additional to determining the data shown in Table 1 for Zr and Hf, we determine the values of R/R_0 and H corresponding to the beginning (R_α/R_0, H_α) and end (R_β/R_0, H_β) of the polymorphic transition. For Zr we find $H_\alpha = 30.5$, $H_\beta = 35.0$, and $H_\beta - H_\alpha = 4.5$ kJ/mole and $R_\alpha/R_0 = 2.82$, $R_\beta/R_0 = 2.36$, and $R_\beta/R_\alpha = 0.836$. For Hf we find $H_\alpha = 58.2$, $H_\beta = 63.4$, and $H_\beta - H_\alpha = 5.2$ kJ/mole and $R_\alpha/R_0 = 4.68$, $R_\beta/R_0 = 4.32$, and $R_\beta/R_\alpha = 0.923$. Comparison with data from the literature[1,11] on Zr, obtained in slow heating, shows that our values of H_α and H_β are higher by $\Delta H_{\alpha\beta} = 5.65$ kJ/mole, while the heat of the polymorphic transition, $H_\beta - H_\alpha$, agrees with the data of refs. 1 and 11. The discrepancy can be attributed to a superheating of the α phase above the phase-equilibrium temperature $T_{\alpha\beta}$. According to the value of $\Delta H_{\alpha\beta}$ and the specific heat of the α phase near $T_{\alpha\beta}$, this superheating is about $T_\alpha - T_{\alpha\beta} = 160$°K (the heating rate is about 10^7 deg/sec). Although we know of no other data for Hf, we would expect its behavior in the region of the α−β transition during pulsed heating to be analogous to that of Zr.

2. DISCUSSION OF RESULTS

Resistance of the liquid d-transition metals. Let us examine the change in the resistivity ρ of the liquid-transition metals during heating on the basis of the data (curves II in Fig. 2, a-f). We use the natural assumption, which has been confirmed experimentally,[14] that in our experiments the thermal expansion of the sample in the solid state occurs in both the radial and axial directions, while that during melting and during the liquid of the heating occurs in the radial direction. Then using the standard equation $R = \rho l/s$, we find the relation between ρ and R/R_0 for the liquid metal to be

$$\rho = \rho_0 \frac{1+2\gamma}{1+\gamma} \frac{R}{R_0} \left(1 + \frac{\Delta V_{me}}{V_1} + \frac{\Delta V_L}{V_1}\right). \tag{1}$$

where $\gamma = \Delta l_1/l_0$ is the relative elongation of the sample during its heating from $T_0 = 298$°K to $T = T_1 = T_2 = T_{me}$, $\Delta V_{me}/V_1$ is the relative change in the volume of the sample during its melting, $\Delta V_{em}/V_1$ is the relative change in the volume of the liquid metal as it is heated from T_2 to T, and ρ_0 refers to $T_0 = 298$°K. It follows from Eq. (1) that over the range in which R/R_0 is constant the value of ρ is governed solely by the thermal expansion of the metal

TABLE 2. Melting Point T_2, Normal Boiling Point T_{nb}, and Critical Parameters T_k and p_k for Zr, Nb, Mo, W, and Pt

Metal	T_2 [1], °K	T_{nb} [1], °K	$T_3 = T_k$ °K	p_k, atm
Zr	2125	4688	8950	1480
Hf	2500	—	—	—
Nb	2740	5007	9880	3240
Mo	2890	4924	7990	270
W	3650	5890	11880	6030
Pt	2043	4097	6450	250

$\Delta V_{em}/V_1$, and that the temperature coefficient of the resistance, $\alpha = d\rho/(\rho_0 dT)$, is directly proportional to the bulk expansion coefficient $\beta \doteq dV_{em}/(V_1 dT)$:

$$\alpha = \frac{1+2\gamma}{1+\gamma}\frac{R}{R_0}\beta. \tag{2}$$

This behavior is observed over a broad temperature range, about 5000°K, for Zr, Hf, Mo, and Nb (Fig. 2, a–e). There are apparently two possible explanations for this effect: (1) The scattering cross-section for conduction electrons for these metals does not change as a function of T in the liquid state of these metals, and ρ is governed solely by the number of atoms per unit volume; (2) the scattering cross-section varies as a function of T, so that there should be a change in ρ. However, some other process, e.g., a change in the concentration of conduction electrons occurs simultaneously in the metal and acts to offset this change in the scattering cross-section. The behavior of the liquid d-transition metals described by Eq. (2) must be taken into account in theories for their electrical conductivity.

Estimate of the critical parameters. We turn now to the possibility of estimating the critical temperature T_k and the critical pressure p_k for these metals on the basis of the experimental data obtained here for H_2 and H_3. Martynyuk[4] specifies conditions under which the beginning of the electrical explosion, T_3, lies near the cusp point T_c, at which the liquid phase becomes thermodynamically unstable. At the cusp points the average kinetic energy corresponding to the thermal motion of atoms is so large that these atoms can overcome the attractive forces acting between atoms in the condensed state. Experimental data on the cusp points for several organic liquids,[12] plotted as p/p_k vs T/T_k (where p is the pressure), can be approximated by

$$\frac{p_c}{p_k} = \frac{10T_c}{T_k} - 9, \tag{3}$$

which ends at the critical point. The continuation of the cusp and of the phase-equilibrium curve beyond the critical point is the transcritical-transition curve.[13] Thermodynamic-similarity conditions are satisfied for the cusps of various liquids,[4] so that we can apparently apply Eq. (3) to liquid metals. For electrical explosions in air we have $p_c = p_{at} = 1$ atm $\ll p_k$ and thus, according to (3), $T_k = (10/9)T_c \approx (10/9)T_3$. For electrical explosions in water, the sample is surrounded by a thin film of dense water vapor, which exerts a significant but unknown pressure on the surface of the sample. However, since, according to (3), T_c is a weak function of p, we do not make a large error in our estimate of T_k in this case if we assume that we have $p = p_c = p_k$ at the beginning of the electrical explosion; then from (3) we find $T_k = T_c = T_3$. We can estimate T_3 from the data on $H_3 - H_2$ and from data in the literature[1,7] on the specific heat of the liquid metal, C_2, near the melting point, T_2; we thus write

$$T_k \approx T_3 = T_2 + \frac{H_3 - H_2}{C_2}. \tag{4}$$

The values found for T_k in this manner are shown for the various metals in Table 2.

To estimate the critical pressures for these metals we used data on the saturation vapor pressure as a function of the temperature, given in ref. 1 for pressures up to p = 1 atm. These data are plotted as log p vs 1/T and extrapolated linearly to the values which we have found for T_k. The results of these estimates of p_k are shown in Table 2. Our calculations show that the highest critical parameters are those of tungsten, for which we find $T_k = 1.2 \cdot 10^4$°K and $p_k = 6$ kbar.

Electronics

Ion-optical system for shaping high-current ion beams

S. D. Grishin, V. F. Kuzovlev, R. V. Orlov, and S. N. Ogorodnikov

(Submitted November 26, 1973)
Zh. Tekh. Fiz., 44, 2374-2377 (November 1974)

A description is given of an ion-optical system capable of shaping high-current hydrogen-ion beams (up to 100 A). Its characteristics are discussed.

At the present time there is a need for high-current ion beams of high average density.[1] A beam of Cs ions with a current of 15.7 A and an average density < 1 mA/cm^2 has been shaped by using an ion-optical slit system.[2] It turns out to be difficult to increase the density because of the severe misalignment of the electrodes caused by thermal distortion. For this reason, an ion-optical slit system cannot be used to shape beams of heavy ions such as Hg, Bi, Pb, etc., with a current of tens of amperes and densities of a few tens of mA/cm^2.

We present here the characteristics of an ion-optical system capable of shaping a high-current beam of heavy ions (20-30 A) with an average density of 25-30 mA/cm^2.

2. The construction of the ion-optical system is shown in Fig. 1. The shaping 1, accelerating 2, and decelerating electrodes 3, are each formed of a flat grid of metal rods fastened at their ends to quartz supports 4, 5, 6. The rods of the accelerating and decelerating electrodes are fastened to their quartz supports with metal clips 7 so arranged that as they heat up they can stretch. This avoids mechanical stresses in the quartz and ensures electrical contact between the electrode rods and the potential source. The grooves in the quartz supports are 20-40 mm long and serve to fasten the electrodes and as high-voltage insulation. The shaping electrode is fastened and adjusted by tightening holder 4 by screws 8 to the front cover of the discharge chamber 9, and by screws 10 through the springs to the surface of the adjusting plate 11. Thus, the electrode rods are in direct contact with the discharge chamber 9. The accelerating and decelerating electrodes are fastened and adjusted in the same way as the shaping electrode except that the ends of their quartz supports are clamped to the cover of the discharge chamber through appropriate bushings 12 or 13, ensuring a gap between the electrodes. Since the grooves in the quartz supports are cut simultaneously, their clamping by screws 10 to one adjusting plate ensures reliable adjustment of the electrodes (alignment of slits). The decelerating and accelerating electrodes are made of tungsten rods 2 mm in diameter, and in three variants of the system the shaping electrodes are made of 2, 1, and 0.5 mm diameter rods on a 4 mm pitch. The 1 and 0.5 mm diameter rods are fastened with individual springs. The accelerating gap, i.e., the distance between the shaping and accelerating electrodes, is 2 mm in the first variant and 2.5 mm in the second and third. The maximum useful length of the rods which can be utilized by the beam is 150 mm. The width of the electrodes measured across the rods, or the useful length of the quartz supports, is also 150 mm, and is determined by the dimensions of the ion source. Thus the maximum cross sectional area of the beam can be 225 cm^2.

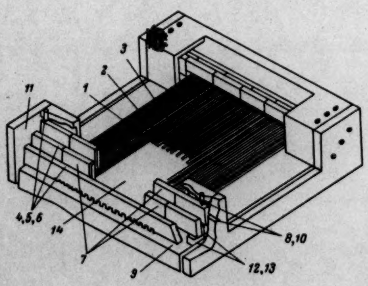

Fig. 1. Ion-optical system.

3. The characteristics of the ion-optical system developed have been investigated together with those of a Bi plasma ion source.

In the shaping of an ion beam from a solid emitter the focusing can be characterized by the dimensionless parameter

$$\gamma=\sqrt{\frac{2e}{\mu}}\frac{U^{3/2}}{d_0^2 j}, \qquad (1)$$

which is a similarity parameter that defines the shape of the beam. Here, U is the accelerating potential, d_0 is the width of the accelerating gap, j is the local beam current density, and e and μ are respectively the charge and mass of the ion. In shaping a beam from the plasma the parameter γ defined by (1) cannot generally be considered a similarity parameter since the emitting surface changes its position and shape with the plasma parameters in the ion source, e.g., the electron temperature. However, with certain restrictions γ can be regarded as a similarity parameter in this case.[3] A theoretical consideration shows that these restrictions reduce to the condition

$$U \geqslant 1.5\cdot 10^3 T_{e\,\max}, \qquad (2)$$

where $T_{e\max}$ is the maximum temperature of the plasma electrons in volts. The validity of condition (2) has been confirmed experimentally.

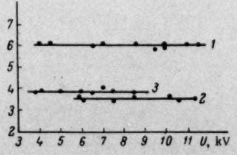

Fig. 2. γ_0 as a function of the accelerating potential.

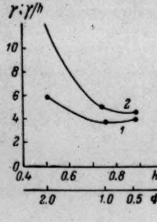

Fig. 3. γ_0 and γ_0/h as functions of the geometrical transmittance of the shaping electrode h.

The experiments are performed with an ion source in which T_e is maintained at 2-3 V. Then condition (2) gives a design value U = 3-4.5 kV.

Curves 1, 2, and 3 of Fig. 2 show the optimum value of γ_0 (best focusing, minimum angle of divergence of the beam) as a function of the accelerating potential for three variants of the ion-optical system. In this case the current density is not constant. The curves show that for the ion-optical systems under consideration γ_0 hardly changes as U varies from 4.5 to 14 kV, which is in good agreement with the calculated value of U, and indicates the validity of the similarity relation.

Thus, under our conditions for $U \geq 4.5$ kV the extraction of a beam from the plasma is described by the similarity relation (1), valid for beams formed from solid emitters, and γ can, in practice, be considered a similarity parameter. In this case knowing γ_0 makes it possible to determine the optimum value of the accelerating potential for specified densities, and to calculate the optimum parameters of geometrically similar structures for any working materials. A second parameter characterizing the ion-optical system is the geometrical transmittance of the shaping electrode:

$$h=\frac{a-\Phi}{a}, \qquad (3)$$

where Φ is the diameter of an electrode rod, and a is the pitch, in our case 4 mm.

Curve 1 of Fig. 3 shows γ_0 as a function of h. It is clear from this curve that as h increases (the diameter decreases) γ_0 at first decreases, reaches a minimum, and then increases. When γ_0 is a minimum the local density of the ion beam is a maximum. According to Eqs. (1) and (3) the reciprocal of γ_0/h characterizes the average current density of the beam or the total beam current. Curve 2 of Fig. 3 shows γ_0/h as a function of h. γ_0/h varies more rapidly than γ_0, but its minimum is smoothed. Beginning with h = 0.75, as h increases γ_0/h varies slowly and reaches a value of about 4.2. According to curve 1, if the local current density (emission density) is doubled, the average beam current density and the total beam current are tripled as h increases from 0.5 to 0.75.

Experiments show that in the forming of a beam from the plasma an increase in the accelerating potential increases the beam current in spite of the fact that the parameters of the plasma in the ion source and the flow through the optical system remain unchanged. The current increases because the plasma density on the boundary (on the meniscus) from which the acceleration of the ions occurs increases with the deepening of the meniscus in the slit of the shaping electrode with an increase in the accelerating potential. The plasma density at the meniscus is determined, on the one hand, by the entrance of ions from the source into the slit of the shaping electrode, and, on the other, by the neutralization of a part of the entering ions at the lateral walls of the slit of the shaping electrode adjoining the plasma and the subsequent emergence from the ion-optical system of part of the neutrals formed.

Figure 4 shows the ratio of the beam current $J(\gamma)$ for arbitrary focusing to the beam current $J(\gamma_0)$ for optimum focusing as a function of γ/γ_0 (proportional to $U^{3/2}$) for constant parameters of the plasma in the ion source. Curves 1 and 2 are for shaping electrodes 2 and 0.5 mm in diameter having geometric transmittances of 0.5 and 0.875 respectively. Figure 4 shows that the beam current increases as γ increases (as U increases), which agrees with the above point of view. The rate of increase of the current decreases with decreasing diameter of the electrode rods (curves 1, 2), which is accounted for by the decrease in the relative thickness of the electrode and the relative area of neutralization of the ions, which is proportional to the ratio of the diameter of a rod to the grid pitch. From this point of view the optimum shaping electrode is made of thin films. Curve 3 in Fig. 4 characterizes the variation of the beam current for a shaping electrode having a transmittance h = 0.5 made of square rods. The fact that curve 3 is steeper than curve 1 (h = 0.5) indicates the relatively larger yield of neutrals from a given ion-optical system for the same discharge and is explained by the fact that for curve 1 the surface of neutralization of plasma ions is largely changed in the discharge chamber. Also from this point of view the optical system with a shaping electrode made of foil is optimum because of the relatively small yield of neutrals.

Thus the beam current is a maximum for minimum γ_0 and a shaping electrode with a transmittance $h \approx 0.75$ and a thickness small in comparison with the slit size (ribbon electrode), all other conditions remaining the same.

4. The experimental investigations of the device have been carried out over several years and show that it is reliable. It has been subject to extended use and the electrodes have remained in good adjustment under all operating conditions. This ion-optical system has been used to

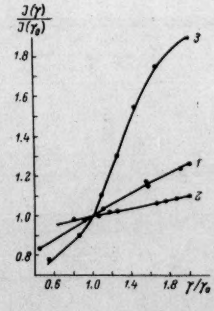

Fig. 4. Relative beam current as a function of γ/γ_0.

shape a 2.0 A beam of Bi ions ~100 cm^2 in cross section, limited by the dimensions of the ion source.

Our results are used to produce an ion-optical system for shaping ion beams with currents of tens of amperes (20-30 A for heavy ions) with a cross sectional area of 10^3 cm^2. In addition the results described here can be used to develop ion-optical systems capable of shaping hydrogen ion beams with currents up to 100 A and average densities of hundreds of mA/cm^2.

Secondary ion–ion emission is used to investigate the process by which platinum is cleansed of carbon impurities when it is heated in an oxygen atmosphere. The carbon contamination of the surface of platinum affects the way in which oxygen acts on the thermal emission current of alkali-metal ions.

INTRODUCTION

Contamination of metal surfaces by carbon atoms markedly affects processes that take place on these surfaces.[1-6] Carbon can be eliminated from these surfaces by heating in a rarefied-gas atmosphere whose molecules form chemical compounds with carbon that can be readily desorbed from the metal surface.[6,7]

In our study the cleansing of heated platinum in an oxygen atmosphere is studied by the method of secondary ion–ion emission.[8] These results, as well as those of certain experiments that establish the effect of a carbon coating on the behavior of the thermal emission current of Na^+ and K^+ ions when oxygen acts on platinum,1) comprise the principal focus of our study.

APPARATUS AND MEASUREMENT PROCEDURE

To investigate cleansing of volume impurities from metals, we set up the mass-spectrometer device shown in Fig. 1. In designing it, we have provided for monitoring the coating of the metal surface by impurity particles using the emission current of secondary ions. Secondary ions are ejected from the surface of the metal under study by bombarding the target with Kr^+ ions at an energy of 4 keV and current density of $5 \cdot 10^{-6}$ A/cm^2. To create the beam of Kr^+ ions we use the gas ion source of the MI-1305 (1) mass spectrometer, into which krypton is admitted at a pressure of $4 \cdot 10^{-5}$ mm Hg. To reduce the krypton pressure in chamber 2, where the target 3 is located, the ion source is isolated from the chamber by a system of three slits 4.

Secondary ions ejected from the target surface are formed into a 2 keV beam by using a four-electrode electrostatic lens 5. By appropriate choice of the electrode potentials of the lens the beam of secondary ions is focused onto the input slit 6 of magnetic mass spectrometer 7. The secondary ions thus separated according to mass-to-charge ratio are incident on the first diode of secondary electron multiplier 8. The output current of the multiplier is amplified by a U1-2 dc amplifier. The sensitivity of the secondary ion detection device is $\sim 1 \cdot 10^{-17}$ A/div.

For an additional check on the cleansing process on the basis of the flux of impurity particles or molecular compounds evaporated from the surface, the device is furnished with Pierce electron gun 9. The electron gun is attached to the wall of the first electrode of the ion lens and creates a plane electron beam at a current of ~300 mA and an energy of 300 eV that passes the target surface at a distance of 3 mm. Particles evaporated from the target surface are ionized by the electrons, and the resultant ions are formed into a beam, analyzed, and detected by the same devices used for secondary ions. When

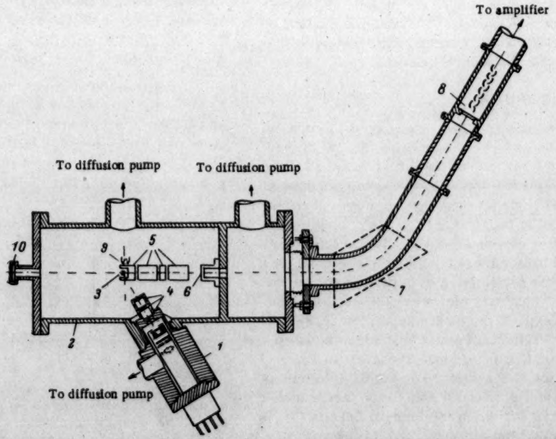

Fig. 1. Cross section of experimental arrangement.

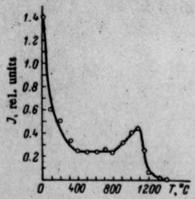

Fig. 2. J(T) for secondary C_2^- ions, for a platinum strip in residual-gas atmosphere.

the ion and electron guns are switched off we observe emission of some impurity particles that are readily ionized in the process of surface ionization (thermionic emission of the alkali metals Mg, Ca, Al, Ba).

The vacuum in the device is created by three DRN-50 mercury diffusion pumps which pump the target chamber, the mass spectrometer, and the ion gun. A carbon adsorption pump is used as a forepump. Mercury vapor is frozen out by three liquid-nitrogen-cooled traps. The limiting pressure in the target chamber is $2 \cdot 10^{-6}$ mm Hg.

Strips with dimensions 35 × 6 × 0.05 mm fabricated from commercially pure platinum (99.93%) are used as targets. These are heated by alternating current. The temperature of the strips in the 900-1400°C interval is measured by an optical pyrometer through quartz window 10. The temperature over the entire interval investigated, 20-1400°C, is measured by a Pt−PtRh thermocouple.

After boiling in alkali and then in distilled water, the platinum strips are inserted into the target chamber. The experiments are performed after the strips are vacuum-annealed at 1300°C for several hours.

In accordance with the data of refs. 5-7, it is established through preliminary experiments that the degree to which the surface of the strip is covered by particles of free carbon can be characterized by the emission current of secondary C^- and C_2^- ions. The basic data on cleansing of platinum from carbon impurities are obtained by investigating the functions J(t) and J(T) (J being the current of the beam of secondary C^- or C_2^- ions, t the isothermic annealing time, and T the strip temperature).

EXPERIMENTAL RESULTS

We first investigate J(T) for secondary C_2^- ions when the strip is in a residual-gas atmosphere (Fig. 2). The sharp drop in the C_2^- current on the initial segment of the curve results from desorption of hydrocarbon molecules from the surface of the strip. The behavior of $J_{C_2^-}(T)$ above 400°C results from the fact that, as the strip temperature increases, the flux of carbon atoms that diffuse from within the strip to its surface increases, on the one hand, and, on the other, the rate of oxidation of carbon on the surface by oxygen in the residual gas increases. These two factors can evidently explain the maximum on the $J_{C_2^-}(T)$ curve in the 1100°C region. We note that when the strip is heated above 1400°C it is no longer possible to detect carbon contamination of the surface on the basis of emission of C_2^- ions. This is evidently due to the fact that the rate of elimination of carbon in the form of CO and CO_2 is high at these elevated temperatures, and this results in a carbon coating that is so small that it can no longer be detected from C_2^- emission.

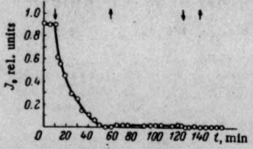

Fig. 3. J(t) for secondary C^- ions; platinum strips in oxygen atmosphere; strip temperature 1200°C. Downward arrows denote admission of oxygen upward arrows indicate oxygen valve shut off.

Experiments involving annealing of platinum strips in an oxygen atmosphere yield markedly different results. The annealing is performed at 1200°C, when the rate of carbon oxidation is fairly high (curve on Fig. 2), and with an oxygen pressure of $1.5 \cdot 10^{-5}$ mm Hg. The $I_{C^-}(T)$ curve characterizing this experiment is shown in Fig. 3. As can be seen from this figure, the C^- ion current drops monotonically immediately after the oxygen is admitted into the chamber; after about 50 min it becomes so small that it cannot be measured. Evacuation of oxygen from the chamber results in the appearance of a small C^- ion current which disappears when oxygen is again admitted, and does not return when oxygen is again pumped out.[2)] When the strip is cooled to room temperature, emission of secondary C^- and C_2^- ions is not observed. From this we can conclude the following: 1) The partial pressure of hydrocarbon vapor in the target chamber is small; 2) annealing the strips in an oxygen atmosphere results in virtually complete elimination of carbon contamination from the surface.

It was pointed out in the introduction that carbon contamination of metal surfaces affects the processes that occur on these surfaces. In this study we observe the effect of carbon contamination of platinum surfaces on the way in which oxygen affects the thermal emission current of alkali-metal ions.[9,10] This can be judged by considering Fig. 4, from which we see the variation in thermal emission current of K^+ ions when oxygen is admitted into a chamber containing a heated platinum strip.

The presence of carbon on the surface of a strip at 1100°C is established from the emission of secondary C^- and C_2^- ions. Admission of oxygen at $1 \cdot 10^{-5}$ mm Hg results in a rapid increase in the K^+ current, which then promptly begins to drop off and reaches a constant value in about an hour. After the oxygen is evacuated, we mea-

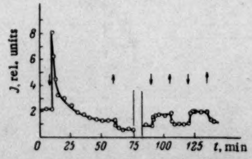

Fig. 4. J(t) for thermal emission current of K^+ ions; platinum emitter temperature 1100°C; downward arrows denote admission of oxygen, upward arrows indicate oxygen valve shut off. Emission currents of secondary C^- and C_2^- ions are measured during the time interval indicated by the discontinuity.

sure the emission currents for C^- and C_2^-. It turns out that these currents are so small they cannot be measured, indicating that the platinum surface has been cleansed of carbon contamination. Admission of oxygen a second time, after the platinum surface is already cleansed, also causes the K^+ current to increase, but the behavior of this current in time differs markedly from what was observed in the first instance. The sharp spike in the K^+ current which is observed when oxygen acts on a carbon-contaminated platinum surface is absent when the surface has already been cleansed. This has been repeated with many platinum strips and, without exception, all cases yield the same qualitative results.

We have also conducted experiments in reverse order on the effect of oxygen on the thermal emission current of K^+ from platinum emitters contaminated by carbon and emitters that had been cleansed of it. First the platinum strip is cleansed, as indicated above, of carbon impurities, and then we observe the behavior of the K^+ current when oxygen is admitted and evacuated. The behavior of this current is the same as in the case of carbon-cleansed platinum (right side of Fig. 4). If we now admit benzene vapor into the emitter chamber after oxygen has been evacuated, pyrolysis of benzene molecules on the heated surface causes a carbon coating to appear there. The presence of this coating is established from the appearance of an emission current of secondary C^- and C_2^- ions. After evacuation of bezene vapor and admission of oxygen, we observe the spikes in the K^+ thermal emission current that are typical of carbon-contaminated platinum.

In conclusion, we can express some preliminary considerations regarding the spike in the K^+ thermal emission current when oxygen acts on a carbon-contaminated platinum strip. As is shown in refs. 9 and 11, the influence of gases on the thermal emission current of alkali-metal ions involves volume impurities of alkali metals that arrive at the surface of the emitter under study through dislocation. Diffusion of carbon atoms onto the emitter surface can also take place through dislocation, but, in view of its low vaporizability, carbon that has diffused from within the emitter can collect near the point where the dislocations emerge onto the surface and thus block the evaporation of alkali-metal ions to some extent. When oxygen is admitted into the emitter chamber, the carbon that has collected around these points is eliminated, and this causes the spike in the alkali-metal ion current. When platinum surfaces are contaminated by pyrolysis of benzene molecules, the carbon may be preferentially deposited around the dislocation points, as is the case, e.g., in the formation of oxide centers when nickel is oxidized.[12] Elimination of this carbon when oxygen is allowed to act on a heated platinum strip can also result in the spike in the K^+ current, and this is in fact observed.

---

[1] Data on this effect are to be found in refs. 9 and 10.

[2] It is possible that a small diffusion flux of carbon atoms onto the surface of the strip still exists in this stage, but the resultant contamination of the surface by carbon is eliminated because oxygen in the residual gas oxidizes the carbon.

Radiation yield of ions in liquid dielectrics as a function of temperature and radiation energy

V. I. Ivanov, E. D. Kleshchenko, Yu. P. Sukhanovskii, and V. V. Frolov

Moscow Engineering Physics Institute

(Submitted July 16, 1973; resubmitted February 27, 1974)
Zh. Tekh. Fiz., 44, 2383-2387 (November 1974)

The Onsager theory is used to obtain the ion radiation yield G as a function of E the energy of the ionizing radiation and the temperature T in analytic form: $G(E, T) = aT \exp[-b(E)/T]$, where $b(E) = c_1[c_2E - \sqrt{c_2E}]^{-1}$; a, c_1, and c_2 are constants. The radiation yield of ions in hexane at T = 217-333°K is measured. The theoretical and experimental functions $G = G(T)$ are in satisfactory agreement, while the temperature dependence of the slope of the volt–ampere characteristic confirms the hypothesis.

INTRODUCTION

There have been many investigations of conduction in liquid dielectrics,[1–4] but as yet there is no unified opinion about the conduction mechanism in such media. In our view, the soundest theory is that developed by Onsager,[5] which takes account of initial or preferential recombination. According to this theory, an electron liberated by ionization can recombine with the parent ion through Coulomb attraction. The probability φ_0 that the electron will avoid such recombination, according to Onsager, is given by the expression

$$\varphi_0 = \exp\left[-\frac{r_k}{r}\right], \tag{1}$$

where r is the distance between the electron and the parent ion at thermalization, r_k is found from the expression $e^2/\omega r_k = kT$, e is the charge of the electron, ω is the permittivity, k is Boltzmann's constant, and T is the temperature of the medium.

A similar process occurs in gases as well, but since the distance r is large, initial recombination is not a factor in gases. Electrons which avoid initial recombination form negative ions which diffuse from the formation site into the liquid and are involved in volume recombination, as in gases.

Jahns and Jacobi[6] use this fact to derive the equation for the volt–ampere characteristic of an ionization chamber filled with a liquid dielectric. They set r = const and determine this parameter from the condition that the experimental and theoretical volt–ampere characteristics should agree. Other authors[1–7] also use parameters which are determined on the basis of such comparisons, a procedure which is not entirely correct.[8]

1. THEORETICAL

In this study we propose an explanation for certain phenomena that occur in liquid dielectrics on the basis of Onsager's theory,[5] using only parameters which can be determined independently.

We take $r = r(E_e)$ in (1), where E_e is the energy of an electron that has been liberated by ionization (the energy of a secondary electron). The probability that the electron will avoid initial recombination, as averaged over the spectrum of secondary electrons, is

$$\bar{\varphi}_0 = \frac{\int\limits_{E_e} n(E_e)\exp\left[-\frac{r_k}{r(E_e)}\right]dE_e}{\int\limits_{E_e} n(E_e)\,dE_e}, \tag{2}$$

where $n(E_e)dE_e = N\sigma(E, E_e)dE_e$ in (1), is the number of secondary electrons whose energy lies in the interval E_e–$E_e + dE_e$, generated by one ionizing particle with energy E; N is the number of molecules per unit volume of liquid and $\sigma(E, E_e)$ is the differential ionization cross section.

The basic difficulties in computing $\bar{\varphi}_0$ are associated with the determination of $r = r(E_e)$. In the $E_e > 10$ keV region we have $r(E_e) \gg r_k$ and $\exp[-r_k/r(E_e)]$ is equal to unity. In this case the exact form of $r(E_e)$ is unimportant. For $E_e = 0.3$–10 keV the function can be described by a relation of the form[9]

$$r = \eta E_e, \tag{3}$$

where η = const. For $E_e \le 0.3$ keV, however, where the form of the function is important since $r(E_e) \le r_k$, we must employ various types of extrapolations[9,10] because of the lack of experimental and theoretical data. To obtain an expression for $\bar{\varphi}_0$ in a form that is convenient for analysis we extrapolate $r(E_e)$ using function (3) for $E_e = 0$.

In conformity with the expression for the differential ionization cross section obtained by Garcia,[11] the numerator and denominator in (2) can be written as the sum of four terms, each of which has the following form: For the numerator $I_i = \int\limits_{\Delta E_e^i} N\sigma_i(E, E_e)\exp[-r_k/r(E_e)]dE_e$ and for the denominator $J_i = \int\limits_{\Delta E_e^i} N\sigma_i(E, E_e)dE_e$, where ΔE_e^i is the interval of secondary-electron energy in which the ionization cross section is determined by the function $\sigma_i(E, E_e)$. Equation (2) becomes simplest when the ionizing particle is an electron. In this case all the terms except the first are zero. We can also show that for protons with $E_p > 0.5$ MeV that $I_1/I_2 < 5 \cdot 10^{-2}$ and $J_1/J_2 < 10^{-2}$. Substituting the value of r from (3) into (2) and using the expression for the ionization cross section from ref. 11 for $\bar{\varphi}_0$, we obtain

$$\bar{\varphi}_0 = aT \exp\left[-\frac{b(E)}{T}\right], \tag{4}$$

where $a = 7\omega k/5e^2$, $b(E) = e^2[4\eta u\omega k(\lambda E/u - \sqrt{\lambda E/u})]^{-1}$, λ is the ratio of the electron mass m_e to that of the ionizing particle m, u is the binding energy of the electron in the molecule.

In integrating we use the change of variable

$$x = \left[1 + \frac{1}{4}\left(\frac{\lambda E}{u} - \sqrt{\frac{\lambda E}{u}}\right)\right]\frac{r_k}{\eta u}$$

and the expression

$$Ei(-x) = -\frac{e^{-x}}{x}\left(1 - \frac{1}{x}\right),$$

which is valid[12] for $x > 2$.

Strictly speaking, in computing $\bar{\varphi}_0$ we should allow for δ electrons of subsequent generations, and this makes the computations much more difficult. The nature of the dependence of $\bar{\varphi}_0$ on E and T remains virtually unchanged in this case.

In an external electric field $\mathcal{E}$ the probability that an electron will avoid initial recombination increases[5] in accordance with the expression

$$\varphi(\mathcal{E}, E, T) = \varphi_0(E, T)\left(1 + \frac{\mathcal{E}e^3}{2\omega k^2 T^2}\right). \tag{5}$$

Following Jahns and Jacobi,[6] for fields in which diffusion and volume recombination are negligible ($\mathcal{E} > 1$-2 kV/cm), we can obtain the equation of the volt–ampere characteristic of an ionization chamber field with liquid dielectrics in the form

$$i(\mathcal{E}, E, T) = \frac{ePV}{w}\varphi(\mathcal{E}, E, T), \tag{6}$$

where i is the ionization current through the chamber, P is the dose rate, V is the sensitized volume of the chamber, and w is the energy of formation of a pair of ions for the type of vapor involved.

The probability $\bar{\varphi}$ that an electron will avoid initial recombination (or the proportion of electrons that result in the ionization current through the chamber) is analogous to the efficiency of ion collection in gas chambers. Unlike gases, in fluids we have $\varphi \ll 1$ and this increases with the field up to field strengths corresponding to electrical breakdown.

In radiation chemistry and radiobiology it is of practical importance to know the ion radiation yield G, this being related to the efficiency of ion collection $\bar{\varphi}$ by the simple expression

$$G(\mathcal{E}, E, T) = \frac{100}{w}\varphi(\mathcal{E}, E, T). \tag{7}$$

The radiation yield can be determined directly from the volt–ampere characteristic.

Figure 1 shows G = G(O, E = const, T) as computed from (4) and (7) for electron-ionized hexane. For small b(E) in (4) the temperature dependence of the radiation yield can be written in the form

$$G(T) = A(T - T_0), \tag{8}$$

where A is a dimensional constant and T_0 = const, which is in qualitative agreement with the measurement results.

Figure 2 shows G = G(O, E, T = const) as determined from (4) and (7). A comparison of G = G(E) with the experimental data is valid only if we allow for the energy variation of the ionizing particle along the track, this being determined by the specific experimental conditions. The results in Fig. 2 are obtained for the case of complete electron absorption in hexane. We should note that since the energy appears in (4) in the form of the dimensionless parameter $\lambda E/u$, the results given in Figs. 1 and 2 are valid for any charged particles.

The authors are unaware of systematic data on the function G = G(E); scattered reports of conduction measurements for liquid paraffins acted on by radiation at various energy levels are unsuited for comparisons with one another and with theory because of the absence of a complete description of the specific experimental conditions.

2. EXPERIMENTAL

We have investigated experimentally the conductivity of liquid dielectrics at various temperatures. We use a plane-parallel ionization chamber, whose design is such that we can measure the distance between electrodes from 0 to 20 mm to within 0.05 mm. The body of the chamber is 60 mm in diameter and 3 mm thick and is fabricated from polyethylene of a tissue-like composition. The diameter of the collecting electrode, which is coaxial with the body, is 20 mm. The chamber is filled with spectroscopically pure hexane and is maintained in a 20 kV/cm electric field for 48 h before the measurement. The conductivity of hexane that has been prepared in this fashion is $5 \cdot 10^{-8}\ \Omega^{-1} \cdot \text{cm}^{-1}$.

Co^{60} sources of varying radioactivity are used to irradiate the hexane. The dose rate at the point at which the hexane chamber is located is measured by a spherical tissue-equivalent ionization chamber filled with propane.[13]

Figure 1 shows the experimentally determined ion radiation yield as a function of temperature (curve 3). Comparison with curves 1 and 2 indicates that the experi-

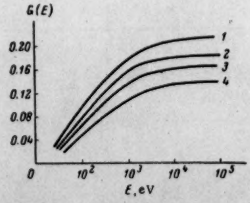

Fig. 1. Radiation yield of ions for hexane irradiated by electrons. Theoretical: 1) E = 0.1 MeV; 2) E = 1 keV; experimental: 3) Co^{60}.

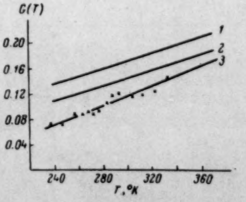

Fig. 2. Radiation yield of ions in hexane as a function of primary electron energy. T(°K): 1) 370; 2) 330; 3) 298; 4) 237.

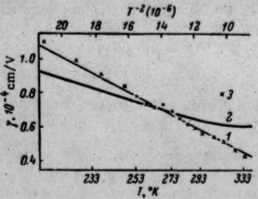

Fig. 3. Temperature dependence of the slope of the volt−ampere characteristic: 1) using Onsager's calculations;[5] 2) using Adamczewski's calculations;[1] 3) experimental.

mental and theoretical values of G = G(T) agree qualitatively. The difference in slope of 1, 2, and 3 is evidently due to errors in extrapolating $r(E_e)$ from (3) to low secondary-electron energies. There is reason to assume[14] that for $E_e > 20$ eV $r(E_e)$ is greater than the expression employed in calculations would imply. Despite the fact that curves 1 and 2 are computed for monoenergetic electrons, a fact which makes comparison with the resultant experimental data not entirely correct, we can assume that Eqs. (4) and (8) basically describe the behavior of G = G(T) accurately.

The efficiency of ion collection, which is also determined by curve 3, is in agreement with the earlier value[15] and with that obtained by Januszaitis[16] using another procedure, within the limits of experimental error (≃ 20%).

Figure 3 shows the slope γ of the linear portion of the volt−ampere characteristic as a function of temperature. It has been shown earlier[8,17] that the behavior of $\gamma = \gamma(T)$ can offer evidence in favor of one of the three hypotheses regarding the conduction mechanism in liquid dielectrics.[1,5,7] It can be seen from Fig. 3 that the experimental values of $\gamma(T)$ fit a straight line in (γ, T^{-2}), a fact which agrees with Onsager's theory[5] [see Eqs. (5) and (6)]. For comparison we also show curve 2 (Adamczewski's data[1]). The error in determining $\gamma(T)$ does not exceed 10%.

The authors thank Yu. V. Semenov for help with the tissue-equivalent ionization chamber.

Steady-state electron density in photoionization of aerosol particles

G. V. Karachevtsev and A. A. Fridman

Moscow Dolgoprudnyi Physicotechnical Institute

(Submitted May 7, 1973; resubmitted November 6, 1973)
Zh. Tekh. Fiz., 44, 2388-2392 (November 1974)

Equations are derived for the steady-state density of electrons generated by photon interaction with aerosol particles. It is assumed that the aerosol particles are of the same size. It is assumed that the photoionization cross sections of the aerosol particles and the electron sticking cross sections to particles are independent of the particle charge in the range from the critical negative charge, for which the work function is equal to the photon energy. A transcendental equation is derived for the electron density in the case of ionization by monochromatic light. Approximate expressions are derived for the limiting cases of high and low light intensities. A curve convenient for numerical calculations is given. Ionization by continuum radiation is also considered. An approximate expression is derived for the electron density for an exponential photon energy. The relaxation time is estimated for low steady-state electron densities.

Consider a gas containing aerosol particles with density n. The aerosol particles are spherical and their particle radius is r. We calculate the steady-state electron density n_e due to photoionization. The upper limit of the charge of the aerosol particles n_+e is determined by the fact that the work function increases for each subsequent electron: $\varphi_m = \varphi_0 + me^2/r$, where me is the particle charge before ionization. The lower limit of the particle charge $n_-e(n_- <$ 0 is defined by zero work function for emission from a particle. It is evident that

$$n_+ = \frac{(E-\varphi_0)r}{e^2}, \tag{1}$$

$$n_- = -\frac{r\varphi_0}{e^2}. \tag{2}$$

Here, E is the photon energy.

For conductors φ_0, the work function of the first electron, is determined[1] by A_0 the work function for a flat surface and by the radius of the aerosol particle. We consider the cases of ionization by monochromatic and by continuum radiation separately.

1. MONOCHROMATIC RADIATION

We write the equations for the densities of aerosol particles with different charges neglecting the coalescence of particles:

$$\left.\begin{aligned}
\frac{dn_{n_-}}{dt} &= -\gamma p n_{n_-} + \alpha n_e n_{n_-+1},\\
\frac{dn_{n_-+1}}{dt} &= \gamma p n_{n_-} - \alpha n_e n_{n_-+1} - \gamma p n_{n_-+1} + \alpha n_e n_{n_-+2},\\
\frac{dn_i}{dt} &= \gamma p n_{i-1} - \alpha n_e n_i - \gamma p n_i + \alpha n_e n_{i+1},\\
&\cdots\cdots\cdots\cdots\cdots\cdots\\
\frac{dn_{n_+-1}}{dt} &= \gamma p n_{n_+-2} - \alpha n_e n_{n_+-1} - \gamma p n_{n_+-1} + \alpha n_e n_{n_+},\\
\frac{dn_{n_+}}{dt} &= \gamma p n_{n_+-1} - \alpha n_e n_{n_+}.
\end{aligned}\right\} \tag{3}$$

Here, $\alpha \simeq v_e\sigma$ is the sticking coefficient for an electron with the mean velocity v_e and a particle with the cross section σ, γ is the photoionization cross section of the particle, which is assumed to be independent of the charge in the range $(n_- - n_+)$, and n_i is the density of particles with the charge ie.

Consider (3) under steady-state conditions $dn_i/dt = 0$ for any i. By adding the first equation in (3) to the second and adding the sum to the third, etc., we obtain a stationarity relationship for $i = n_-, \ldots, n_+ - 1$:

$$\alpha n_e n_{i+1} = \gamma n_i p. \tag{4}$$

We use the notation

$$q = \frac{n_{i+1}}{n_i} = \frac{\gamma p}{\alpha n_e}. \tag{5}$$

Then, from the electrical neutrality of the system and the mass balance, we find

$$\frac{n_e}{n} = \frac{\sum\limits_{k=n_-}^{n_+} k n_k}{\sum\limits_{k=n_-}^{n_+} n_k} \simeq \frac{\int\limits_{n_-}^{n_+} x q^x dx}{\int\limits_{n_-}^{n_+} q^x dx}.$$

Integration yields

$$\frac{n_e}{n} = \frac{n_+ q^{n_+} - n_- q^{n_-}}{q^{n_+} - q^{n_-}} - \frac{1}{\ln q}. \tag{6}$$

The problem of calculating n_e as a function of A_0, r, E, n, and p is solved by Eq. (6). In general, this dependence cannot be expressed in explicit form. Let us analyze the cases in which $n_e = f(A_0, r, E, n, p)$ can be expressed in simple explicit form.

1) Let $q \gg 1$. This means that $p \gg \alpha n_e/\gamma$. Equation (6) is then simplified:

$$\frac{n_e}{n} \simeq \frac{n_+ q^{n_+}}{q^{n_+}} = n_+. \tag{7}$$

Hence, the condition $q \gg 1$ means that

$$p \gg \frac{\alpha n n_+}{\gamma}. \tag{8}$$

2) We now reduce the flux p. Since $p \gg \alpha n n_+/\gamma$, n_e is independent of p. Consider Eq. (6). We note that its two terms vary in different ways when g is reduced ($q >$ 1): The first term remains virtually unchanged (for large values of n_+ and n_-), while the second increases in constant fashion. The value of n_e decreases and depends on p. The value of $q = \gamma p/\alpha n_e$ decreases at a lower rate for smaller p, and, for small p,

$$p \ll \frac{\alpha n}{\gamma} \tag{9}$$

the density n_e is low, $n_e/n \ll 1$, while q assumes the limiting value q_1, which is close to unity and is determined by Eq. (6) under the assumption that $n_e/n = 0$. If (9) is satisfied,

$$n_e = \frac{\gamma p}{\alpha q_1}, \tag{10}$$

where q_1 is determined by

$$\frac{n_+ q_1^{n_+} - n_- q_1^{n_-}}{q_1^{n_+} - q_1^{n_-}} = \frac{1}{\ln q_1}. \tag{11}$$

It can be shown that (11) has the following approximate solution:

$$q_1 = \begin{cases} e^{1/n_+} \text{ for } \delta \gg 1, \\ e^{1/n_-} \text{ for } \delta \ll 1, \\ \text{close to unity for } \delta \simeq 1. \end{cases} \tag{12}$$

Here, $\delta = |n_-/n_+|$. It is evident from (12) that q_1 is always close to unity. Consequently, the approximate solution of the basic equation (6) is

$$n_e = \frac{\gamma p}{\alpha} \text{ for } p \ll \frac{\alpha n}{\gamma}. \tag{13}$$

The curves of constant values of n_e, plotted by means of Eqs. (7), (8), and (13), are shown in Fig. 1 in a plot of log p vs log (nn_+). Estimates of the errors in (7), (8) and (13) with respect to the more accurate equation

$$\frac{n_e}{n} = n_+ - \frac{1}{\ln q} \tag{14}$$

are given in the figure.

If $p \gg \alpha n n_+/\gamma$ and $\eta = \Delta n_e/n_e$ is the relative error in measuring n_e, then

$$p = \frac{\alpha}{\gamma} n n_+ e^{1/\eta n_+}. \tag{15}$$

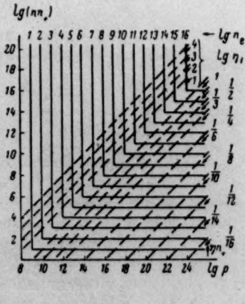

Fig. 1

For $p \ll \alpha n/\gamma$,

$$p = \frac{\alpha}{\gamma} \eta_1 n n_+, \tag{16}$$

where $\eta_1 = \Delta n_e/2.3 n_e \log n_e$ is the relative error in the measurement of log n_e. The results of calculations based on expressions (7), (8), (13), (15), and (16) for $\alpha/\gamma = 10^{-8}$ cm/sec are given in Fig. 1 as the dependences of log n_e, log η_1, and ηn_+ on log p and log (nn_+). The value of n_e is constant along the solid curves, while the approximation error is constant along the dashed curves.

II. IONIZATION BY CONTINUUM RADIATION

The basic stationarity equation (4) is

$$\gamma p_i n_i = \alpha n_e n_{i+1}, \tag{17}$$

where p_i is the flux density of photons with an energy sufficient for the (i + 1)-th ionization. We introduce the notation $\xi_i = p_i/p_0$. Then, from (17)

$$\left.\begin{aligned} n_1 &= n_0 \left(\frac{\gamma p_0}{\alpha n_e}\right) \xi_0, \\ n_2 &= n_1 \left(\frac{\gamma p_0}{\alpha n_e}\right) \xi_1 = n_0 \left(\frac{\gamma p_0}{\alpha n_e}\right)^2 \xi_0 \xi_1, \\ &\cdots\cdots\cdots\cdots\cdots \\ n_k &= n_0 \left(\frac{\gamma p_0}{\alpha n_0}\right)^k \prod_{i=0}^{k-1} \xi_i. \end{aligned}\right\} \tag{18}$$

Relationships (18) hold also for k < 0; in this, $\prod_{i=0}^{k} \xi_i$ is to be considered as $\prod_{i=0}^{-k} (1/\xi_{-i})$. By taking account of the electrical neutrality of the system and the mass balance, we obtain a generalization of Eq. (6):

$$\frac{n_e}{n} = \frac{\sum\limits_{k=n_-}^{\infty} k n_k}{\sum\limits_{k=n_-}^{\infty} n_k} = \frac{\sum\limits_{k=n_-}^{\infty} k q_0^k \prod\limits_{i=0}^{k-1} \xi_i}{\sum\limits_{k=n_-}^{\infty} q_0^k \prod\limits_{i=0}^{k-1} \xi_i}. \tag{19}$$

Here, $q_0 = \gamma p_0/\alpha n_e$. Determination of n_e by means of expression (19) is complicated for an arbitrary photon energy distribution, i.e., for arbitrary values of ξ_i. The problem is much simpler if $p(E) = pe^{-\delta E}$, which is fairly accurate in the tail of thermal radiation.

We determine p_0 and ξ_i for this case:

$$p_0 = \int_{\varphi_0}^{\infty} p(E)\,dE = \frac{p}{\delta} e^{-\delta \varphi_0}, \tag{20}$$

$$\xi_i = \frac{p_i}{p_0} = \frac{\int_{\varphi_i}^{\infty} p(E)\,dE}{\int_{\varphi_0}^{\infty} p(E)\,dE} = e^{-\delta i \frac{e^2}{r}}. \tag{21}$$

Then,

$$\prod_{i=0}^{k-1} \xi_i = e^{-\frac{\delta e^2}{r} \frac{k(k-1)}{2}}.$$

We write $\delta e^2/r = \lambda$ and substitute in (19), assuming that $n_- \to -\infty$ for the sake of simplicity. Then,

$$\frac{n_e}{n} = \frac{\sum\limits_{-\infty}^{\infty} k q_0^k e^{-\lambda \frac{k(k-1)}{2}}}{\sum\limits_{-\infty}^{\infty} q_0^k e^{-\lambda \frac{k(k-1)}{2}}}. \tag{22}$$

The problem of solving (22) is identical mathematically to the problem of thermal ionization of aerosol particles.[2] The solution is

$$\frac{n_e}{n} = y + \frac{\rho}{2\pi}\frac{d}{dy}\theta_3(y,\ \rho), \tag{23}$$

where $\theta_3(y, \rho)$ is an elliptic θ function, and $y = (1/\lambda)\ln q_0 + 1/2$, $\rho = 2\pi/\lambda$. For $\rho \gg 1$, we obtain the equation

$$\frac{n_e}{n} = \frac{1}{\lambda}\ln q_0 + \frac{1}{2}, \tag{24}$$

while, for $\rho \ll 1$,

$$\frac{n_e}{n} \simeq \frac{q_0}{1+q_0}. \tag{25}$$

It should be noted that, if $p(E)$ is not an exponential, but decreases sharply with E for $E \to \infty$, we can determine n_e by means of (19), retaining a finite number of terms, depending on the required accuracy.

III. ESTABLISHMENT OF THE STEADY STATE

In considering the establishment of the steady state, it is necessary to solve the system of kinetic equations for the densities of electrons and aerosol particles. For instance, in order to solve this problem for the case of monochromatic radiation it is necessary to solve system (3) by observing the condition of electrical neutrality of the system as a whole.

Even if stated in this way, this problem involves mathematical difficulties and requires numerical methods. The solution can be obtained in explicit form for $p \ll \alpha n/\gamma$, since $q \simeq 1$ in this case and $n_{n+} \ll n$ and $n_{n-} \ll n$. Then, the equation assumes the following form:

$$\frac{dn_e}{dt} = \gamma p n - \alpha n_e n. \tag{26}$$

It follows from this equation that

$$n_e(t) = \frac{\gamma p}{\alpha}\left(1 - e^{-\alpha n t}\right) \tag{27}$$

and the characteristic time for the establishment of steady-state conditions is

$$\tau = \frac{1}{\alpha n}. \tag{28}$$

Numerical estimates based on (28) for $n = 10^7$ cm^{-3} and $\alpha = 10^{-5}$ cm^3/sec yield $\tau = 10^{-2}$ sec.

General

Surface evaporation of a solid transparent dielectric under the action of laser radiation

A. M. Bonch - Bruevich, Ya. A. Imas, A. A. Kovalev, P. S. Kondratenko, and B. I. Makshantsev

(Submitted December 28, 1973)
Zh. Tekh. Fiz., 44, 2393-2397 (November 1974)

A method is suggested for the solution of the problem of self-similar surface evaporation of a solid transparent dielectric under the action of laser radiation. Simple equations are derived for the quantities which characterize the absorption wave front of the laser radiation. Expressions are obtained for the temperature of the surface and its evaporation rate.

INTRODUCTION

As shown in refs. 1 and 2 microinclusions absorbing laser radiation can, under certain conditions, lead to the onset of a thermal ionization avalanche in the basic material. The local temperature of the material then reaches values of $T \sim 10^{4\circ}$. If such a microinclusion lies close to the surface of a transparent dielectric, the ionization avalanche can reach the surface; as a result, the corresponding section of the latter will start to evaporate. Thus, there arises the problem of the evaporation rate and the corresponding surface temperature. This problem has been studied in the case of a metal surface.[3] The situation which exists in transparent dielectrics is, broadly speaking, substantially different from that in a metal, and requires special consideration.

It should be noted that at temperatures $T \sim 10^{4\circ}$ the local electron density n_e is already so high that further ionization of the material proceeds by electron impact.[4] Since the response time of the local temperature for values of the parameters of the problem considered below is much larger than the characteristic ionization and recombination times, the electron density will be determined solely by the temperature, i.e., $n_e = n_e(T)$. For $T \lessdot 10^{4\circ}$ the plasma can, at least qualitatively, be considered as ideal; therefore, the quantity $n_e(T)$ can be estimated from the Saha equation. As the ionization potential J is much larger than the temperature, we shall, for the sake of simplicity, retain for all values only the exponential temperature dependence, i.e, $\exp(-I/T)$, where $I = J/2$. Let us note that we are only interested in the range where the temperature is much larger than the initial temperature of the material. The latter can, therefore, be taken as zero.

It follows from the foregoing that the temperature $T(\mathbf{r}, t)$ is given by the thermal conductivity equation, the heat source $g(T, |\mathbf{E}|^2)$ of which is a function of the electric field E. The latter is determined by the corresponding Maxwell equation. The system of equations has the form

$$\frac{\partial T}{\partial t} = \chi \Delta T + g(T, |\mathbf{E}|^2), \tag{1}$$

$$\Delta \mathbf{E} + \left(\frac{\omega}{c}\right)^2 \varepsilon(T) \mathbf{E} = 0. \tag{2}$$

Here, χ is the thermal conductivity, $g(T, |\mathbf{E}|^2) = (\omega/8\pi c)\, \mathrm{Im}\,\varepsilon(T)\, |\mathbf{E}|^2$, ω is the frequency of the laser radiation, c is the velocity of light, $\tilde{c}$ is the thermal capacity of a unit volume of the dielectric, $\varepsilon(T)$ is the complex dielectric constant, which, in the collision-time approximation, can be written in the form

$$\varepsilon(T) = 1 - \frac{\tilde{\omega}^2 e^{-I/T}}{\omega^2 + \nu^2}\left(1 - \frac{i\nu}{\omega}\right), \tag{3}$$

where $\tilde{\omega} e^{-I/2T}$ is the electron plasma frequency, and ν is the electron collision frequency.

Equation (2) for the electrical field E takes account of the fact that the wave period is considerably shorter than the characteristic times of heat propagation.

The system of equations (1), (2) describes the motion of the volatile surface. We shall consider such times when the width of the temperature front near the surface is much smaller than its radius of curvature. If, therefore, we are interested in the surface, the problem can, at least qualitatively, be considered as one-dimensional. It should be noted that since the heat source function $g(T)$, $|\mathbf{E}|^2$ is proportional to $\exp(-I/T)$, the problem under consideration resembles the problem of the heat propagation of a flame.[5,6]

GENERAL RELATIONS

As in refs. 5 and 6 we seek a solution of the system (1), (2) which depends only on the combination of variables $\xi = x - vt$, where the positive direction of the x axis coincides with the light propagation direction, while the point $\xi = 0$ is taken as the origin, at which the heat source function $g(\xi)$ is maximum. Below, we examine the stability of such a solution.

It is necessary to add to the system of equations (1), (2) the boundary conditions

$$\left.\begin{aligned} T_1' &= \frac{\Lambda v}{\chi}, \\ T(\xi = +\infty) &= 0, \end{aligned}\right\} \tag{4}$$

where

$$T_1' = \left.\frac{dT(\xi)}{d\xi}\right|_{\xi=-\xi_0},$$

$T_1 = T(\xi)|_{\xi=-\xi_0}$; ξ_0 is the distance of the surface boundary from the point $\xi = 0$, Λ is the evaporation heat, expressed in degrees,

$$v = s e^{-\Lambda/T_1}, \tag{5}$$

s is the order of magnitude of the sound velocity. The electrical field of the wave is given by

$$\left.\begin{aligned} \mathbf{E}(-\xi_0 - 0) &= \mathbf{E}(-\xi_0 + 0), \\ \left.\frac{d\mathbf{E}}{d\xi}\right|_{\xi=-\xi_0-0} &= \left.\frac{d\mathbf{E}}{d\xi}\right|_{\xi=-\xi_0+0}, \end{aligned}\right\} \tag{6}$$

the incident plane wave at $\xi < -\xi_0$ being given by the flux density q of the laser radiation.

Let us remark that the boundary conditions formulated above correspond, as in ref. 3, to the neglect of the effect of the evaporated material on the evaporation process.

In accordance with the foregoing, we have

$$\frac{I}{T_0} \gg 1, \tag{7}$$

where $T_0 = T|_{\xi=0}$. In addition, we shall assume, and this is supported by the results that the temperature can be written in the form

$$T(\xi) = T_0 + T'_0 \xi, \tag{8}$$

where $T'_0 = (dT/d\xi)_{\xi=0}$ for all values of the variable ξ satisfying the following inequality

$$\left.\begin{aligned} &\frac{T_0}{I}\beta|\xi| \ll 1, \\ &\beta = \frac{I}{T_0^2}T'_0, \quad -\xi_0 \leqslant \xi \leqslant \xi_+, \text{ where } \xi_+ > 0, \end{aligned}\right\} \tag{9}$$

$$g(\xi_+) \ll g(0). \tag{10}$$

We then have $\exp(-I/T) \simeq \exp(-I/T_0)e^{\beta\xi}$. When Eq. (2) is solved taking (5) in consideration, Eq. (1) takes the form

$$\chi\frac{d^2T}{d\xi^2} + v\frac{dT}{d\xi} + g(\xi) = 0, \tag{11}$$

where

$$g(\xi) = \frac{\frac{4\nu\alpha^2 q}{\varepsilon c} y^2 |K_{i\mu}(\eta y)|^2}{\left|K_{i\mu}(\eta y_1) - i\frac{y_1}{\mu}\frac{d}{dy_1}K_{i\mu}(\eta y_1)\right|^2},$$
$$\alpha^2 = \frac{\tilde{\omega}^2 e^{-I/T_0}}{\omega^2 + \nu^2}, \quad \mu = \frac{2\omega}{\beta c}, \quad \eta = \mu\alpha\sqrt{1 - i\frac{\nu}{\omega}}, \quad y = e^{\beta\xi/2},$$

$y_1 = y|_{\xi=-\xi_0}$; $K_{i\mu}(\eta y)$ is the Bessel function of imaginary index. We shall subsequently assume the validity of the inequality

$$\frac{\nu}{\omega} \ll 1. \tag{12}$$

The extremum condition of $g(\xi)$ at the point $\xi = 0$ leads to

$$|K_{i\mu}(\eta)| + \eta\frac{\partial|K_{i\mu}(\eta)|}{\partial\eta} = 0. \tag{13}$$

Integrating Eq. (11) in the interval from $\xi = -\xi_0$ to $\xi = +\infty$ taking (4) into consideration, we obtain

$$v(\Lambda + T_1) = \frac{\varkappa q}{\tilde{c}}, \tag{14}$$

where $\varkappa = (\tilde{c}/q)\int_{-\xi_0}^{\infty} d\xi\, g(\xi)$ is the absorption coefficient of light.

On account of Eq. (8), we have

$$T'_1 = T'_0, \tag{15}$$

$$T_1 = T_0 - T'_0\xi_0. \tag{16}$$

Equations (4), (5), (13)-(16) constitute a closed system of equations for the determination of the unknown quantities T_1, T'_1, T_0, T'_0, v, and ξ_0. It is thereby easy by means of (11), to find the temperature profile $T(\xi)$, the electron density $n_e(\xi)$, etc. Let us emphasize that the system of equations mentioned is only valid when the inequalities (7)-(10) are fulfilled.

Two limiting cases are of real interest, one of which corresponds to the classical electromagnetic field, while the other to the presence of strong reflection from the absorption wave front.

The quasiclassical limit corresponds to the inequalities $\mu \gg 1$ and $\alpha|\sqrt{1 - i\nu/\omega}| \simeq \alpha < 1$, which are satisfied at small values of q. Therefore, when the expression for the function $g(\xi)$ is taken into account, we find that the quantity ν in Eq. (15) is equal to unity. The corresponding equations for the quantities T_1 and v will be analogous to the equations for these quantities in the problem of the evaporation of a metal surface.[3] Consequently, a detailed discussion of this situation is not necessary. We shall present only the expressions for v and T_1 valid for small values of the ratio T_1/λ

$$\left.\begin{aligned} &v \simeq \frac{q}{\Lambda\tilde{c}}, \\ &T \simeq \frac{\Lambda}{\ln\left(\frac{\tilde{q}_0}{q}\right)}, \end{aligned}\right\} \tag{17}$$

where $\tilde{q}_0 = s\Lambda\tilde{c}$.

The case of strong reflection requires special examination.

STRONG REFLECTION

The situation in which strong light reflection from the absorption wave front occurs corresponds to the inequalities

$$\left.\begin{aligned} &\mu^2 \ll 1, \\ &\alpha^2 \gg 1. \end{aligned}\right\} \tag{18}$$

Below, it will be important for us to be able, because of the first of the inequalities in (18), to retain the first terms in the series expansion of the function $K_{i\mu}(\mu\alpha\sqrt{1 - i\nu/\omega}\cdot e^{\beta\xi/2})$ for $\xi \neq 0$. Taking this fact as well as inequality (12) into consideration the absorption coefficient $\varkappa$ in Eq. (14) is given by $\varkappa = 2\mu\nu/\omega$. Bearing in mind the expression for the quantity μ as well as relations (15), (16), we have

$$\varkappa = \frac{4\nu T_1^2}{IcT'_1}(1 + x)^2, \tag{19}$$

where $x = T'_1\xi_0/T_1$.

Because of inequality (9), the quantity x is small enough in comparison with unity, so that, if we are not interested in ξ_0, we can in the first approximation, set x = 0 in Eq. (13). In principle, the quantity x can be determined in the following way. It follows from Eq. (13) that $\mu\alpha = 2e^{-1-c}$, where $c \simeq 0.58$ is Euler's constant. Hence, taking relations (15), (16) and the expression for α into consideration, we obtain the equation

$$\frac{\tilde{\omega}}{c}\frac{T_1^2}{IT_1'}(1+x)^2\exp\left(-\frac{I}{2T_1(1+x)}+1+C\right)=1. \tag{20}$$

Setting x = 0 in Eq. (19) and substituting the expression for the coefficient $\varkappa$ in Eq. (14), we find, after solving it jointly with Eqs. (4), (5),

$$T_1=\frac{\Lambda}{\ln\sqrt{\frac{q_0}{q}}+\ln\ln\sqrt{\frac{q_0}{q}}}, \tag{21}$$

$$v=\frac{2s\sqrt{\frac{q}{q_0}}}{\ln\frac{q_0}{q}}, \tag{22}$$

where

$$q_0=\frac{Is^2c\tilde{c}}{4\varkappa\nu}.$$

Let us recall that the intensity interval of the laser radiation flux for which Eqs. (21), (22) are valid is determined by the inequalities (7), (9), (10), (18).

We shall evaluate from Eqs. (21), (22) the characteristic values of the temperature T_1 and the velocity v. Assuming $I \simeq 4\cdot 10^{4\circ}$, s $\sim 10^5$ cm/sec, $\tilde{c} \sim 1$ J/cm^3/deg, $\varkappa \sim 10^{-2}$ cm^2/sec, $\nu \sim 10^{14}$ sec^{-1}, $\lambda = 3\cdot 10^{4\circ}$, we obtain for q $\sim 10^8$ W/cm^2, $T_1 \approx 8\cdot 10^{3\circ}$, v = 10^2 cm/sec, which agrees with the experimental data of ref. 7.

In conclusion, let us note that the stability of the solution obtained above must be investigated. For this purpose, as usual, a small perturbation must be added to the solution found above for the system (1), (2), i.e.,

$$T(\xi,t)=T(\xi)+\tilde{T}(\xi)e^{-pt},\quad \mathbf{E}(\xi,t)=\bar{\mathbf{E}}(\xi)+\tilde{E}(\xi)e^{-pt}.$$

The problem of stability is then reduced to the finding of a range of the problem parameters where the system (1), (2), linearized with respect to $\tilde{T}(\xi)$, $\tilde{E}(\xi)$, has no eigenvalues of p the real part of which is negative. As a result of the elimination of $\tilde{E}(\xi)$ from the system of equations we obtain, substituting $\tilde{T}(\xi) = e^{(-v/2\varkappa)\xi}\psi(\xi)$, an equation of the Schrödinger type with a nonlocal non-Hermitian potential and with the corresponding boundary condition at $\xi = -\xi_0$ for the logarithmic derivative of the "wave function" $\psi(\xi)$. It turns out that this equation corresponds to the case of a shallow potential well. Without showing the rather cumbersome calculations, let us note that the characteristics of the boundary conditions lead to the absence of bound states. Thereby, there are no eigenvalues of p with Rep < 0, i.e., within the framework of the assumptions made in the examination of the problem, the question of stability is solved favorably.

The authors wish to express their appreciation to S. I. Anisimov and I. P. Perstnev for helpful discussion.

Zh. Tekh. Fiz., 44, 2398-2403 (November 1974)

The interaction of intense laser radiation with solid targets of lithium deuteride has been investigated. A neutron yield of $6 \cdot 10^5$ neutrons per pulse is recorded. The reflection coefficient is measured and the second harmonic is detected in the reflected radiation. The results indicate the intrinsically nonlinear character of the interaction.

Progress in the construction of lasers has made it possible to concentrate large energies in small volumes for short times. This opens the way to the utilization of ultrahigh-power sources of light radiation and the investigation of controlled thermonuclear fusion. However, the interaction process of high-intensity radiation with solid targets has not yet been studied well enough. This is due, in particular, to the complexity of the phenomena. It is, therefore, of obvious interest to carry out investigations which clarify the relative role and influence in these processes of both the plasma parameters and the radiation in the simplest cases. Thus, for instance, using short radiation pulses, it is possible to reduce the effect of the material disintegration on the target parameters in question. The regime in which the material disintegration can be neglected is realized[1] during the time interval

$$t \leqslant 8 \cdot 10^{-25} I_{in}, \tag{1}$$

which for $I_{in} \sim 10^{15}$ W/cm² gives $t \leq 8 \cdot 10^{-10}$ sec, if the target material is lithium deuteride. The shape of the radiation pulse is also an important parameter.

It is known that the main pulse is preceded by some background level E_p, which can contain an energy sufficient for the evaporation of an appreciable quantity of material. The vapor cloud thus formed will affect the subsequent interaction between the radiation and the plasma. It is necessary to lower the background level E_p to a level E_c, which will not, under the experimental conditions, affect the state of the target:

$$E_p < E_c. \tag{2}$$

The measurement of the number of neutrons produced per flash allows an evaluation of the ion energy contribution. Since, however, nonthermonuclear neutron generation is possible,[2] the measurable yield cannot be unambiguously associated with the ion temperature. Assuming that during the time τ a Maxwellian ion velocity distribution is established, a calculation has been carried out[3] for short pulses of duration

$$t \ll \tau = 3 \cdot 10^{10} \frac{Q^{1/3}}{n_m}, \tag{3}$$

according to which the number of neutrons is determined by the magnitude of the energy Q(J/cm²) absorbed by the target:

$$N_{d-d} = 2.5 \cdot 10^{18} \left(\frac{n}{n_m}\right)^2 Q^{11/18} \exp\left\{-\left(\frac{10^{17}}{Q}\right)^{1/9}\right\}. \tag{4}$$

Here, n is the ion density in the interaction region, n_m is the density of target atoms, and N_{d-d} is the number of electrons emitted from 1 cm² of the illuminated surface of deuterated ice.

The electron temperature in a target illuminated by a short pulse[1] is related to the light intensity by

$$T_e \sim I_{in}^{\alpha},$$

where $4/9 < \alpha < 2/3$, and depends on the hydrodynamics of the corona disintegration. The measurement of the electron temperature and the reflection coefficient of light from the target plasma makes it possible to clarify the character of the interaction of radiation with the target material. Thus, when this interaction has a classical character, i.e., when the absorption is due to bremsstrahlung, the absorption coefficient[4] is given by the expression

$$K = \frac{\omega_p^2}{[c\omega\tau_{ei}(\omega^2 - \omega_p^2)^{1/2}]}, \tag{5}$$

where c is the velocity of light in vacuum, ω is the frequency of the incident radiation, and $\omega_p = (4\pi n_e e^2/m)^{1/2}$ is the plasma frequency.

Hence, it follows that as the intensity is increased, and consequently the temperature, the absorption must decrease. If, however, the character of the interaction is determined by a nonlinear process (for example ref. 5), the effective electron collision frequency can exceed the Coulomb frequency by one order of magnitude and, since it grows with intensity, it leads to an increased absorption. When the character of the interaction is nonlinear, intense harmonics of the radiation: 2ω, $3\omega/2$, $\omega/2$, where ω is the frequency of the pumping wave, may also appear.[6]

We have carried out experiments on the heating of

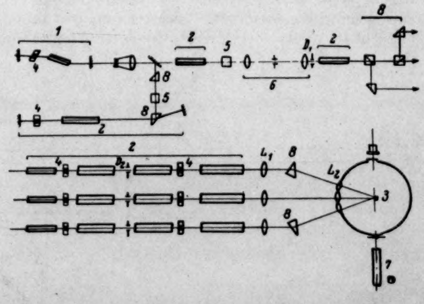

Fig. 1. Diagram of the experimental arrangement. 1) Master oscillator; 2) amplifier stages; 3) target; 4) passive switches; 5) Pockels switches; 6) lens selector; 7) aligning He–Ne laser; 8) rotating prisms; L_1, L_2) focusing lenses; D_1, D_2) collimating slits.

LiD plasma by means of a neodynium-glass laser with an output aperture of 60 mm, which makes it possible to satisfy conditions (1), (2). A diagram of the experimental arrangement is shown in Fig. 1. Working with three light channels, the single pulse energy can attain 1000 J. In the given series of experiments, carried out with the use of a single channel, the maximum energy does not exceed 120 J. This is the case because in carrying out these experiments special attention is paid to increasing the contrast of the laser pulse. The magnitude of the contrast, i.e., the ratio of the energy in the main pulse and the background energy, reaching values of > 10^4, is provided by two Pockels cells 5 and three liquid passive Q switches 4. The use of switches reduces, naturally, the magnitude of the maximum energy. It also, however, permits a substantial reduction of the quantity of material being evaporated from the target by the background radiation. The system of optical decoupling makes it possible to ensure laser operation under conditions in which the background energy at the target surface does not exceed 10 mJ. Figure 2 gives an idea of the effect of the magnitude of background energy on the evaporation of the target.

The angular divergence of the main radiation pulse is $\psi = 10^{-3}$ rad. A focusing lens with an aperture of 90 mm and focal distance of 235 mm ensures a focal spot size of

$$a = \psi f \cong 230\ \mu. \tag{6}$$

When the length of the pulse is $t = 9 \cdot 10^{-11}$ sec, the intensity of the laser light flux at the target surface $I_{in} = 10^{15}$ W/cm^2.

The target being illuminated is in a vacuum of $p = 10^{-5}$ torr and can, by means of a special mechanism, be displaced in the focal plane and along the optical axis with an accuracy of $\sim 5\ \mu$. An auxiliary He–Ne laser is used with a set of slits and focusing lenses.

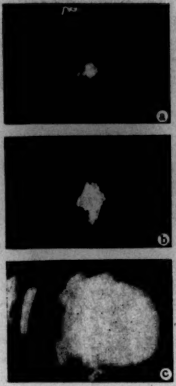

Fig. 2. Evaporation of the material of a LiD target by background radiation. The radiation is incident from the right side of the target, its duration is 100 μsec. The background energy (in mJ) is a) 10; b) 30; c) 100. The scale is 2 : 1. Photographed in white light.

Fig. 3. Oscillogram of the pulse from the x-ray radiation detector (a) and from the neutron detector (b). The pulse delays are not synchronized. The sweep duration is 250 nsec.

The neutron yield is measured by means of an activation unit with indium tracer, the sensitivity of which (at the existing background level) permits the measurement of 10^4 neutrons emitted in an angle of 4π. In addition, a plastic scintillator of 80 × 80 mm with an FÉU-110 M unit is used, recording separate neutrons. When the scintillator is placed at a distance of 30 cm from the target each count corresponds of 10^3 neutrons emitted in an angle of 4π. In the experiments, the electron temperature is measured by means of a method according to which a set of Al foils are placed in front of the scintillators. These are connected with an ÉLU photomultiplier through flexible lightguides of various lengths, constituting a light delay. A characteristic signal from an x-ray "thermometer" is shown in Fig. 3. Also shown is a pulse due to the incidence of a neutron on a scintillator. The electron temperature, determined by the measurement of the fraction of absorbed radiation in foils of different thicknesses,

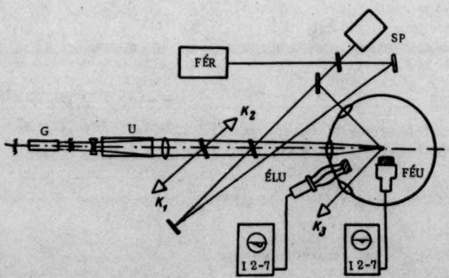

Fig. 4. Arrangement of the diagnostic apparatus.

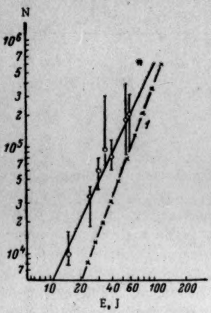

Fig. 5. Dependence of the neutron yield on the energy input to the target. The asterisk denotes the maximum yield of $6 \cdot 10^5$ n/4π. Curve 1 shows the results of calculation according to expression (4) for LiD.

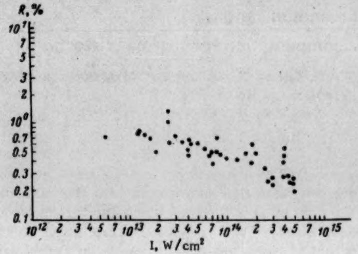

Fig. 6. Dependence of reflectivity $R = E_2/E_{in}$ on the intensity of light incident on the target.

is 1-2 keV. The estimate of the total energy of the x-ray radiation, taking into account the conversion efficiency of the scintillators, the quantum yield of the ÉLU photocathode, the transmission of the optical filters and the lightguide, gives a magnitude of 100 mJ. These figures agree satisfactorily with theoretical models of heating matter by short light pulses. The energy incident on the target, the backward reflected energy, and that scattered at an angle of 135° are measured by the calorimeters K_1, K_2, and K_3, respectively (Fig. 4). Simultaneously, the time development of the incident and reflected light intensity was recorded by means of the photoelectronic detector unit FÉR. The spectral composition of the scattered radiation was recorded by the spectrograph SP with a dispersion of 30 Å/mm. The disposition of the diagnostic apparatus is shown on Fig. 4.

In experiments with solid crystalline targets of lithium deuteride, a neutron yield attaining $6 \cdot 10^5$ neutrons in an angle of 4π is recorded. As a rule, the neutron yield is largest when the focal plane of the focusing lenses coincides with the target surface.

The dependence of the neutron yield on the magnitude of the absorbed energy is presented in Fig. 5. Expression (4) gives a somewhat lower value for the neutron yield. Since $t \sim \tau$, the agreement can be reckoned as satisfactory. As the input energy is increased, the "zero-time" condition (3) is more accurately satisfied and the difference between the experimentally obtained values and theoretical predictions decreases. The scatter in neutron yield is due mainly to the variation in the state of target surfaces. The variation can arise both because of isotope exchange and because of chemical processes.

The experimentally determined dependence of the reflectivity

$$R = \frac{E_r}{E_{in}} \qquad (7)$$

on the intensity I_{in} of the light incident on the target is shown in Fig. 6 (E_r is the light energy reflected into the aperture of the focusing lenses). A similar dependence is found[8] in similar experiments in which deuterated polyethylene is illuminated. The characteristic feature of this dependence is the reduction of the reflection coefficient with increasing I_{in}, which may indicate the presence of nonlinear absorption by the target material. This is supported by the detection in the experiments of a noticeable amplitude of the second harmonic of the incident radiation, with maximum intensity recorded at an angle of 162°. No second harmonic can be detected at an angle of 135° to the incident radiation. However, at this angle a large number of spectral lines of lithium, deuterium, and impurities is recorded, the brightest of which is a Li II line corresponding to the transition $2s^3S-2p^3P^0$ with λ = 5484.7 Å. The total energy radiated by the plasma at an angle of 135° into the aperture of the collecting lenses, equal to the aperture of the focusing lenses (0.12 sr), constitutes 10^{-4} of the laser-pulse energy. This magnitude agrees satisfactorily, within the limits of accuracy, with the energy radiated by a plasma having a temperature of ~1 keV.

In conclusion, it should be noted that the small reflection coefficient measured in the experiments can be due to the large contrast of the laser radiation and its short duration, which ensures that the main pulse interacts with a practically stationary target, reduces the contribution of the corona region, and leads to and increase of the effectiveness of nonlinear absorption processes. The relatively high neutron yield also supports the conclusion about the strong influence of the laser-radiation parameters on the character of the interaction. Consequently, it may be assumed that in experiments with an easily evaporable target (deuterated ice), considerably higher contrast is required in order to obtain similar results.

The authors wish to thank V. B. Ivanov for assistance in carrying out the experiments.

Laser compensation for thermal distortion in optical pumping

V. K. Zaitsev, V. A. Il'inskii, A. M. Marugin, and V. M. Ovchinnikov

(Submitted January 24, 1974)
Zh. Tekh. Fiz., 44, 2404-2405 (November 1974)

References 1-5 investigate phenomena associated with the nonuniformity of optical pumping in an active element that result in distortion of the wave front and birefringence. A number of studies$^{1-4,6-10}$ propose various procedures for eliminating or compensating for distortion resulting from the nonuniform temperature distribution associated with optical pumping.

In this paper we investigate a procedure that makes it possible to substantially reduce birefringence and distortion of the wave front by eliminating the temperature nonuniformity induced in the active element by optical pumping. A compensating temperature field is produced in the element, i.e., a field whose gradient is roughly equal but opposite to that caused by the optical pumping.

Reference 11 proposes heating of the active element by open-circuit optical pumping pulses for this purpose.

In our case the compensating temperature field is created by alternately pumping "cold" and "hot" water through the chamber containing the active element. During the experiment we measure the angle of divergence of a probe beam passed through the element. Figure 1 shows the experimental arrangement. The angle of divergence is determined from the diameter of the slit (at the 0.1 maximum amplitude level) that forms in the focal plane of lens 7. Photomultiplier 11 measures the delay time of the probe pulse relative to the pumping pulse of the element. Active element 3, fabricated from GLS-1 glass with dimensions Ø 30 × 280 mm is placed in cooling chamber 4 (volume about 1.2 l) together with four symmetrically arranged IFP-8000 pump lamps. The width of the pump pulse (at the 0.1 maximum intensity level) is 2000 μsec. A ruby laser with selection of transverse modes makes it possible to obtain a probe pulse 30 nsec wide at an energy $W_{\text{gener}} = 0.2$ J and divergence angle $\theta_{0.1}^{\text{gener}} = 2' \, 30''$. The divergence angle of the probe beam $\theta_{0.1}^{\text{probe}}$ is 1' on the other side of the × 2.5 telescope. The focal length of lens 7 is 1600 mm. The spot in the focal plane of the lens is photographed on KN-1 film.

Fig. 1. Diagram of experimental apparatus. 1) Telescope; 2) light-splitting cube; 3) active element under investigation; 4) cooling chamber; 5) rotating plate; 6) neutral density light filters; 7) long-focus lens; 8) red filter; 9) camera; 10) light filters; 11) photomultiplier; 12) oscilloscope; 13) thermometer; 14) valve; I indicates the "cold-water" system, II the "hot-water" system.

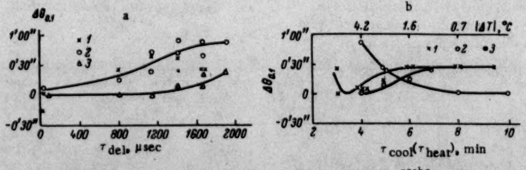

Fig. 2. Change in angle of divergence of probe beam $\Delta\theta_{0.1} = \theta_{0.1} - \theta_{0.1}^{\text{probe}}$ after passing through a passive element with nonuniform temperature: a) without thermal compensation depending on the delay time of the probe pulse; W_{pump}, kJ, as follows: 1) 26, 2) 17, 3) 11; b) with preliminary creation of nonuniform temperature field depending on the cooling (or heating) time τ_{cool} (τ_{heat}); curve 3 is for temperature gradient in same direction as that induced by pumping, no pump; curves 1 and 2 are for the temperature gradient directed opposite to that induced by pumping, pumping 26 and 17 kJ. $\Delta T = T_c - T_s$ is the temperature difference between the center and surface of the active element as computed from the cooling (or heating) time.

The system for creating the temperature field consists of two parallel water systems. The temperature in cold-water system I is maintained at 20°C by the stabilizer of a GOS-1001 device, while the temperature in system II is maintained at 35°C. The pumping rate in both systems is 8 liter/min. Since the center of the active element is heated less than the peripheral layers with optical pumping, the active element is first heated for around 20 min by system II, then cooled by system I, after which the pumping lamps are switched on. The cooling time for the specific experimental conditions is calculated or selected experimentally. Figure 2a shows the change in the angle of divergence of the probe beam passing through the active element as a function of the delay time relative to the beginning of optical pumping (W_{pump} being the pumping energy stored in the capacitors).

Figure 2b shows the change in angle when a temperature field, nonuniform over the cross section, is artificially created in advance. Compensation is selected for the time of maximum population inversion for a probe-pulse delay time $\tau_{\text{probe}} = 1100$ μsec relative to the beginning of the pump pulse for two different pump levels.

The results in Figs. 1 and 2 indicate that temperature compensation of the change in angle of divergence resulting from optical pumping is possible.

In conclusion, we note that our procedure for compensating for temperature nonuniformities in an active element is basically suitable for modes of operation with a low repetition frequency with pulse lengths short compared to the pump on-time.

Theory of nonequilibrium shock waves

R. A. Glatman and I. V. Ioffe

A. F. Ioffe Physicotechnical Institute,
Academy of Sciences of the USSR, Leningrad
(Submitted February 18, 1974)
Zh. Tekh. Fiz., 44, 2405-2407 (November 1974)

The propagation of a shock wave is treated in a binary mixture of monatomic gases in which the mean velocities of the component molecules are not the same. Under certain conditions rarefaction shock waves can exist. If the difference between the mean molecular velocities for the lighter and heavier components is directed against the motion of the front, compression shock waves can only occur at high strength.

The propagation of a shock wave in a binary gas mixture has been studied by Cowling[1] for the case in which the mean velocities of the molecules of the two components are everywhere the same except for the region of the shock front. It turns out that the effect of diffusion in the front can be important. If the mean molecular velocities differ in the unperturbed gas ahead of the front, we can expect even more serious discrepancies relative to the analogous process in a single-component medium.

We consider a mixture of monatomic gases $\gamma_1 = \gamma_2 = 5/3$ (γ being the ratio of the heat capacities, the subscripts 1 and 2 referring to the components with larger and smaller molecular mass respectively, $m_1 > m_2$). It is also assumed that the front does not create additional ionization, dissociation, etc., and that the number of molecules of each component remains unchanged across the front. Hence the proportion of molecules of the first component in the overall number

$$f = \frac{n_1}{n}$$

(n_1 and n being the number of molecules of the first component and the total number of molecules per unit volume ahead of the front respectively) remains constant everywhere except for the region of the front itself.

We introduce a moving coordinate system associated with the front whose x axis is directed from the unperturbed gas toward the gas beyond the discontinuity. At the discontinuity we have[1]

$$\rho u = \rho' u'; \quad \rho_i u_i = \rho_i' u_i' \quad (i = 1,\ 2), \tag{1}$$

$$p + \rho u^2 = p' + \rho' u'^2, \tag{2}$$

$$\frac{5}{2} p\,[f u_1 + (1-f)\,u_2] + \frac{1}{2}\rho u^3 = \frac{5}{2} p'\,[f u_1' + (1-f)\,u_2'] + \frac{1}{2}\rho' u'^3, \tag{3}$$

where ρ, ρ', u, u', and p, p' are the density of the mixture, the mean-mass velocity, and the pressure ahead of and behind the front. The difference of the mean velocities in (3) of the light and heavy components ahead of the front is

$$v_0 = u_2 - u_1 \neq 0.$$

We note that

$$\frac{\rho_1}{\rho} = \frac{m_1 n_1}{m_1 n_1 + m_2 n_2} = \frac{m_1 f}{m_1 f + m_2 (1-f)} = \text{const} = \frac{\rho_1'}{\rho'}, \tag{4}$$

and, allowing for (1),

$$\frac{u_1}{u} = \frac{u_1'}{u'}; \quad \frac{u_2}{u} = \frac{u_2'}{u'}. \tag{5}$$

Introducing

$$z = \frac{p}{\rho u^2},$$

and transforming (1)-(5), we obtain

$$5\varkappa\sqrt{z} = \frac{4z\varepsilon + z - 3}{1 - z\varepsilon}. \tag{6}$$

Here

$$\varkappa = v_0 \sqrt{\frac{\rho}{p}}\left(\frac{\rho_1}{\rho} - f\right); \quad \varepsilon = \frac{p'}{p}.$$

Equations (1) and (2) imply that

$$\frac{\rho}{\rho'} = 1 - z(\varepsilon - 1). \tag{7}$$

Equation (6) can be analyzed graphically. It turns out that three points of intersection of the curves $\varphi_1(z) = 5\varkappa\sqrt{z}$ and $\varphi_2(z) = (4z\varepsilon + z - 3)/(1 - z\varepsilon)$ are possible:

for $\varkappa \geq 0$

$$z = X, \quad \frac{3}{4\varepsilon + 1} \leqslant X < \frac{1}{\varepsilon},$$

for $\varkappa < 0$

$$z = \tilde{X}_1 < \frac{3}{4\varepsilon + 1}, \quad z = \tilde{X}_2 > \frac{1}{\varepsilon}.$$

Since

$$\frac{\rho_1}{\rho} - f = \frac{(m_1 - m_2)\,f\,(1-f)}{m_1 f + m_2 (1-f)} > 0,$$

the sign of $\varkappa$ is the same as that of v_0.

The criterion for the process to be possible can be taken, as before, to be the sign of the entropy difference on both sides of the front if the external forces there are independent of the molecular velocity:[2]

$$S' - S = C \ln I, \quad I = \frac{\rho}{\rho'}\varepsilon^{3/5} \tag{8}$$

($C = \text{const} > 0$). To investigate the behavior of (8), it is convenient to compute the derivative of the entropy difference at $\varepsilon = 1$ (here $z = z_0$):

$$\frac{d}{d\varepsilon}(S' - S) = \frac{C}{I}\frac{dI}{d\varepsilon} = \frac{C}{I}\left(\frac{3}{5} - z_0\right).$$

For $\varkappa = 0$ the derivative vanishes; for $\varkappa < 0$ and $z = \tilde{X}_1$ it is positive and for a weak compression shock wave ($\varepsilon > 1$, $\varepsilon - 1 \ll 1$) the entropy difference is positive (since

$S' - S$ for $\varepsilon = 1$). For $\varkappa > 0$, $z_0 > 3/5$, and for $|\varepsilon - 1| \ll 1$ the difference $S' - S$ is negative (if a compression wave is involved). Consequently for $\varkappa > 0$ a weak compression shock wave is impossible but there is no energy prohibition on the existence of a weak rarefaction shock. By (6) in the limiting cases of strong compression and rarefaction shock waves (such solutions can readily be obtained in the form of series in $1/\sqrt{\varepsilon}$ and ε respectively) we can show that for both possible solutions ($z = X, \tilde{X}_1$) there exists a strong compression shock wave, while a strong rarefaction shock wave ($\varepsilon \to 0$) cannot occur.

Thus, for $\varkappa > 0$ (when the molecules of the light component move on average toward the front of the shock wave relative to the behavier molecules) only a fairly strong compression shock wave can exist; moreover, there is no energy prohibition on the existence of rarefaction shock waves of sufficiently low intensity.

Two types of shock waves are possible for $\varkappa < 0$. For one of these ($z = \tilde{X}_1$) only compression shock waves can occur (but at any intensity – as for $\varkappa = 0$). The other root ($z = \tilde{X}_2$) corresponds for $\varkappa = 0$ to an entropy wave (as graphic analysis indicates, as $\varkappa \to 0$, $\tilde{X}_2 \to \infty$, and $u \to 0$); the condition $S' - S > 0$ holds for it, it turns out, for any $\varepsilon < 1$.

Radio-frequency absorption in a plasma confined by rf plugs

K. S. Golovanivskii, V. D. Dougar-Jabon, and L. A. Pokhmel'nykh

Patrice Lumumba Friendship of Nations University, Moscow

(Submitted February 15, 1973; resubmitted September 21, 1973)
Zh. Tekh. Fiz., 44, 2407-2410 (November 1974)

The absorption of radio-frequency energy is investigated in a plasma with energetic ions which is confined by radio-frequency plugs operated at the electron cyclotron resonance (ECR). With a magnetic field gradient of 10-40 G/cm in the ECR region and with longitudinal ion energies of 1 keV the plasma reflection is essentially elastic.

1. The possibility of confining a plasma by an RF "plug" in a mirror device was first pointed out by Consoli,[1] who used a single-particle model with tensor mass. Experiments have confirmed this possibility,[2,3] but the question of the energy exchange between the plasma and the high-frequency field and the final energy balance in this combination of fields remains unresolved. In general, when a plasma is reflected from a barrier the plasma can be heated by absorbing energy from the high-frequency field. It is of interest to determine the minimum amount of high-frequency power which must be introduced into the plasma to ensure that it will be reflected for a given profile of the mirror magnetic field.

The high-frequency energy dissipated in the plasma in the process of reflection of the beam characterizes the adiabaticity of the barrier. In passing through the resonance zone each electron accumulates some transverse energy $W_{e\perp}$, which in the mirror magnetic field, stops ions with longitudinal energy $W_{i\parallel}$ by the ambipolar mechanism. The local value of the mirror ratio R^* in the plane of the turning point with respect to the resonance plane is B/B_{res}. Using the expresion[4]

$$W_{e\perp}=\frac{W_{i\parallel}}{R^*-1}, \tag{1}$$

we obtain the high-frequency power absorbed by the plasma flux in one pass through the resonance zone:

$$P_1=\frac{J_i W_{i\parallel}}{q(R^*-1)}, \tag{2}$$

where J_i is the flux of plasma ions and q is the ion charge. When the reflected plasma passes back through the ECR zone the energy exchange between the plasma and the field is characterized by the power P_2, which is positive if the energy goes from the plasma to the field or negative if energy is transferred in the reverse direction. The total reflection energy balance will be characterized by the power P taken by the plasma from the high-frequency field:

$$P=P_1+P_2. \tag{3}$$

We introduce the recovery factor

$$\eta=-\frac{P_2}{P_1}=1-\frac{P}{P_1}, \tag{4}$$

which characterizes the energy recovered from the plasma or introduced into it in repeat passage through the resonance zone. Using (2), we have for η

$$\eta=1-\frac{Pq(R^*-1)}{J_i W_{i\parallel}}. \tag{5}$$

Since the second term on the right side of (5) is always positive, the maximum value of η is unity, corresponding to total recovery of high-frequency energy and, thus, elastic reflection of the plasma flux from the barrier. When $0 < \eta < 1$ the recovery is partial, in which case the plasma does not completely give up in the reverse pass the energy that is acquired in the first pass. The case $\eta < 0$ corresponds to additional absorption of energy by the plasma in passing back through the resonance zone.

2. Our experiments employ the apparatus shown schematically in Fig. 1. A Penning plasma source 1 yields a stationary argon plasma flux with density in the range $5\cdot10^7$-$5\cdot10^8$ cm^{-3}, longitudinal ion energy $W_{i\parallel}=0.3$-1.6 keV, and electron thermal energy 20-40 eV, depending on the mode in which the source operates. The flux moves, along a glass tube 5 cm in diameter. The residual gas pressure in the system does not exceed $1\cdot10^{-5}$ torr with dynamic pumping with gas leaked continuously into the source. Coil 2 creates a magnetic mirror that is axisymmetric with the beam; the profile is shown in Fig. 1. A high-frequency TE_{111} field with electric vector perpendicular to the direction of motion of the plasma flux is excited in cylindrical cavity resonator 3. The resonator is driven by generator 4 at 2375 MHz, the peak generator power being 10 W. The magnetic field in the center plane of the resonator is kept equal to the ECR resonance value of 850 G; the gradient in the neighborhood of this plane varies over the range 10-40 G/cm. The ion flux J_i, the longitudinal energy $W_{i\parallel}$, and the turning point of the plasma flux are found by using a movable five-grid charged-particle energy analyzer 5. In the experiments, the turning point is 5-6 cm from the resonance plane. From this we can readily determine the local mirror ratio R*.

The absolute value of the high-frequency loss in the plasma is given by

$$P=P_0\left(1-\frac{E^2}{E_0^2}\right), \tag{6}$$

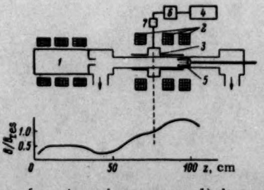

Fig. 1. Diagram of experimental arrangement: 1) plasma source; 2) dc coils; 3) resonator; 4) high-frequency generator; 5) movable analyzer; 6) attenuator; 7) ferrite isolator.

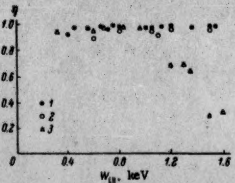

Fig. 2. Recovery factor as a function of the longitudinal ion energy for various magnetic-field gradients dB/dz in the ECR zone.

where E_0 and E are the electric component of the field in the empty resonator and with plasma; P_0 is the power loss in the empty resonator, this being determined by customary methods. This equation holds for $E^2/E_0^2 \simeq Q/Q_0$, which is the case in this experiment. Here, Q_0 and Q are the quality factors of the empty resonator and the resonator with plasma. The absolute value of E is determined by using a calibrated detector.

3. Figure 2 shows the experimental results obtained for all three longitudinal magnetic-field gradients in the resonance region (10, 32, and 40 G/cm; points 1, 2, and 3, respectively). Experimental data for the gradients are not given in the 10–32 G/cm range since the results are identical to the case of 10 and 32 G/cm over the entire $W_{i\parallel}$ range we have investigated.

As can be seen from Fig. 2, for all gradients below 32 G/cm we have total recovery of the transverse electron energy in the range of longitudinal ion energies 0.4–1.6 keV. Consequently, under these conditions the plasma flux is reflected with low energy loss. As the field gradient increases to 40 G/cm effective recovery is observed at energies $W_{i\parallel} \nless 1.0$ keV. For $W_{i\parallel} > 1.0$ keV we observe a sharp decrease in the recovery level, all the way to $\eta = 0.3$ for $W_{i\parallel} = 1.6$ keV, in which case the electrons maintain about 70% of the recovered energy in passing back through the ECR zone.

4. The total energy for recovery for appropriate field gradients is a result of the double resonance interaction between the electrons and the high-frequency field; this is associated with the ambipolar coupling between the ions and electrons beyond the resonance plane. If the electrons and ions are not coupled in the ECR zone the model proposed in ref. 5 is valid; in this model the electrons are reflected directly in the ECR plane and the interaction between the electrons and the field is a single-pass process so that energy recovery is impossible. But the present results indicate that recovery occurs and the plasma particles penetrate beyond the resonance plane by distances that are much greater than the distances traversed in a Larmor period. The existence of a broad range of field gradients for which elastic reflection occurs indicates that an automatic phase-focusing mechanism exists for particles when they pass back through the resonance plane. This self-focusing could result from the relativistic change in electron mass, as shown in ref. 6. According to ref. 6, phase self-focusing and energy recovery occur when the electrons pass back through the ECR zone:

$$\frac{dB}{dz} < 4.7 \cdot 10^{-7} \mu \frac{E^2}{W_{i\parallel}} B_{\text{res}} |z - z_0| \tag{7}$$

in this region, where z_0 is the classical ECR point; z is the coordinate along the axis (in cm), dB/dz is the magnetic field gradient at z, μ is the ion mass number; E is the high-frequency field in the zone (in V/cm), $W_{i\parallel}$ is the longitudinal ion energy (in keV), and B_{res} is the magnetic field corresponding to classical ECR (in G).

According to the experimental data, energy recovery occurs when the magnetic-field gradients in the ECR zone are small; as dB/dz increases, recovery occurs for smaller $W_{i\parallel}$ values. These facts are in qualitative agreement with (7). To compare (7) quantitatively with experimental results we must have experimental data on dB/dz as a function of z within the resonance zone, i.e., over a length of a few millimeters. It does not seem possible to make such measurements, and therefore the theoretical and experimental results can only be compared roughly, using parameter values that are averaged over the ECR zone. Taking the average value of dB/dz = 40 G/cm, the width of the resonance zone $d = |z - z_0|$, using the experimental parameters $\mu = 40$, $B_{\text{res}} = 850$ G, E = 70 V/cm, and assuming that the limiting ion energy for phase self-focusing is $W_{i\parallel} = 1$ keV, we find from (7) that d = 0.5 cm. The magnetic field varies by about 2% of B_{res} for this length, and therefore for ECR to occur in this zone the relativistic change in mass on d should also be about 2% i.e., the transverse electron energy starting the second pass reflection should be $W_{e\perp} \simeq 0.02 \cdot mc^2 = 10$ keV. According to (1), this value of $W_{e\perp}$ will stop ions for $R^* = 1.1$, this being of the same order as the experimentally measured value of $R^* = 1.3$ for this case. Thus criterion (7) agrees roughly with the experimental results, and we can explain the observed effect of quasiadiabatic plasma reflection from a magnetic mirror with local ECR by a phase self-focusing effect, associated with the relativistic change in electron mass.

Motion of stable aerosol particles

O. A. Barsegyan and Yu. I. Yalamov

Kalinin State University

(Submitted July 9, 1973; submitted January 22, 1974)
Zh. Tekh. Fiz., 44, 2410-2412 (November 1974)

The velocity of stable (nonvolatile) aerosol particles is compared with that of drops that increase in size or vaporize. When a phase transition occurs the material in the drop becomes one of the components of a binary gas mixture; the aggregate of drops and aerosol particles in such a mixture is considered. The derivation of the expression for aerosol-particle speed is based on the theory of thermophoresis and diffusophoresis in binary gas mixtures, as elaborated in earlier studies by Yalamov and coworkers. This study takes account of the radial components (relative to the drop) of the center of inertia for a binary gas system consisting of two parts that are proportional to the concentration and temperature gradients respectively. The time required to cleanse a given volume of dust aerosols can be estimated from the results.

Aerosol particles suspended in gases acquire a directed motion when the components of the gas mixture are subject to a concentration field or temperature gradient. The theory of this motion (thermophoresis and diffusophoresis) is elaborated most rigorously in refs. 1 and 2 for stable aerosol particles. The present paper is concerned primarily with computing the velocity of stable aerosol particles toward increasing or vaporizing drops that are capable (as a result of phase transition of the drop material) of changing into one of the components of the binary gas mixture in which the entire system of drops and aerosol particles is suspended. By determining the concentrations and temperatures near the drop, when there is a decrease in these quantities on the surface of the drop and within the gas mixture, we obtain the radial components of the concentration gradients of the mixture component undergoing phase transition on the surface of a particle, and the temperature gradient:

$$(\nabla C_1)_r = (C_{1\infty} - C_{10}) \frac{R_0}{r^2}, \tag{1}$$

$$(\nabla T)_r = (T_\infty - T_0) \frac{R_0}{r^2}, \tag{2}$$

where C_1 is the relative concentration in the volume of gas that evaporates (or condenses) on a drop, $C_{1\infty}$ and C_{10} are the concentrations at a great distance from the drop and on its surface respectively, T is the gas temperature, T_∞ and T_0 are the temperature at a great distance from the drop and on its surface, R_0 is the drop radius, and r is the distance from the center of the drop to a point within the volume of gas ($r > R$).

Knowing the concentration and temperature gradients ∇C_1 and ∇T and allowing for the Stefan transfer velocity of the center of inertia of a binary gas mixture from ref. 3 and the rates of thermophoresis and diffusophoresis of nonvolatile aerosol particles in binary gas mixtures,[4,5] we can obtain the following expression for the radial velocity of the aerosol particles relative to the drop:

$$u_r = -(\gamma_1 + \gamma_2) \frac{R_0}{r_2}, \tag{3}$$

$$\gamma_1 = \frac{2\left(K_{Tsl}\eta_0 + K_{TD}^{(sl)} T_0\rho_0\right)\varkappa_e (T_\infty - T_0)}{(\varkappa_i + 2\varkappa_e)\, T_0\rho_0}, \tag{4}$$

$$\gamma_2 = \left(K_{sl} + \frac{n_0^2 m_1}{n_2\rho_0}\right) D_{12} (C_{1\infty} - C_{10}). \tag{5}$$

We have employed the following notation in (4) and (5): η_0 and ρ_0 are the average viscosity and density of the gas mixture, $\varkappa_e$ and $\varkappa_i$ are the thermal conductivities of the gas mixture and particle, m_1 is the molecular mass for the mixture component with relative concentration C_1, $K_{Tsl}K_{TD}^{(sl)}$ are the thermal and thermal-diffusion slipping coefficients respectively, K_{sl} is the diffusion slipping coefficient, D_{12} is the mutual diffusion coefficient for the mixture component, $n_0 = n_{01} + n_{02}$ is the total number of gas molecules per unit volume as $r \to \infty$, and n_{01} and n_{02} are for the first and second components taken separately.

Equation (3), with (4) and (5), is written under the assumption that λ, the mean free path of the gas molecules, is much smaller than the radius R of the gas particles.

Furthermore, it is assumed that n_{01} is comparable to n_{02}, i.e., the numerical concentration of molecules of the first component, which undergoes phase transition on the particle surface, is not small as compared to the numerical concentration of the carrier-gas molecules. In terms of the relative concentrations, this condition is

$$C_{10} = \frac{n_{01}}{n_0} \sim C_{20} = \frac{n_{02}}{n_0}.$$

Equation (3) can be refined by allowing for thermal-diffusion transport of the center of inertia of a binary mixture in a temperature-gradient field. Like thermal-diffusion slipping, which is proportional to $K_{TD}^{(sl)}$ in (4), this effect is important for comparable concentrations n_{01} and n_{02}. It can be shown that the velocity of thermal-diffusion transport of the center of inertia is

$$v_{\mathrm{ci}}^{(TD)} = -\frac{n_0 D_{12}}{\rho_0} (m_1 - m_2) K_{TD} \frac{\nabla T}{T_0}, \tag{6}$$

where m_2 is the molecular mass for the carrier gas and K_{TD} is the coefficient of the volume thermal diffusion (see, e.g., ref. 6). Substituting (2) into (6), we obtain

$$v_{r,(\mathrm{ci})}^{(TD)} = -\frac{n_0 D_{12}}{\rho_0 T_0} (m_1 - m_2)(T_\infty - T_0) K_{TD} \frac{R}{r^2}. \tag{7}$$

Finally, from (3)-(5) and (7) we obtain

$$u_r = -\frac{2\left(K_{Tsl}\eta_0 + K_{TD}^{(sl)} T_0\rho_0\right)\varkappa_e}{T_0\rho_0(\varkappa_i + 2\varkappa_e)} (T_\infty - T_0)\frac{R}{r^2} - \frac{n_0 D_{12}}{\rho_0 T_0}(m_1 - m_2)(T_\infty - T_0) \times K_{TD}\frac{R}{r^2} - \left(K_{sl} + \frac{n_0^2 m_1}{n_{20}\rho_0}\right) D_{12} (C_{1\infty} - C_{10}) \frac{R}{r^2}. \tag{8}$$

The relative value of the terms obtained in (8), the sign of the velocity, and the cleansing time (for aerosol particles attracted to drops) of a given volume (cleansing of dust aerosols) can be computed from (8) for specific systems.

The authors are grateful to V. S. Galoyan for comments.

Motion of charged particles in a nonneutral plasma

E. N. Agafonova and L. I. Grechikhin

(Submitted March 6, 1973; resubmitted October 16, 1973)
Zh. Tekh. Fiz., 44, 2412-2414 (November 1974)

We analyze the nonlinear oscillations of a charged particle in the field of a nonneutral plasma. This is done by first finding the electric field equivalent to that of a stack of plates each with a charge density which varies linearly in a given direction. The equations for the nonlinear oscillations are integrated by methods due to Newcomb and Lindstedt. It is found that the charged particle oscillates in the field with a period which depends on the charge and mass of the particle and on the maximum density of the uncompensated charge, its dimensions, and the conditions of formation.

Regions with uncompensated electric charge can form in a plasma in an electric or a magnetic field. These can be regions near the electrodes in electric discharges or in thermionic converters. Regions with an uncompensated electric charge can be formed in a plasma moving at right angles to a magnetic field as a result of the Hall effect. We consider the behavior of charged particles in a plasma with an uncompensated electric charge. In such a plasma the oscillatory phenomena can have an effect on the operation of various plasma power devices. We consider the oscillations of charged particles in a plasma with an uncompensated electric charge of the opposite sign.

In the first approximation the distribution of uncompensated charge can be described by the linear relation

$$n=n_0(1-c|x|), \tag{1}$$

where n_0 is the maximum value of the uncompensated charge density, n is the charge density at a distance x from the position of the maximum, and c is a constant depending on how the uncompensated charge is formed.

We use Gauss' theorem to calculate the intensity of the electric field E produced by the charge distribution (1). We represent the field as the sum of the fields of a stack of plates each of thickness dx and carrying a surface density of uncompensated charge $d\sigma = n dx = n_0(1-c|x|)dx$, which decreases from the center to the edges. The total charge of a stack of thickness 2x is $Q = S_0\int_{-x}^{x} d\sigma$. Here, S_0 is the area of a plate and x is the distance from the center of the stack to the points with coordinates x and −x. The electric field is

$$E=\frac{n_0 x}{\varepsilon}-\frac{n_0 c x^2}{\varepsilon}. \tag{2}$$

A charged particle in this field experiences a force, and its equation of motion is

$$m\ddot{x}=-\alpha x+\alpha_1 x^2, \tag{3}$$

where $\alpha = en_0/\varepsilon$, $\alpha_1 = en_0c/\varepsilon = \alpha c$. Equation (3) describes nonlinear oscillations. It can be put in a simpler form by the change of variables

$$t=\sqrt{\frac{m}{\alpha}}\,\tau. \tag{4}$$

Then (3) becomes

$$\frac{d^2x}{d\tau^2}+x=cx^2. \tag{5}$$

To determine the limits of variation of x we use the conservation of energy:

$$\left(\frac{dx}{d\tau}\right)^2+x^2=V_0^2+\frac{2}{3}cx^3, \tag{6}$$

where V_0 denotes the generalized velocity at x = 0. By setting $dx/d\tau = 0$ in (6) we find the equation for the limiting positions

$$x^2=V_0^2+\frac{2}{3}cx^3. \tag{7}$$

We solve Eq. (7) for x by expanding x in a power series in V_0 with undetermined coefficients and substituting into (7). This gives the upper and lower limits for x:

$$\left.\begin{aligned} x_1&=V_0+\frac{1}{3}cV_0^2+\frac{5}{18}c^2V_0^3+\ldots,\\ x_2&=-V_0+\frac{1}{3}cV_0^2-\frac{5}{18}c^2V_0^3+\ldots.\end{aligned}\right\} \tag{8}$$

We specify the initial conditions in the form

$$\tau=0,\quad x=x_1,\quad \frac{dx}{d\tau}=0. \tag{9}$$

In order to ensure a finite solution we replace τ by η, as in ref. 1:

$$\tau=\frac{\eta}{\sqrt{1+\mu}}, \tag{10}$$

$$t=\eta\sqrt{\frac{m}{\alpha(1+\mu)}}. \tag{11}$$

We seek the solution of Eq. (5) in the form of a power series in x_1 (or x_2), i.e.,

$$\left.\begin{aligned} x&=x_1y_1(\eta)+x_1^2y_2(\eta)+x_1^3y_3(\eta)+\ldots,\\ \mu&=\mu_1x_1+\mu_2x_1^2+\mu_3x_1^3+\ldots.\end{aligned}\right\} \tag{12}$$

By substituting (12) into (5) and comparing coefficients of the same powers of x_1 we obtain the equations

$$\left.\begin{aligned} \ddot{y}_1+y_1&=0,\\ \ddot{y}_2+y_2&=-\mu_1\ddot{y}_1+cy_1^2,\\ \ddot{y}_3+y_3&=-\mu_2\ddot{y}_1-\mu_1\ddot{y}_2+2cy_1y_2,\\ \ldots&\ldots\ldots\end{aligned}\right\} \tag{13}$$

We solve these equations in sequence, arranging the coefficients μ_i so that the solutions do not increase without bound with time. Limiting ourselves to the first three terms in expansion (12) we obtain

$$\begin{aligned} x=\frac{c}{2}x_1^2-\frac{c^2}{3}x_1^3+\ldots+\left(x_1-\frac{c}{3}x_1^2+\frac{29}{144}c^2x_1^3+\ldots\right)\cos\eta_1\\ +\left(-\frac{c}{6}x_1^2-\frac{c^2}{9}x_1^3+\ldots\right)\cos 2\eta+\frac{c^2}{48}x_1^3\cos 3\eta+\ldots,\end{aligned} \tag{14}$$

where

$$\eta=t\sqrt{\frac{\alpha}{m}(1+\mu)}=t\sqrt{\frac{\alpha}{m}\left(1-\frac{5}{6}c^2x_1^2+\ldots\right)}. \tag{15}$$

The period of series (14) for x is 2π. If we return to the characteristic time scale t the period of the series is

$$T = 2\pi \sqrt{\frac{m}{a(1+\mu)}} \simeq 2\pi \sqrt{\frac{m}{a}} \left(1 - \frac{5}{6} c^2 x_1^2\right)^{-1/2}. \qquad (16)$$

Neglecting higher-order terms (16) can be written in the form

$$T = 2\pi \sqrt{\frac{m}{a}} \left(1 + \frac{5}{12} c^2 x_1^2\right) = 2\pi \sqrt{\frac{m\varepsilon}{en_0}} \left(1 + \frac{5}{12} c^2 x_1^2\right). \qquad (17)$$

Thus a charged particle moving in the field of an uncompensated charge distribution of the opposite sign oscillates with a period which depends on the mass and charge of the particle and on the parameters of the field of the uncompensated charge -- the maximum density of the uncompensated charge n_0, the conditions of formation of the uncompensated charge, and its dimensions.

Initial stage of a high-current discharge in air

A. F. Aleksandrov, V. V. Perebeinos, A. T. Savichev, and I. B. Timofeev
M. V. Lomonosov State University, Moscow

(Submitted July 31, 1973; resubmitted February 27, 1974)
Zh. Tekh. Fiz., 44, 2414-2415 (November 1974)

The present work investigates the initial stage of a discharge in air created by an exploding wire. The initial stage of rupture, whose development depends on the rate of rise of the current, determines the subsequent development of the discharge and the validity of the self-similar description.

Reference 1 is an investigation of the dynamics and radiation of high-current discharges in air. Experimental results are compared with those given by the self-similar model and numerical calculations.

For a linear rate of rise of the current, I = Ft, the plasma parameters in the discharge[1,2] depend on the initial conditions; more specifically, they depend on the rate of rise $F = I_0 2\pi/T$, where I_0 is the maximum current and T is the period. The physical picture of the discharge presupposes that there is a shock wave that propagates through the unperturbed gas immediately ahead of the edge of the thermal zone $R_{sw} = \lambda R_{tz}$ (where R_{sw} and R_{tz} are the radii of the shock front and the current zone, while $\lambda = 1.1$); the shock wave carries off a constant proportion of the energy introduced into the discharge channel[3] $E_{sw} = 0.2\ E_{tz}$. Here, $E_{tz} = Q - W - E_{sw}$, Q being the energy contained in the discharge and W the energy radiated in the transparency band of air ($\lambda > 1860$ Å).

At high rates of energy input into the discharge ($F > 10^{10}$ A/sec) we observe satisfactory agreement between the theory and the experimental data; as F decreases the discrepancy between theory and experiment increases. This result is evidently to be associated with processes that occur in the initial stage of the discharge.

The numerical solution of the magnetohydrodynamic equations on a computer is also extremely sensitive to the choice of initial conditions. Hence we give results pertaining to the initial stage of a high-current discharge in air, 40 cm long. Our experiments employ the apparatus described in ref. 1. The current period is $T \simeq 70$ μsec. Wires of varying diameter and of different materials (nichrome, aluminum, iron, tungsten, and molybdenum) are used with various initial conditions (the injected energy $Q' = Q/l$ per unit discharge length over the first half-period of the discharge current varies from 0.125 to 1.6 kJ/cm, to variation in F from $1.5 \cdot 10^9$ to $1.6 \cdot 10^{10}$ A/sec).

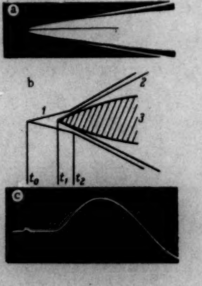

Fig. 1

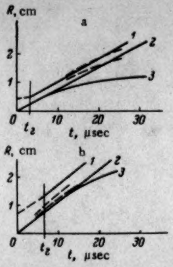

Fig. 2

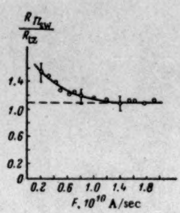

Fig. 3

Figure 1a (rupture of aluminum wire 0.3 mm in diameter, $CU^2/2l = 0.72$ kJ/cm, $F = 7 \cdot 10^9$ A/sec) gives a typical slit luminescence scan of the discharge channel with time. The basic details which can be seen in the photograph are shown schematically in Fig. 1b (1 being the front of I_{sw}, 2 the front of II_{sw}, and 3 the current zone), while Fig. 1c gives an oscillogram of the discharge current. We can readily discern all three characteristic phases of the discharge: the first current pulse (at time t_0), then the pause, and secondary breakdown of the discharge channel ($t_0 - t_1$). It can be seen from Fig. 1 that the first shock wave (1) appears at time t_0, corresponding to the first current pulse; this is evidently associated with the rapid phase transition in the wire. Some time later there is a secondary breakdown (t_1), resulting in the appearance and broadening of the thermal zone. As it expands, the thermal zone generates a second shock wave (II), which propagates immediately ahead of the thermal zone of the discharge. The first shock wave arising at t_0 has low velocity and weak luminescence. A few microseconds after the formation of the thermal zone, the luminescence and rate of propagation of shock wave I increase, this probably being due to its interaction with shock wave II and the radiation of the thermal zone. Then (at t_2) shock wave II breaks away from the current channel; for these experimental conditions shock wave II never overtakes the first wave. In most cases we observe a few post-breakdown shock waves corresponding to the formation of streamer channels.

Figure 2 shows the radii of the fronts of shock waves I and II and the current zone of the discharge channel (curves 1, 2, and 3 respectively), these being obtained by processing the raw data, for the rupture of a thin aluminum wire (0.1 mm in diameter) and various values of the energy per unit discharge length [$Q' = 0.2$ kJ/cm, $F = 2.5 \cdot 10^9$ A/sec (*a*) and $Q' = 1.2$ kJ/cm, $F = 1.3 \cdot 10^{10}$ A/sec (b)]. The dashed curves correspond to calculations using self-similar theory. It can be seen from Fig. 2 that for small F (low rate of energy input) there is a considerable discrepancy between the experimental data and the self-similar calculations (up to a factor of 2), whereas for large F (Fig. 2b) the agreement is good.

Figure 3 shows the ratio of the radius of the front of shock wave II to the radius of the thermal zone $\lambda = R_{sw}/R_{tz}$ as a function of F. The dashed line corresponds to calculations using self-similar theory. It can be seen from Fig. 3 that for small F the experimental data differ markedly from self-similar theory; for large F they are virtually the same. As implied by the above results, this is associated with the fact that the self-similar theory does not take account of events at the beginning of the process — the phase transition and subsequent breakdown of the gap, the duration and features of these processes, the appearance of shock wave I, and its interaction with the current zone of the discharge channel.

Electron energy distribution in a constricted, low-pressure hydrogen discharge

M. A. Abroyan, Yu. M. Kagan, N. B. Kolokolov, and B. P. Lavrov

A. A. Zhdanov Leningrad State University

(Submitted February 22, 1974)
Zh. Tekh. Fiz., 44, 2416-2417 (November 1974)

The distribution function is measured in a constricted arc discharge in hydrogen. The probe-current modulation method is used. The measurements are carried out in the pressure range 0.02-0.2 torr at discharge currents up to 0.55 A. The distribution of fast electrons is found to be strongly non-Maxwellian; this feature must be taken into account in computing direct dissociation, excitation, and ionization from atomic and molecular states. A qualitative description of the formation of the distribution function is given .

Constricted arc discharges at low pressures are used[1] widely.

In the available studies of this discharge[2-4] the electron energy distribution function $f(\varepsilon)$ is assumed to be Maxwellian. This assumption is unjustified. Since theoretical calculation of the distribution function entails substantial difficulties under these circumstances, it becomes particularly important to make a direct experimental determination of $f(\varepsilon)$.

In this paper we study a hot-cathode arc discharge in hydrogen, constricted by the effect of a cone-shaped electrode between the cathode and the anode.[5] A double space-charge sheath forms at the point at which the discharge gap contracts.[1] Our investigations pertain to the pressure range 0.02-0.2 torr and current range 0.1-0.55 A with the intermediate electrode at floating potential.

We introduce a movable electric probe of molybdenum wire 0.035 mm in diameter sheathed in a quartz capillary into the region between the intermediate electrode and the anode. The length of the uninsulated part is 1.0 mm. In measuring the energy distribution function of the electrons in the plasma near the anode we used the procedure based on probe-current modulation.[6] We calibrate the measurement system so as to be able to obtain $f(\varepsilon)$ in absolute value.[7] The electron density n is found by integrating the distribution function.

Figure 1 shows the $f(\varepsilon)$ obtained at the axis 4 mm from the anode. The axial variation in the energy distribution function of the electrons is illustrated by Table 1. This table gives the electron density n, the average distribution energy $\bar{\varepsilon}$, the relative number of electrons whose energy exceeds the value required for effective hydrogen dissociation (9 eV), and the relative number of electrons making up a pronounced group in the high-energy region. The measurements are performed at various distances l from the anode. For comparison, the table includes the same quantities with a Maxwellian distribution. The distribution of slow electrons ($\varepsilon \leq 5$ eV) in our experiments is quasiequilibrium with a temperature that is determined by taking the logarithm of the second derivative of the probe current with respect to the potential in this energy region. The temperature as determined in this manner is 1 eV at a distance of 4 mm from the anode. It is clear from Fig. 1 and Table 1 that $f(\varepsilon)$ is markedly a nonequilibrium function.

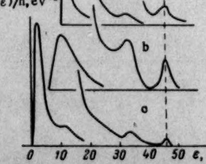

Fig. 1. Energy distribution function of electrons: p (in torr) and i (in A) as follows: a) 0.1, 0.4; b) 0.1, 0.2; c) 0.2, 0.2.

TABLE 1. Axial Variation in the Energy Distribution Function of Electrons for p = 0.1 torr, i = 0.4 A

		n, 10^{11}cm^{-3}	$\bar{E}$, eV	$\frac{\Delta n_\varepsilon > 9 \text{ eV}}{n}$	$\frac{\Delta n_\varepsilon > 32.5 \text{ eV}}{n}$
l, mm	6.5	7.0	5.2	0.16	0.004
	5.0	5.4	4.6	0.14	0.003
	4.0	3.4	3.8	0.12	0.002
Maxwellian distribution, ε = 3.8 eV		—	3.8	$7 \cdot 10^{-2}$	$1 \cdot 10^{-5}$
Maxwellian distribution, kT = 1 eV		—	1.5	$4 \cdot 10^{-4}$	$5 \cdot 10^{-14}$

Our results can be interpreted qualitatively as follows: A group of electrons that accelerate in the field of the double sheath relax with respect to energy through inelastic collisions with atoms and molecules of the gas. The maximum in the high-energy region comes from electrons that experience only elastic collisions on their path to the probe. When the discharge conditions change the position of this maximum varies in accordance with the change in the potential drop in the sheath but the configuration of the maxima and the form of the distribution function in the high-energy region remain the same.

Thus, in a constricted arc discharge the electron energy distribution function is markedly different from the equilibrium distribution; this must be taken into account in computing direct dissociations, excitation, and ionization from atomic and molecular states.

Spectral narrowing of a single-mode beam oscillator

V. A. Buts and V. I. Kurilko

Physicotechnical Institute, Academy of Sciences of the Ukrainian SSR, Khar'kov

(Submitted March 18, 1974)
Zh. Tekh. Fiz., 44, 2417-2419 (November 1974)

The correlational characteristics of the signals of a single-mode beam generator resulting from fluctuations in the beam distribution function (at the input to the interaction regions) are studied. The intensity of the fluctuations depends on the stationary signal level. It is also shown that preliminary modulation of the beam at the system input, at the frequency of the generated signal, causes a marked reduction in spectral width.

The possibilities for practical utilization of high-frequency signals excited through collective interaction between beams of charged particles and plasmas[1,2] and vacuum waveguide (resonance) systems[3,4] depend markedly on the degree to which the signals are monochromatic. In this connection, ref. 1 poses the problem of controlling the spectra and intensity of beam instabilities, and proposes methods for solving this problem (see also ref. 2). This paper will consider the theory of controlling the spectrum of a single-mode beam generator. The spectral shape for nonequilibrium systems with lumped parameters has been studied in the approximation of known sources of fluctuation perturbations.[5] When the problem can be reduced to a system of exact differential equations, this approach can be generalized to self-oscillatory systems with distributed parameters, e.g., multimode lasers.[6] Below we consider the spectral shape of a single-mode beam generator with distributed wave attenuation in the interaction region; the self-excitation of this type of generator is investigated in refs. 7, 8.

Assume we are given a slow-wave resonator in which the beam excites a field

$$E_z = E(t)\,\Phi_m(r)\sin k_m z\cos(\omega_m t-\varphi)\ (\Phi_m(0)=1;$$
$$k_m = 2/L\,\pi(m+1/2);\ |z|\leqslant L/2).$$

If the average beam velocity V_0 is close to the phase velocity of the wave $V_m \equiv \omega_m/k_m$ and the transit time for the beam particles through the resonator $T_p \equiv L/V_0$ is small as compared to that of the amplitude and phase of the field in the resonator $T_f (T_p \ll T_f)$, these quantities are given by the equations

$$\left.\begin{array}{c} \dfrac{dR}{d\theta} = \langle \overset{\bullet}{S}(R,\psi\, q_0)\,F(q_0)\rangle; \\[2ex] R\dfrac{d\varphi}{d\theta} = \langle C(R,\ \varphi,\ q_0)\,F(q_0)\rangle;\quad R\equiv\dfrac{|e|\,Ek_m}{m_0\omega_m^2}, \\[2ex] C(R,\ \varphi,\ q_0)+iS(R,\ \varphi,\ q_0) \\[1ex] \equiv\displaystyle\int\limits_{\tau_0}^{\tau_f} d\tau\exp\{i[\Delta(\tau,\ q_0)+\varphi-\vartheta_0]\};\quad \vartheta_0\equiv\omega_m t_0, \\[2ex] \langle U(q_0)\rangle\equiv\displaystyle\int\limits_{\theta-\pi}^{\theta+\pi} d\vartheta_0\int dv_0 2\pi r_0 dr_0 U(q_0);\ \theta\equiv\omega_m t;\ q_0\equiv(\vartheta_0,\ v_0,\ r_0). \end{array}\right\}\quad(1)$$

Here $F(q_0)$ is the distribution function for beam particles at the resonator input $(z=-L/2)$ with respect to the entrance time ϑ_0, the initial velocities v_0, and radius r_0, the dependences on the Lagrangian time τ of the deviations $\Delta\equiv k_m Z_l-\tau$ in the particle trajectories $Z_l(\tau,\ q_0)$ from the straight line $k_m Z_l = \tau-\tau_0$ and the instant these particles leave the resonator $\tau_f(q_0)$ are given by the equations of the characteristic

$$\dot\Delta = (\dot\Delta_0^2 + R[\cos(\Delta+\varphi-\vartheta_0)-\cos(\varphi-\vartheta_0)])^{1/2}\operatorname{sgn}\dot\Delta_0,$$

$$\tau_f(q_0)+\Delta[\tau_f(q_0);\ q_0] = \pi\left(m+\frac{1}{2}\right). \qquad (2)$$

Writing $F(q_0)$ as the sum of regular (F) and stochastic ($\mathcal{F}$) functions, we can reduce the study of the field dynamics in the resonator to the solution of coupled linear equations for the perturbations $\rho\equiv R-R_0$ and $\xi\equiv\varphi-\varphi_0$ of the amplitude and phase respectively that are induced by the fluctuation forces:[5,7,8]

$$\left.\begin{array}{c} \dfrac{d\rho}{d\theta} = a_{11}\rho + a_{12}\xi + g_\rho(\theta);\ R\dfrac{d\xi}{d\theta} = a_{21}\rho + a_{22}\xi + g_\xi(\theta). \\[2ex] a_{11}+ia_{12}\equiv\left(\dfrac{\partial}{\partial R}+i\dfrac{\partial}{\partial\varphi}\right)\langle SF\rangle;\ a_{21}+ia_{22}\equiv\left(\dfrac{\partial}{\partial R}+i\dfrac{\partial}{\partial\varphi}\right)\langle CF\rangle; \\[2ex] \langle CF\rangle = \langle SF\rangle = 0;\ g_\xi + ig_\rho \\[1ex] \equiv\displaystyle\int\limits_{\theta-\pi}^{\theta+\pi} a\vartheta_0\int dv_0 2\pi r_0 dr_0\mathcal{F}(q_0)\,[C(R_0,\ \psi_0\, q_0)+iS(R_0,\ \varphi_0,\ q_0)]. \end{array}\right\}\quad(3)$$

Using (3) to compute the perturbation correlation functions for the amplitude and phase, we obtain the correlation function of the field and the shape of the line excited by the beam in the resonator. When the beam is not modulated at the resonator input, $a_{12} = a_{22} = 0$, for δ-correlated functions $\overline{g_\rho(\theta)}$ and $g_\xi(\theta)$ this line is a resonant curve with width $\nu_- \equiv \overline{g_\xi^2}/2R_0^2 \ll 1$ and height $H_- \simeq \nu_-^{-1}$, rising above a pedestal of width $\nu_+ \equiv -a_{11} > 0$ and height $H_+ \equiv \overline{g_\rho^2}/R_0^2\nu_+ \ll 1$. Unlike the results in refs. 5, in this case the functions $\overline{g_\rho^2}$ and $\overline{g_\xi^2}$ depend on the amplitude and phase of the steady-state field, which, in particular, results in a change in the effective linewidth.[9]

The basic reason for line broadening in the case in question is diffusion of the mean-square phase of the field as a result of fluctuation forces. To stabilize this diffusion, and thus narrow the line, we must introduce restoring forces that depend on the phase of the field φ. When such forces are present, the fluctuation deviations of the phase attenuate exponentially in time, so that the line shape becomes a δ-shaped peak against the background of two pedestals, whose widths $\nu_\pm \ll 1$ and heights $H_\pm \equiv \overline{g^2}/2R_0^2\nu_\pm$, where $\nu_\pm$ are the characteristic numbers of the corresponding (3) homogeneous system of equations $(dU_\pm/d\theta = -\nu_\pm U_\pm)$.

For a beam generator, such phase stabilization can be provided by modulating the beam at the resonator input. For regular periodic modulation of the form

$$F(q_0)\equiv\left[\frac{1-h}{2\pi}+h\delta(\vartheta_0)\right]\delta(v_0-V_0)\,G(r_0);\ |\vartheta_0|\leqslant\pi;\ \langle F(q_0)\rangle = 1$$

spectral narrowing is observed when the condition $h > h_{cr}$ holds, where h_{cr} is determined from the equation $H_-(h_{cr}) = 1$:

$$h_{cr} \simeq \frac{\mathcal{E}_{\zeta}^{2}}{R_{0}^{2}} \quad \left(\nu_{-} \equiv -a_{22} + \frac{a_{21}a_{12}}{a_{11}} \sim h\right).$$

Physically, the basis of this method of controlling the spectra of self-oscillators is provided by the amplification effect for the induced interaction with the field of bunched beam particles. This bunching imposes the phase of the signal on the self-oscillator; deviations from this phase attenuate exponentially as a result of the corresponding frequency drift ($\sim a_{22}$) or change in field amplitude ($\sim a_{12}$).

Thus our examination shows that the intensity of the effective fluctuation forces in a beam generator depends on the steady-state signal amplitude, and the use of the method proposed in ref. 1 of controlling the spectrum by preliminary beam modulation makes it possible to markedly narrow the signal spectrum. Unlike ref. 10, which considers the dynamics of interaction of regular perturbations of finite amplitude in a plasma–beam system, in our study the spectrum of a beam generator in the steady-state mode is controlled by preliminary modulation of the beam at the system input, so as to suppress fluctuation broadening of the line through the use of negative feedback.

The authors are grateful to Ya. B. Fainberg and B. B. Kadomtsev for comments.

Stabilization of two-stream instabilities

V. A. Buts

Physicotechnical Institute, Academy of Sciences of the Ukrainian SSR, Khar'kov

(Submitted March 23, 1974)
Zh. Tekh. Fiz., 44, 2419-2420 (November 1974)

It is shown that two-stream instabilities can be stabilized by electromagnetic waves or by variation of the beam velocity.

It is well known that the strength of the two-stream instability is determined by the elementary emission mechanism and by the number of coherent particles.[1,2] Instabilities develop as follows. In the unperturbed beam spontaneous emission from individual particles is quenched by mutual interactions. A perturbation causes particle bunching. The field which arises as a result of coherent radiation of the particles in these bunches, allowing for coherence between bunches, increases the perturbation amplitude, which in turn increases the bunching, and so on. The growth rate is greater, the greater the emission of the beam particles and the greater the number of coherent particles. This picture not only provides a qualitative representation of the process but also yields quantitative results which are in good agreement with those obtained in calculations.[2-4] Moreover, the picture indicates that there are three parameters of system instability which can be used to control the instability. These parameters are the emission from an individual beam particle, the number of coherent particles in a bunch, and the number of coherent bunches. All possible stabilization mechanisms can be considered in terms of these three parameters. In this note we consider two simple and effective means of affecting two-stream instabilities.

1. Assume that an electromagnetic wave propagates in a system containing an electron beam. If the wave characteristics are such that it smears out bunches that result from the growing perturbations, even a weak wave might inhibit the instability. As an example, let us consider the effect of a wave on two-beam instability. In the reference system which moves with the phase velocity of the wave, assuming that the unperturbed velocities of the beam and plasma v_{0S} only vary in space, we obtain the following system for the electrostatic oscillations:

$$\Psi_s'' + \Psi_s\left[\frac{\omega_{ps}^2}{v_{0s}^2} - \frac{3}{4}\left(\frac{v_{0s}'}{v_{0s}}\right)^2 - \frac{3}{2}\frac{v_{0s}''}{v_{0s}}\right] = -\frac{\omega_{ps}^2}{v_{0s}^2}\Psi_{1-(1)^s}e^{(-1)^s\varphi}, \tag{1}$$

where

$$\Psi_s \equiv j_s \exp\left[\frac{1}{2}\int^x P_s dx_1\right]; \quad P_s \equiv -2\frac{i\omega}{v_{0s}} + 3\frac{v_{0s}'}{v_{0s}} \quad (s = 0;\ 1),$$

and $\varphi \equiv (1/2)\int^x (P_0 - P_1)dx_1$; j_S is the perturbation current.

Assume that the unperturbed velocities vary in accordance with $v_{0S} = v_S(1 - (2/3)\alpha_S \sin \varkappa x)$, $\alpha_S \ll 1$. If $\omega_{pS}/v_S\varkappa \sim 1$, then by applying an averaging procedure to (1) we obtain the following dispersion equation (in the laboratory system):

$$1 - \frac{\omega_p^2}{\omega^2} - \frac{1}{2}\frac{\varkappa^2\tilde{v}_p}{\omega^2} = \frac{\omega_b^2\left(\omega^2 - \frac{1}{2}\varkappa^2\tilde{v}_p^2\right)}{\omega^2\left(\omega^{*2} - \frac{1}{2}\varkappa^2\tilde{v}_b^2\right)}, \tag{2}$$

where $\tilde{v}_p$, $\tilde{v}_b$ are the variable plasma and beam velocities in the field of the external wave, $\omega^* \equiv \omega - kv$, and v is the beam velocity.

From (2) we find that the waves which grow in space satisfy the following condition:

$$\frac{1}{2}\varkappa^2\tilde{v}_b^2 < (kv)^2 < \omega_{pe}^2 \equiv \left(\omega_p^2 + \frac{1}{2}\varkappa^2\tilde{v}_p^2\right). \tag{3}$$

Only modes for which $\omega = \omega_{pe}$ and $kv \simeq (\omega_{pe} - (1/\sqrt{2})\varkappa\tilde{v}_b)$ are unstable in time. The growth rate is

$$\gamma = \frac{\omega_p\omega_b}{(2)^{3/4}\sqrt{\omega_{pe}\varkappa\tilde{v}_b}}. \tag{4}$$

These results imply that the convective instability is damped when $\varkappa\tilde{v}_b = \sqrt{2}\omega_{pe}$. Moreover, since the wavelength of the absolute instabilities rises sharply in this case ($\tilde{v}_b \gg \tilde{v}_p$), these can be quenched by the finite dimensions of the apparatus.

2. Accelerating or retarding the beam should disrupt the synchronism between the wave and the particle bunches (the number of coherent bunches will decrease); moreover, when the beam is accelerated in space the density decreases (the number of coherent particles decreases). Moreover, the conditions for the emission mechanism can change (emission may not occur at a specified frequency). This indicates the possibility of inhibiting instabilities by beam acceleration or retardation. As an example, let us consider the effect of acceleration on the Pierce instability. Assuming that the beam velocity depends on the coordinate as $v_0 = v(1 + \alpha z)$, in the WKB approximation we find

$$\omega = i\frac{v}{L}\frac{\pi n}{4}\left[\delta - \frac{3}{4}\alpha L\pi n\right] \quad (n = 1;\ 3;\ 5\ldots), \tag{5}$$

where L is the distance between electrodes. We can show (and we have been able to solve this problem rigorously) that a beam accelerated in a diode is stable, while one that is retarded in it is unstable. We can also show that a beam moving between two cylindrical surfaces with constant velocity is stable if it moves from the smaller one to the larger one, and unstable if the motion is the reverse. The anisotropy in all these cases is evidently the result of the change in the number of coherent particles in the bunches.

To confirm the possibility of cutting off instabilities by using acceleration, Izmailov has added to the glass tube of the apparatus described in ref. 5 a narrow electrode ($d \simeq 3$ cm), to which constant retarding and acceleration potentials are applied. It is found that an accelerating potential of 200 V cuts off all the instabilities described in ref. 5. Retarding potentials up to 1.5 kV have no effect. Certain other instabilities are also cut off; the details of the experiments are to be published in the future.

We should note that the use of external fields can result in the appearance of new instabilities. In many cases, however, the cutoff conditions for these oscillations can be satisfied or the growth rates are small.

The author is grateful to Ya. B. Fainberg and V. I. Kurilko for discussion.

Acceleration of plasma electrons in strong electric fields

Z. A. Al'bikov, M. I. Ivanov, V. I. Kazacha, O. V. Kozlov, V. D. Rusanov, and S. S. Sobolev

(Submitted April 10, 1974)
Zh. Tekh. Fiz., 44, 2421-2423 (November 1974)

The present paper reports a study of the acceleration of plasma electrons in electric fields ($2 \cdot 10^2$ to 10^3 V/cm) with rise times of 10-15 nsec. Stefanovskii[1] and Skarsgard[2] show that in electric fields from 50 to 200 V/cm all the electrons of a previously produced plasma are initially freely accelerated; the acceleration then stops either because of the attenuation of the electron beam[5] or because of a loss of stability of equilibrium. At the same time papers on turbulent heating[3,4] report the acceleration of a small group of electrons; therefore it is of particular interest to find the conditions under which all the plasma electrons are accelerated. This can be expected to occur for a high rate of growth of the potential in the plasma. In addition the experimentally observed time of free acceleration of electrons, which is 50-100 nsec in ref. 5, leads one to hope that in a stronger electric field all the plasma electrons can be accelerated to relativistic energies in the initial stage of the process. This in turn should decrease the instability growth rate in the plasma during the passage of an electron beam, and thus increase the acceleration and plasma lifetime.

The experimental arrangement consists of a copper toroidal chamber with a minor diameter of 7 cm and a major diameter of 70 cm. The chamber walls are 3 mm thick. The chamber is divided along a major diameter (Fig. 1) and Teflon insulators are inserted in both gaps. The voltage from two capacitor banks is fed through spark-gap switches to the edges of the chamber through bus bars. Each bank consists of six 0.5 μF capacitors with a working potential of 25 kV. By firing the spark gaps the two banks are connected in series and a potential of 300 kV is applied to the circuit. A steady toroidal magnetic field H_0 up to 7 kG is produced by 24 coils uniformly spaced around the circumference of the chamber. Argon is fed in continuously and symmetrically from both sides of the chamber, which is pumped continuously. Preionization is produced by two loops inserted into the chamber through the pumping connections, which are driven with 20 kW from two high-frequency oscillators at 15 MHz. The chamber is first pumped to 10^{-6} mm Hg, and argon is then introduced to maintain the pressure at 10^{-4} mm Hg.

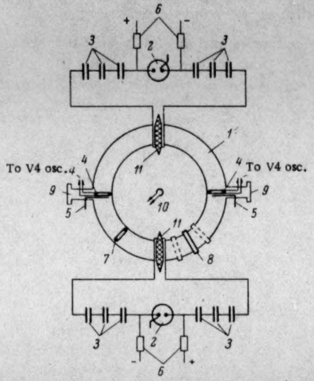

Fig. 1. General view of apparatus. 1) Copper chamber; 2) spark-gapswitch; 3) capacitor banks; 4) loop of high-frequency preionization oscillator; 5) gas admission tube; 6) capacitor bank charging resistor; 7) Rogowski loop; 8) one of 24 coils producing a steady magnetic field; 9) connection to evacuation system (grounded point of chamber); 10) loop for measuring circuit voltage; 11) dielectric gap in chamber.

The distribution of the density n_e of the preionization plasma in a cross section of the chamber and T_e are measured with a movable double Langmuir probe and are calculated by the usual equations. The quantity n_e is measured along a diameter of the plasma column with a two-channel 1.6 cm interferometer. The voltage across the circuit is measured with a loop at the center of the torus in the horizontal plane (resolving time 1 nsec). Because of the parasitic inductances of the capacitor banks and the busbars it is 15% smaller than the voltage across the charged capacitor banks. The plasma current is measured with a self-integrating Rogowski loop with a resolving time of 25-30 nsec located inside the chamber and encircling the plasma loop. The intensity and hardness of the x-ray spectrum are measured with four detectors and a plastic scintillator. The detectors have a resolving time of 7 nsec and a linear photomultiplier current up to 5 A.

The quantity n_e varies from $3 \cdot 10^{10}$ to 10^{11} cm^{-3}; for neutral atom densities of 10^{13} to $2 \cdot 10^{13}$ cm^{-3} this is 1%

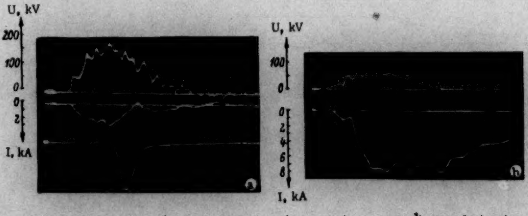

Fig. 2. Oscillograms of voltage, current, and x-ray pulse. n_e(cm^{-3}), U_{cir} (kV): a) $3 \cdot 10^{10}$, 150; b) 10^{11}, 50.

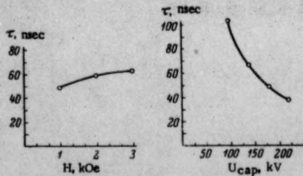

Fig. 3. Time of appearance of x-ray pulse relative to the voltage front across the circuit as a function of the toroidal magnetic field and the capacitor bank voltage.

ionization. The initial T_e is ~20 eV. The preionization plasma is collision-free.

The first experiments show that a current begins to flow in the plasma when the voltage is applied to the circuit; it reaches a value of about 3 kA in 50-100 nsec and then falls to zero, although the voltage across the circuit is still higher. Simultaneously with the fall of the current a pulse of hard x rays appears from the chamber wall, with its maximum coinciding with the drop in current (Fig. 2a, lower oscillogram). The current obtained in the experiment is equal to the expected value of the current of accelerated electrons under the assumption that all the plasma electrons are accelerated. The calculation is performed with the equation $J = en_eSc$, where S is the cross-sectional area and c is the velocity of light. As H_0 is increased the plasma current remains essentially unchanged, but becomes smoother and the interval between the voltage front and the maximum of the x-ray pulse increases slightly. The current also remains unchanged as the capacitor bank voltage is increased. Both these relations are shown in Fig. 3. The x-ray measurements using filters in all regimes show that the average energy of an x-ray photon is always between 200 and 250 keV, which corresponds to to an accelerated electron energy of about 500 keV. The smallest number of accelerated electrons is estimated independently from absolute measurements of the total energy of the accelerated electrons from the whole apparatus during a pulse. This is measured by placing x-ray detectors around the apparatus in such a way that the radiation from each part of the apparatus can fall on only one detector. We estimate the readings of calibrated detectors, introducing corrections for the spectral sensitivity of the detectors, and using the conversion coefficient for electrons on copper. Dividing this energy by 500 keV, the energy of one electron, we obtain the number of accelerated electrons. This number is 30% of the total number of plasma electrons. This result is clearly an underestimate since the calculation assumes that the electrons are incident normally on the wall, i.e., the wall is a thin target and the maximum of the x-ray directional diagram is along a major radius of the torus. But even these crude measurements show that most of the plasma electrons are accelerated, rather than a fraction of a percent as in refs. 2 and 3. The drop in current and the loss of accelerated electrons to the chamber wall require more detailed investigation. It is believed that the effect is related to the inhomogeneity of the magnetic field in the gaps. Under our experimental conditions the drop in current plays a positive role since it permits an estimate of the number of accelerated electrons from the intensity and hardness of the x rays; therefore we have not tried to prevent it. Further experiments show that by decreasing the circuit voltage and increasing the initial value of the density a mode of operation can be obtained with no fall of current. In this case the voltage and current oscillograms are of a different character (Fig. 2b). In this case there is no electron drift to the chamber wall; therefore no quantitative calculations can be made of the number of accelerated electrons from the x-ray intensity, which is three orders of magnitude smaller than in the case with the fall in current.

Thus, the current of about 3 kA observed in the plasma, the fact that the current and the integrated x-ray intensity are independent of the circuit voltage and the longitudinal magnetic field, and the absolute x-ray measurements lead us to the conclusion that most of the electrons are accelerated to energies of the order of 500 keV in the first 50-100 nsec. Problems of further acceleration and confinement of an electron beam require additional work.

Two modes of operation of an arc plasma source in an external magnetic field

A. G. Korsun and S. A. Meshcheryakov

(Submitted February 27, 1973)
Zh. Tekh. Fiz., 44, 2423-2425 (November 1974)

Two different modes of operation are found for a plasma source with an external axial magnetic field. In the "cathode" the predominant axial voltage drop occurs near the axis. In this case the source produces an electron flux which carries a high proportion of the discharge power. As the discharge current and working gas flow rate increase, a transition to an "anode" mode occurs, in which the voltage drop is concentrated in a sheath near the anode, where an ion flux is formed.

We have investigated a coaxial arc plasma source with an external magnetic field (Fig. 1), known in the literature as a source with a magnetoplasma arc[1] or an end-on Hall arc.[2] The molybdenum anode is funnel-shaped, its minimum diameter being 3.6 cm. The thermionic cathode is a disk of lanthanum hexaboride 2 cm in diameter heated to 1500-2000°K. The magnetic field is created by a solenoid. Iron disks at the output of the source shape magnetic lines of force (dashed lines in Fig. 1) so that three magnetic regions can be distinguished inside the source: lines intersecting the anode in the peripheral region, lines intersecting the cathode near the axis, and lines intersecting the insulators in the space between these two regions. The source power comes from a constant-voltage generator through a ballast resistor. The working gas, argon, is fed in through a slit between the anode and the insulator. The plasma source operates with the following parameters: : flowrate G, 10 mg/sec; current I, 30 A; voltage V, 500 volts; magnetic field B, 1000 G; power consumption W_h, 1 kW; pressure, 10^{-3} mm Hg.

We observe two different modes of operation of the source. At low discharge currents, a mode with a volt–ampere characteristic that rises steeply is found (Fig. 2). As the discharge current increases the ignition voltage drops abruptly and the volt–ampere characteristic rises slowly. The momentum of the plasma flow as measured by a pendulum is much lower in the first mode than in the second.

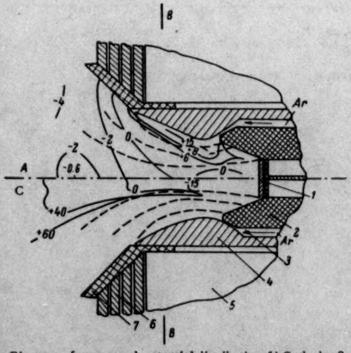

Fig. 1. Diagram of source and potential distribution. 1) Cathode; 2, 7) insulators; 3) gas feed channel; 4) anode; 5) solenoid; 6) iron disks. A represents the anode mode and C the cathode mode. In mode C: I = 2A, V = 160 volts, B = 250 G, W_h = 450 W, G < 0.1 mg/sec; in mode A: I = 18.5 A, V = 50 volts, B = 250 G, W_h = 650 W, G = 3.5 mg/sec.

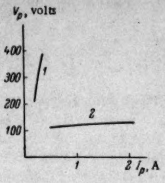

Fig. 2. Volt–ampere characteristics. 1) C mode, G = 0.3 mg/sec, W_h = 530 W, B = 250 G; 2) A mode, G = 0.3 mg/sec, W_h = 800 W, B = 250 G.

Investigation of the electrostatic potential distribution inside the source confirms that the two modes are qualitatively different. We measure the floating potential of the plasma by using a long cylindrical probe oriented along the flow axis. Since the electron temperature as estimated by the probe characteristic does not exceed a few electron volts, this potential is roughly the same as the space potential. The corresponding equipotential lines are shown in Fig. 1 by solid lines, below the axis for the first mode and above the axis for the second; the numbers next to the curves represent the potential.

The radial potential distribution is shown in Fig. 3. As can be seen from Figs. 2 and 3, in the first mode a potential jump, located approximately on those magnetic lines of force which intersect the edge of the anode, forms near the cathode. The length of the region in which the potential is close to the cathode potential is roughly the same as the anode length. This potential distribution is similar to the distribution in a Penning source when the density of neutrals is fairly high.[3] In both devices we observe a potential jump in the radial direction in the space between the cathode and anode (Fig. 3). A major difference in our source, however, is the large voltage drops along the axis (Fig. 1). A characteristic feature of this mode, therefore, is the formation of a plasma jet, whose potential is close to the anode potential and which carries a considerable amount of energy concentrated on the axis.[4]

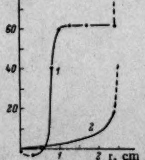

Fig. 3. Radial potential distribution in the cross-section B–B: 1) cathode mode; 2) anode mode.

Thermal measurements and probe measurements[5] using this source and similar ones show that a well-focused electron flux forms in the cathode region, and this flux transports up to 90% of the energy imparted to the discharge. Hence the first mode can be called a cathode mode. In the second mode the potential distribution is restructured so that most of the voltage drop is concentrated in an anode sheath about 0.5 cm thick. The marked increase in flow momentum in going from one mode to another is evidently associated with the formation and acceleration of ions near the anode in a sheath similar to that considered in ref. 6. Therefore the second mode can be called an anode mode. The potential of the plasma jet leaving the source is close to the cathode potential, and at elevated magnetic fields and cathode temperatures it reaches a value of −20 V relative to the cathode.

We have made oscillograms of the discharge voltage and current in the 10^3-10^6 Hz range. It turns out that the current fluctuations are small. This is evidently associated with the high generator inductance in the circuit. The amplitude of the voltage fluctuations increases sharply in going from the cathode to the anode mode, particularly in the 10^5-10^6 Hz range. In the cathode mode we observe regular oscillations; in the anode mode the fluctuations are random. For flowrates below 0.1 mg/sec, voltage fluctuations arise on the electrode in the anode mode such that air breakdown between the conductors occurs. The air gaps in question are greater than 1 cm; consequently the voltage fluctuations[7] are not less than 10 kV. This is evidently associated with the fact that the discharge gap periodically breaks a circuit containing a large inductance.

Loss of neutralization for a stable neutralized ion beam

M. D. Gabovich
Institute of Physics,
Academy of Sciences of the Ukrainian SSR, Kiev
(Submitted November 14, 1973)
Zh. Tekh. Fiz., 44, 2425-2428 (November 1974)

The view is developed that the achievable degree of neutralization of an ion beam passing through a rarefied gas is associated with the transfer of energy to neutralizing electrons in Coulomb collisions with beam ions and in the excitation of electron plasma oscillations by the beam.

The passage of a beam of fast positive ions through a rarefied gas is accompanied by ionization; the resulting electrons neutralize the space charge of the beam to a certain degree. In studying this familiar phenomenon, two basic questions arise: the achievable degree of neutralization of a stable ion beam (i.e., a beam whose current fluctuations are small in the initial cross section or are characterized by frequencies that lie outside of some danger range) and the loss of neutralization of a neutral ion beam caused by current fluctuations. Whereas the second question has been studied satisfactorily,[1-4] the first is not resolved. We can cite the following considerations.

1. The spreading of a neutral ion beam is determined by the residual radial potential drop φ, which can be much smaller than the potential drop in an unneutralized beam $\varphi_+ = \pi e R^2 n_+$, where R is the beam radius and n_+ the density of beam ions. In a beam neutralized by electrons that are formed through gas ionization φ is frequently expressed by an expression like[3,5,6] $\varphi \approx (kT_e/e) \ln \xi$, T_e being an electron temperature that actually depends on φ. In practice, therefore, equations of this type cannot be used to calculate φ.

2. A beam of positive ions with space charge that is not fully neutralized is a self-consistent potential well of depth φ which traps the slowest-moving electrons. The overall number of electrons formed per cm^3 per sec is $\nu = \int_0^\infty f(\varepsilon)\, d\varepsilon = n_+ v_+ n_a \sigma_i$, where $f(\varepsilon)\, d\varepsilon$ is the number of electrons per cm^3 per sec formed in ionization whose energy is in the interval between ε and $\varepsilon + d\varepsilon$; v_+ is the velocity of the beam ions; and n_a and σ_i are the density of atoms on the beam path and the corresponding ionization cross section. The ratio of the number of electrons trapped by the well to the total number of those formed is $\beta = \int_0^{e\varphi} f(\varepsilon)\, d\varepsilon \Big/ \int_0^\infty f(\varepsilon)\, d\varepsilon$. When the potential well is rectangular the energy of each trapped electron $\leq e\varphi$, the energy of each (previously trapped) electron that leaves the well $\geq e\varphi$, and in the steady state a total of $\nu\beta$ electrons is lost from the well in time. Thus, when electrons cannot escape along the beam a steady state is impossible without an additional energy source. In the usual definition of φ, however,[6] the number of electrons trapped by the well and the number leaving are taken to be the same, without any indication of the need for an additional energy source and without the appropriate allowance for energy balance.

In this note we are evidently the first to point out that the ion beam itself can be the source of this additional energy. Coulomb collisions between beam ions and neutralizing electrons, as well as the excitation of electron plasma oscillations by the beam, cause the trapped electrons to obtain additional energy and leave the beam. Allowance for the interaction between the beam and the plasma permits us to compute the depth of the potential well that is set up.

To determine φ we use the energy balance equation for the electrons trapped by the well and those trapped earlier which leave it:

$$W + Q = \nu'(e\varphi + \varepsilon_T), \tag{1}$$

where $W = \int_0^{e\varphi} f(\varepsilon)\, \varepsilon d\varepsilon$ is the energy of the electrons trapped per cm^3 per sec; Q is the additional energy imparted to the ion beam by the electron gas per cm^3 per sec; $\bar{\varepsilon}_T$ is the mean kinetic energy of the electrons trapped earlier beyond the limits of the well. We would note that the conservation of the number of electrons is also taken into account in (1), since the number of electrons ν' that leave from 1 cm^3 per sec is taken to be equal to the number trapped per cm^3 per sec, $\nu\beta$.

Equation (1) can be put in the form

$$\varepsilon + \frac{Q}{\nu\beta} = e\varphi + \varepsilon_T, \tag{2}$$

where $\bar{\varepsilon}$ is the mean energy of the trapped electrons.

The distribution function of the electrons that are generated is fairly complicated.[7] For simplicity, we approximate $f(\varepsilon)$ by the expression $f(\varepsilon) \sim 1/(\varepsilon + \varepsilon_i)^2$, which can be obtained from the classical Thomson theory of ionization,[8] where $\varepsilon_i = e\varphi_i$, φ_i being the ionization potential. In this case

$$\varepsilon = \frac{W}{\nu\beta} = \frac{\int_0^{e\varphi} f(\varepsilon)\, \varepsilon d\varepsilon}{\int_0^\infty f(\varepsilon)\, d\varepsilon} \frac{1}{\beta} = \frac{\int_0^{e\varphi} f(\varepsilon)\, \varepsilon d\varepsilon}{\int_0^{e\varphi} f(\varepsilon)\, d\varepsilon} = e\varphi_i \left[\left(1 + \frac{\varphi_i}{\varphi}\right) \ln\left(1 + \frac{\varphi}{\varphi_i}\right) - 1\right]. \tag{3}$$

Then β is

$$\beta = \frac{\int_0^{e\varphi} f(\varepsilon)\, d\varepsilon}{\int_0^\infty f(\varepsilon)\, d\varepsilon} = \frac{\varphi}{\varphi + \varphi_i}. \tag{4}$$

If we neglect the excitation of electron plasma oscillations by the beam and use the available expression for fast-ion energy transfer to electrons,[9] we can obtain the following expression for Q:

$$Q = n_+ v_+ \frac{\partial\left(\frac{Mv_+^2}{2}\right)}{\partial z} = Mn_+ v_+ \frac{\partial v_+}{\partial t} = \frac{n_+ n_e e^4 \alpha}{m v_+}, \qquad (5)$$

where $\alpha = 4\pi \ln(1\ m^{3/2} v_+^3 / 1.78\pi^{1/2} n_e^{1/2} e^3)$; M is the ion mass.

The Poisson equation in conjuction with (2)-(5) yields φ. It is of greatest practical interest to determine φ for a well-neutralized beam, i.e., to determine the degree of neutralization. In this case we can use the neutrality condition

$$n_e + n_{ef} \approx n_+ + n_{+s}, \qquad (6)$$

where n_{ef} is the density of fast electrons not trapped by the well; n_{+m} is the density of slow ions formed by ionization and ejected by the field from the beam. The balance equation for the formation and loss of fast electrons implies the inequality $n_{ef} \ll n_+$. The analogous balance equation for slow ions leads to the relationship

$$n_{+s} = \frac{n_+ v_+ n_a \sigma_i' R}{2\bar{v}_{+s}}, \qquad (7)$$

where $\bar{v}_{+s}$ is the mean slow-ion velocity; σ_i' is the cross section of formation of slow ions.

In a well-neutralized ion beam, e.g., when $\varphi \ll \varphi_i$, we can obtain the desired expression for φ, neglecting $\bar{\varepsilon}_T$ in (2) and using (2)-(7):

$$\varphi = \alpha^{1/3} e \left(\frac{M}{m}\right)^{1/3} \left(\frac{\varphi_i}{\varphi_0}\right)^{1/3} \left(\frac{1}{n_a \sigma_i} + \frac{v_+ \sigma_i' R}{v_{+s} \sigma_i 2}\right)^{1/3} n_+^{1/3}, \qquad (8)$$

where $e\varphi_0$ is the energy of the beam ions.

Errors in determining φ are associated with inaccuracies in the approximation for $f(\varepsilon)$ and with the assumption $\bar{\varepsilon}_T \ll e\varphi$. As regards the latter, we can observe that even when $\bar{\varepsilon}_T \approx e\varphi$ (Maxwellian electron distribution in a shallow well) the error involved does not change the order of φ. It would seem that the greatest discrepancy between values of φ computed from (8) and the experimental values would occur when the beam excites intense electron plasma oscillations. In this case the energy is transferred to the electrons and facilitates their leaving the well. Here the maximum value of Q can be evaluated as follows:

$$Q_{\max} \approx \gamma_{\max} \frac{E_{\max}^2}{4\pi}. \qquad (9)$$

Here $\gamma_{\max} = (\sqrt{3}/2)\,\omega\,(m/2M)^{1/3}$ is the maximum growth rate for excitation of electron plasma oscillations by an ion beam, the ion and electron densities being equal;[10] ω is the plasma frequency; and $E_{\max} = k\tilde{\varphi}_{\max} = (\omega/v_+) \cdot mv_+^2/4e$ represents the maximum field, a quantity which is limited by electron trapping by the wave field.[11] Using (2)-(4), (6), and (9), we can obtain an expression for the potential well depth at maximum amplitude:

$$\varphi_{\max} \approx 0.46 \left(\frac{m}{M}\right)^{5/12} \frac{\varphi_0^{1/4} \varphi_i^{1/3} n_+^{1/6} e^{1/6}}{(n_a \sigma_i)^{1/3}}. \qquad (10)$$

Equations (8) and (10) pertain to the two limiting cases of no oscillation or maximum oscillation. A detailed experimental verification of these equations is a problem in itself; we note the following. At a gas pressure of 10^{-3} mm Hg, when the ion beam does not excite oscillations (because of the relatively large number of electron neutral collisions) the experimental value $\varphi = 1$ V is in good agreement with the value of 0.9 V as computed from (8) (with the following parameter values: $\varphi_i = 15$ V, $\varphi_0 = 25$ kV, $M = 3.2 \cdot 10^{-24}$ G, $n_+ = 10^8\ \text{cm}^{-3}$, $\bar{v}_{+s} = 3 \cdot 10^5$ cm/sec, $\sigma_i = 9 \cdot 10^{-16}\ \text{cm}^2$, $\sigma_i' = 1.6 \cdot 10^{-15}\ \text{cm}^2$). For the range of gas pressure $p = 10^{-4}$–10^{-5} mm Hg, when the amplitude of electron oscillations excited by the ion beam is a maximum (see ref. 10), the experimental values of φ, as expected, are substantially greater than those computed by (8), and are close to those computed by (10). The most convincing confirmation of the important role of the effect in question is the experimentally established correlation[12] between the amplitude of the oscillations excited by the ion beam and the electron heating, which is accompanied by an increase in φ.

Thus our comparison of φ with experimental data, as well as the results of an experimental study,[12] confirm the view that the loss of neutralization of an ion beam is due to energy transfer to neutralizing electrons through Coulomb collisions between these electrons and ions and through excitation of electron plasma oscillations by the beam.

The author is grateful to É. A. Pashitskii and I. A. Soloshenko for useful discussions.

Analysis of magnetic deflection systems

O. M. Vovk and O. Ya. Popov

(Submitted March 11, 1974)
Zh. Tekh. Fiz., 44, 11, 2428-2429 (November 1974)

The field analysis for the basic types of magnetic deflection systems can be reduced to the solution of integral Fredholm equations of the first kind[1] whose kernels are the functions

$$f_n^m(a,\ b)=\frac{1}{2\pi}\int_0^{2\pi}\frac{\cos m\varphi d\varphi}{(a+b\cos\varphi)^{n+1/2}},$$

where

$$a=r^2+R^2+(z-z')^2;\quad b=-2rR.$$

These can be expressed simply in terms of associated Legendre functions of half-integral argument:[2]

$$f_n^m(a,\ b)=(-1)^m c^{-(n+1/2)}\frac{\Gamma\left(n-m+\frac{1}{2}\right)}{\Gamma\left(n+\frac{1}{2}\right)}P_{n-1/2}^m(x), \tag{1}$$

where x = a/c; c = $\sqrt{a^2-b^2}$.

Representations of the Legendre function in terms of a hypergeometric series[3,4] are frequently used in computation of (1). The following recursion relation is known[5] for n = 0:

$$(2m+1)f^{m+1}+(2m-1)f^{m-1}=2m\left(\frac{u}{v}+\frac{v}{u}\right)f^m, \tag{2}$$

where

$$u=\frac{1}{2}\{\sqrt{(z-z')^2+(R+r)^2}+\sqrt{(z-z')^2+(R-r)^2}\},$$
$$v=\frac{1}{2}\{\sqrt{(z-z')^2+(R+r)^2}-\sqrt{(z-z')^2+(R-r)^2}\}.$$

The basic functions can be expressed in terms of complete elliptic integrals:

$$f^0=\frac{2}{\pi u}K\left(\frac{v}{u}\right),$$
$$f^1=\frac{2}{\pi v}\left[K\left(\frac{v}{u}\right)-E\left(\frac{v}{u}\right)\right].$$

Derivatives of $f_n^m(a,\ b)$ are expressed in terms of these same functions, but with n' = n + 1.

In problems in electron optics we frequently must determine the components of a magnetic field which are derivatives of a potential, i.e., it becomes necessary to make computations of $f_n^m(a,\ b)$ for n > 0.

We can derive the following recursion relations:

$$\left(n+\frac{1}{2}\right)\left(n+\frac{3}{2}\right)c^2f_{n+2}^m(a,\ b)=(n+1)(2n+1)xcf_{n+1}^m(a,\ b)-\left[\left(n+\frac{1}{2}\right)^2-m^2\right]f_n^m(a,\ b), \tag{3}$$

$$\left(n-m-\frac{3}{2}\right)f_n^{m+2}(a,\ b)=\frac{2(m+1)x}{\sqrt{x^2-1}}f_n^{m+1}(a,\ b)+\left(n+m+\frac{1}{2}\right)f_n^m(a,\ b), \tag{4}$$

$$\left(n-m-\frac{1}{2}\right)\sqrt{x^2-1}f_n^{m+1}(a,\ b)=\left(n+m+\frac{1}{2}\right)xf_n^m(a,\ b)-\left(n+\frac{1}{2}\right)cf_{n+1}^m(a,\ b), \tag{5}$$

$$\left(n+\frac{1}{2}\right)c\sqrt{x^2-1}f_{n+1}^{m+1}(a,\ b)=\left(n+m+\frac{1}{2}\right)f_n^m(a,\ b)-\left(n+\frac{1}{2}\right)cxf_{n+1}^m(a,\ b). \tag{6}$$

Recursion relations (3)-(6) are valid for all n and m, except for real |x| < 1, a situation which holds in virtually every case. The basis functions for these relations have the form

$$f_0^0(a,\ b)=\frac{2}{\pi(a-b)^{1/2}}K(k),$$
$$f_1^0(a,\ b)=\frac{2}{\pi(a-b)^{3/2}}\frac{1}{k'^2}E(k),$$

where K(k) and E(k) are complete elliptic integrals of the first and second kind respectively, while k and k' are respectively the modulus and complementary modulus of the elliptic integrals,

$$k'=\sqrt{1-k^2};\quad k^2=-\frac{2b}{a-b}.$$

By simple manipulation we can show that (2) is identical to (4) for n = 0.

The need for using the above recursion relations for $f_n^m(a,\ b)$ is dictated by the great expenditures of machine time that are involved when these functions are represented by a hypergeometric series.[4] When (3)-(6) are used the computation time can be reduced by a factor of 5.

Nonlinear behavior of monochromatic surface waves excited by a beam

A. B. Kitsenko, I. M. Pankratov, and K. N. Stepanov

(Submitted December 21, 1973)
Zh. Tekh. Fiz., 44, 2430-2432 (November 1974)

The motion of a charged particle in the electric field of a monochromatic electrostatic surface wave of small but finite amplitude in an external magnetic field is analyzed by the method of averaging. The amplitude of a monochromatic surface wave excited by a monoenergetic low-density beam of particles is estimated in the saturation stage, in which the oscillation frequency of the trapped particles is of the same order as the linear growth rate.

The amplification of volume and surface waves becomes appreciable in the interaction of beams of charged particles with a plasma under laboratory conditions. The particles of the beam are trapped by the wave field in the nonlinear stage. The theory of the nonlinear stage of volume-wave amplification in an unconfined plasma has been developed for the cases of zero external magnetic field[1-3] and a finite external magnetic field.[4]

In this work we estimate the amplitude of a monochromatic potential surface wave propagating along the plane boundary of a plasma (dielectric, slow-wave) in the nonlinear stage.

To estimate the amplitude of the oscillations in the saturation regime it is necessary to consider the motion of a single particle of the beam in the constant magnetic field and the electric field of the monochromatic electrostatic surface wave of finite amplitude. We assume that wave potential is of the form

$$\varphi = \mathrm{Re}\,\varphi_0 e^{-\varkappa y + i(\mathbf{kr} - \omega t + \alpha)}. \tag{1}$$

The y axis is perpendicular to the plane along which the surface wave propagates (the interface between the two media) and the z axis is parallel to the external magnetic field $\mathbf{B}_0$, which is directed along the interface. The quantity $\varkappa$ has different forms, depending on the type of surface wave, the oscillation frequency ω, and the wave vector $\mathbf{k} = (k_x, 0, k_z)$. We assume for simplicity that the beam particles do not cross the boundary y = 0. Making the following change of variables in the equations of motion for the charged particle:

$$\left.\begin{aligned} v_x &= v_\perp \cos\theta, \quad v_y = v_\perp \sin\theta, \\ x &= \xi - \frac{v_\perp}{\omega_B}\sin\theta, \quad y = \eta + \frac{v_\perp}{\omega_B}\cos\theta \quad \left(\omega_B = \frac{eB_0}{mc}\right), \end{aligned}\right\} \tag{2}$$

where θ is the azimuthal angle in velocity space and ξ and η are the transverse coordinates of the guiding center, we obtain

$$\left.\begin{aligned} \frac{d\xi}{dt} &= \frac{e\varkappa\varphi_0}{m\omega_B} e^{-\varkappa\eta} \sum_l A_l(v_\perp)\cos(\Phi_l + \alpha), \\ \frac{d\eta}{dt} &= -\frac{ek_x\varphi_0}{m\omega_B} e^{-\varkappa\eta} \sum_l A_l(v_\perp)\sin(\Phi_l + \alpha), \\ \frac{dv_z}{dt} &= \frac{ek_z\varphi_0}{m} e^{-\varkappa\eta} \sum_l A_l(v_\perp)\sin(\Phi_l + \alpha), \\ \frac{dv_\perp}{dt} &= \frac{e\varphi_0}{m}\frac{\omega_B}{v_\perp} e^{-\varkappa\eta} \sum_l lA_l(v_\perp)\sin(\Phi_l + \alpha), \\ \frac{d\theta}{dt} &= -\omega_B - \frac{e\varphi_0}{m}\frac{\omega_B}{v_\perp} e^{-\varkappa\eta} \sum_l \frac{d}{dv_\perp} A_l(v_\perp)\cos(\Phi_l + \alpha). \end{aligned}\right\} \tag{3}$$

Here, $J_n(x)$ is a Bessel function, $I_n(x)$ is the Bessel function of an imaginary argument, and

$$\left.\begin{aligned} A_l(v_\perp) &= \sum_s (-1)^s I_s\left(\frac{\varkappa v_\perp}{\omega_B}\right) J_{l-s}\left(\frac{k_x v_\perp}{\omega_B}\right), \\ \Phi_l &= k_x\xi + k_z z - \omega t - l\theta. \end{aligned}\right\} \tag{4}$$

We assume that the wave amplitude is small:

$$c\frac{k\varphi_0}{B_0} \ll \frac{|\omega_B|}{k}, \quad c\frac{k_x\varphi_0}{B_0} \ll v_\perp, \quad c\frac{\varkappa\varphi_0}{B_0} \ll v_\perp. \tag{5}$$

Then the system (3) contains rapidly varying phase angles θ and $k_z z - \omega t$ and can be investigated by the method of averaging.[5]

We consider only resonance frequencies, for which

$$\omega - k_z v_z \approx n\omega_B \quad (n = 0, \pm 1, \ldots). \tag{6}$$

Averaging Eqs. (3), we obtain a system of first-approximation equations for the average variables $\bar{\xi}$, $\bar{\eta}$, $\bar{v}_z$, $\bar{v}_\perp$, $\bar{\theta}$ under resonance conditions (6):

$$\left.\begin{aligned} \frac{d\bar{\xi}}{dt} &= \frac{e\varkappa\varphi_0}{m\omega_B} e^{-\varkappa\bar{\eta}} A_n(\bar{v}_\perp)\cos(\bar{\Phi}_n + \alpha), \\ \frac{d\bar{\eta}}{dt} &= -\frac{ek_x\varphi_0}{m\omega_B} e^{-\varkappa\bar{\eta}} A_n(\bar{v}_\perp)\sin(\bar{\Phi}_n + \alpha), \\ \frac{d\bar{v}_z}{dt} &= \frac{ek_z\varphi_0}{m} e^{-\varkappa\bar{\eta}} A_n(\bar{v}_\perp)\sin(\bar{\Phi}_n + \alpha), \\ \frac{d\bar{v}_\perp}{dt} &= \frac{e\varphi_0}{m}\frac{\omega_B n}{\bar{v}_\perp} e^{-\varkappa\bar{\eta}} A_n(\bar{v}_\perp)\sin(\bar{\Phi}_n + \alpha), \\ \frac{d\bar{\theta}}{dt} &= -\omega_B - \frac{e\varphi_0}{m}\frac{\omega_B}{\bar{v}_\perp} e^{-\varkappa\bar{\eta}} \frac{d}{d\bar{v}_\perp} A_n(\bar{v}_\perp)\cos(\bar{\Phi}_n + \alpha). \end{aligned}\right\} \tag{7}$$

It is also convenient to introduce the following equation for the resonance phase $\bar{\Phi}_n$:

$$\frac{d\bar{\Phi}_n}{dt} = n\omega_B - \omega + k_z\bar{v}_z + \frac{e\varphi_0}{m} e^{-\varkappa\bar{\eta}}\left[\frac{\varkappa k_x}{\omega_B} A_n(\bar{v}_\perp) + \frac{n\omega_B}{\bar{v}_\perp}\frac{d}{d\bar{v}_\perp} A_n(\bar{v}_\perp)\right]\cos(\bar{\Phi}_n + \alpha). \tag{8}$$

For simplicity we drop the bar over the averages below. In the case of the Cerenkov resonance (n = 0) Eqs. (7) and (8) have integrals of the motion ($k_z \neq 0$)

$$v_\perp = C_1, \quad \eta + \frac{k_x}{k_z\omega_B} v_z = C_2, \tag{9}$$

$$\frac{e\varphi_0}{m} A_0(C_1)\cos(\Phi_0 + \alpha) = \left[C_3 - \frac{1}{2}\left(v_z - \frac{\omega}{k_z}\right)^2\right]\exp\left(\varkappa C_2 - \frac{\varkappa k_x}{\omega_B k_z} v_z\right). \tag{10}$$

In the case of cyclotron resonance (n = ± 1, ± 2, . . .) we obtain the following integrals from (7) and (8):

$$v_z - \frac{k_z}{2n\omega_B} v_\perp^2 = C_1, \quad \eta + \frac{k_x}{2n\omega_B^2} v_\perp^2 = C_2, \tag{11}$$

$$\frac{e\varphi_0}{m} A_n(v_\perp)\cos(\Phi_n + \alpha) = -\left[\frac{n\omega_B - \omega + k_z C_1}{n\omega_B}\frac{v_\perp^2}{2} + \frac{k_z^2}{(n\omega_B)^2}\frac{v_\perp^4}{8} + C_3\right]\exp\left(\varkappa C_2 - \frac{\varkappa k_x}{2n\omega_B^2} v_\perp^2\right). \tag{12}$$

The integrals (10) and (12) describe completely the motion of the charged particle in the phase planes (v_z, Φ_0) for n = 0 and $(v_\perp, \Phi_n)$ for n ≠ 0. It follows from (10) and (12) that the motion of the particle in the phase plane can be unlimited or bounded. In the latter case the particle is trapped by the wave field.

For example, in the case of a wave that propagates at an angle not too close to $\pi/2$ relative to the magnetic field the motion of the charged particles near centers whose coordinates Φ_n are given by the relation $\sin(\Phi_n + \alpha) = 0$ is described by the oscillation frequency

$$\left.\begin{aligned} \Omega_{tr}^2 &= \left|\frac{ek_z^2\varphi_0}{m} A_0(C_1)\right| \exp\left(-\varkappa C_2 + \frac{\varkappa k_x}{k_z^2}\frac{\omega}{\omega_B}\right) \quad (n = 0),\\ \Omega_{tr}^2 &= \left|\frac{ek_z^2\varphi_0}{m} A_n(v_{\perp 0})\right| \exp\left(-\varkappa C_2 + \frac{\varkappa k_x}{2n\omega_B^2} v_{\perp 0}^2\right) \quad (n \neq 0), \end{aligned}\right\} \tag{13}$$

where $v_{\perp 0}$ is the coordinate of the center in the $(v_\perp, \Phi_n)$ plane.

In the case $k_z \sim k_x$ the trapping domain with respect to the variable v_z for Cerenkov resonance is

$$\Delta v_z \sim \left|\frac{e\varphi_0}{m} A_0 \exp\left(-\varkappa C_2 + \frac{\varkappa k_x}{k_z^2}\frac{\omega}{\omega_B}\right)\right|^{1/2} \quad (n = 0),$$

and the trapping domain with respect to $v_\perp$ for cyclotron resonances (n ≠ 0) is

$$\Delta v_\perp \sim \left|\frac{e\varphi_0}{m} A_n \exp\left(-\varkappa C_2 + \frac{\varkappa k_x}{2n\omega_B^2} v_{\perp 0}^2\right)\right|^{1/2}.$$

The presence of the factors $\exp(-\varkappa C_2)$ in the expressions for Ω_{tr}^2, Δv_z, and $\Delta v_\perp$ is due to the fact that the typical particle "senses" the field in the domain $\Delta y \sim C_2$. If $k_z \ll k_x$ (n ≠ 0), the trapping domain with respect to $v_\perp$ grows larger, and the oscillation frequency of particles near the centers is lower than in the case $k_z \sim k_x$ (this situation is analogous to the case of particle motion in the field of a volume wave).

Let us assume that a charged-particle beam with a small thermal velocity spread moving parallel to B_0 with velocity v_{z0} has dimensions $\Delta y \lessdot \varkappa^{-1}$ in the y direction. If a surface wave is generated at the plasma–vacuum interface, the beam can be located inside the plasma near the surface or in the vacuum outside the plasma. In this case, under Cerenkov resonance conditions (n = 0) the linear growth rate $\gamma_L \sim (n_b/n_p)^{1/3}\omega$ for $k_z \sim k_x$, where $n_{p,b}$ are the respective densities of the plasma and beam. The same growth rate occurs for waves excited by a beam of oscillators (charged particles with the same Larmor radius and a uniform distribution with respect to the phase angles θ) for both Cerenkov and cyclotron resonances ($|n| \geq 1$) if the Larmor radius of the beam particles is too large ($|\varkappa| v_\perp / |\omega_B| \sim 1$, $k_x v_\perp / |\omega_B| \sim 1$, $v_\perp \sim v_{z0}$). The oscillation level is saturated when Ω_{tr} is of the same order as γ_L, i.e., when

$$E \sim k\varphi_0 \sim \sqrt{4\pi n_b m v_{z0}^2}\left(\frac{n_b}{n_p}\right)^{1/3}, \quad (k_z \sim k_x). \tag{14}$$

Expression (14) for the surface-wave amplitude in the saturation stage is of the same order of magnitude as the analogous expression for plasma volume waves.[4]

Electron lifetimes in atmosphere at high pressure

V. N. Kapinos, Yu. A. Medvedev, N. N. Morozov, and B. M. Stepanov
All-Union Scientific Research Institute of Optical and Physical Measurements, Moscow

(Submitted September 17, 1973)
Zh. Tekh. Fiz., 44, 2432-2433 (November 1974)

Electron lifetimes θ are measured by a waveguide method in an air afterglow plasma produced by a short pulse of relativistic electrons. For air pressures p from 50 to 600 torr we find $\theta \sim p^{-2}$.

Up to the present time direct measurements of electron lifetimes in air have been restricted to pressures p not exceeding[1,2] 160 torr because of the relatively low time resolution of the measurement procedure employed. In ref. 1, for example, the length of the pulse of ionizing radiation is $5\ \mu$sec, and in ref. 2 it is $1.5\ \mu$sec. This poor time resolution leads to appreciable errors in measurements at high pressures and, apparently, to a false interpretation of the measurements in ref. 1, where the observed deviation of the dependence of the two-particle attachment coefficient of electrons from a linear relation at pressures $p \geqslant 50$ torr is related to the Bloch and Bradbury mechanism.[3]

In view of the above situation we have measured electron lifetimes in an air afterglow plasma at pressures from 50 to 600 torr.

The experimental arrangement is similar to that shown in ref. 1. The H_{10} mode at 2.9 GHz is excited in a waveguide cell. To eliminate the effect of power at the characteristic frequency of the waveguide accelerator ($\sim$2.2 GHz), a reentrant cavity tuned to the microwave frequency is inserted in the waveguide cell. This eliminates the strong signal induced in the detector section by the bunched beam of electrons from the accelerator. A plasma is produced in the waveguide cell by a pulse of 8 MeV electrons of 40 nsec duration and a maximum pulse current of 2 A: The resolving time of the measurement is $\sim 10^{-8}$ sec; this permits direct measurements of electron lifetimes in air up to atmospheric pressure.

The electron lifetime θ is determined from a log–log plot of the ratio of the amplitudes of the signals from the detector with and without plasma in the waveguide. Figure 1 shows the electron lifetime θ as a function of the air pressure. The data show that $\theta \sim p^{-2}$ in the pressure range 50-600 torr.

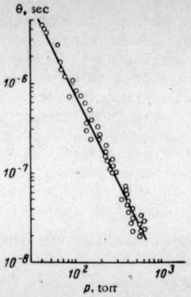

Fig. 1

The maximum experimental error is estimated to be 30% and decreases at lower pressures because of the improved resolving time.

The experimental value of the three-particle attachment coefficient $K = 2.8 \cdot 10^{-30}$ cm^6/sec is in satisfactory agreement with the results reported in refs. 2, 4-6.

Low-frequency helical instability in a high-frequency electric field

V. S. Paverman and D. D. Tskhakaya

Tbilisi State University and Institute of Physics, Academy of Sciences of the Georgian SSR

(Submitted October 22, 1973; resubmitted January 21, 1974)
Zh. Tekh. Fiz., 44, pp. 2433-2436 (November 1974)

Low-frequency helical waves that propagate in an electron magnetoplasma in an external time-varying electric field are treated. These waves are unstable in a weak high-frequency field when certain decay conditions hold.

Of late there has been increased interest in problems of the interaction between an external high-frequency field and a plasma. One reason for this interest is the need for a detailed investigation of the phenomena that occur when electromagnetic waves propagate in the ionosphere and in plasmas in outer space. It has been shown in a number of studies[1] that a plasma becomes unstable to both electrostatic and electromagnetic modes in a high-frequency field. These instabilities, however, are due to wave motion of the plasma ions or the coupling of electron radiation to wave processes in the plasma.

In this paper we investigate the behavior of a pure electron plasma in a weak high-frequency electric field and a fixed magnetic field. The high-frequency field $\mathbf{E}_0(t)$ and the external magnetic field $\mathbf{H}_0$ are in the same direction $\mathbf{H}_0(0, 0, H_0)$. This means that an external transverse high-frequency wave propagates across $\mathbf{H}_0$. The wavelengths we consider are assumed to be much smaller than the length of the external high-frequency wave. As a result, the external high-frequency field can be written in the form $\mathbf{E}_0(t) = \mathbf{E}_0 \sin\omega_0 t$. Under these conditions, for external frequencies close to the electron plasma frequency even in weak high-frequency fields the plasma is unstable against low-frequency transverse modes (whistlers) that propagate along the magnetic field.

The equations are

$$\left.\begin{aligned} \operatorname{curl}\ \mathbf{E} &= -\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t}, \\ \operatorname{curl}\ \mathbf{H} &= \frac{1}{c}\frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi}{c} en\mathbf{V}, \\ \frac{d\mathbf{V}}{dt} &= \frac{e}{m}\mathbf{E} + \frac{e}{mc}[\mathbf{VH}], \\ \frac{\partial n}{\partial t} &+ \operatorname{div}(n\mathbf{V}) = 0. \end{aligned}\right\} \tag{1}$$

The behavior of the plasma in equilibrium is described by the equations

$$\frac{d\mathbf{V}_0}{dt} = \frac{e}{m}\mathbf{E}_0(t); \quad \frac{\partial n_0}{\partial t} = 0. \tag{2}$$

If we assume that the deviations from the unperturbed values $\mathbf{V}_0(t)$, $\mathbf{E}_0(t)$, n_0, and $\mathbf{H}_0$ are small, we can linearize system (1) and write the coordinate dependence of the nonequilibrium quantities in the form $e^{i\mathbf{kr}}$. We consider perturbations that propagate along the z axis. It is easy to show that the equations for the longitudinal and transverse waves separate in this case. The effect of the high-frequency field on the longitudinal waves appears only in the Doppler shift. For the transverse waves we have

$$\frac{d^2H_\pm(t)}{dt^2} + (\omega_L^2 + c^2k^2)H_\pm(t) \mp i\omega_H\omega_L^2 e^-(t)\, e^{\mp i\omega_H t}\int_{-\infty}^{t} e^+(t_1)H_\pm(t_1)\, e^{\pm i\omega_H t_1}dt_1, \tag{3}$$

where

$$H_\pm(t) = \frac{H_x(t) \pm iH_y(t)}{\sqrt{2}},$$

$$e^\pm(t) = \exp\left\{\pm ik\int_{-\infty}^{t} V_0(t_1)\,dt_1\right\} = \sum_{n=-\infty}^{\infty} J_n(a)\, e^{\pm in\omega_0 t},$$

$$\omega_L^2 = \frac{4\pi e^2 n_0}{m}; \quad \omega_H = \frac{eH_0}{mc}; \quad a = \frac{kV_0}{\omega_0},$$

and $J_n(x)$ is the Bessel function. Changing to Fourier components

$$H_\pm(\omega) = \int_{-\infty}^{\infty} H_\pm(t)\, e^{i\omega t}dt$$

and setting $a \ll 1$ (i.e., considering weak high-frequency fields), we obtain

$$\Psi_\pm(\omega)H_\pm(\omega) = a\,(A_\pm(\omega, \omega_0)H_\pm(\omega + \omega_0) - A_\pm(\omega, -\omega_0)H_\pm(\omega - \omega_0)), \tag{4}$$

where

$$A_\pm(\omega, \omega_0) = \pm\frac{\omega_0\omega_H\omega_L^2}{2(\omega \mp \omega_H)(\omega + \omega_0 \mp \omega_H)},$$

$$\Psi_\pm(\omega) = \omega^2 - c^2k^2 - \omega_L^2 \mp \frac{\omega_H\omega_L^2}{\omega \mp \omega_H}. \tag{5}$$

In the absence of an external electric field ($a = 0$), we obtain the familiar dispersion relations for a plasma in a constant magnetic field (see, e.g., ref. 2) from this equation. Each of the equations $\Psi_\pm(\omega) = 0$ describes the characteristic modes of a plasma with a given polarization and has three solutions, one of which is the low-frequency whistler; the other two are high-frequency modes.

First we consider Eq. (4) for H_+. Successively eliminating $H_+(\omega \pm \omega_0)$, $H_+(\omega \pm 2\omega_0)$, ..., we obtain the dispersion relation in the form of an infinite continued fraction,[3] which can be truncated for $a \ll 1$. We have

$$\Psi_+(\omega) = a^2\left\{\frac{A_+^2(\omega, \omega_0)}{\Psi_+(\omega + \omega_0) + O(a^2)} + \frac{A_+^2(\omega - \omega_0)}{\Psi_+(\omega - \omega_0) + O(a^2)}\right\}. \tag{6}$$

Here, $O(a^2)$ denotes terms of order a^2. We assume below that $\omega_0 \sim \omega_L \gg \omega_H$, ck. For $a = 0$ we choose the low-frequency solution of the dispersion equation $\Psi_+(\omega) = 0$:

$$\omega_1 = \frac{c^2k^2}{\omega_L^2}\omega_H\left(1 - \frac{c^2k^2}{\omega_L^2}\right).$$

We will seek a solution of (6) that is close to ω_1. Assume that $\omega = \omega_1 + i\gamma(|\gamma| \ll \omega_1)$ and $\omega_0 = \omega_2 + \omega_1 + \Delta$, where the detuning $|\Delta| \ll \omega_1$ and

$$\omega_2 \approx \omega_L \left\{1 + \frac{c^2k^2}{\omega_L^2} - \frac{\omega_H}{\omega_L} + \frac{1}{2}\frac{\omega_H^2}{\omega_L^2} + \frac{1}{2}\frac{c^2k^2}{\omega_L^2}\frac{\omega_H}{\omega_L}\right\}^{1/2} \tag{7}$$

is the high-frequency solution of the equation

$$\Psi_+(\omega_1 - \omega_0) = \Psi_+(-\omega_2) = 0.$$

Under these assumptions, the first term in brackets in (6) is small. The quantity γ is given by

$$\gamma = i\frac{\Delta}{2} \pm \frac{1}{2}\left\{\frac{a^2}{2}\omega_H\omega_L - \Delta^2\right\}^{1/2}. \tag{8}$$

The maximum growth rate is obtained for $\Delta = 0$:

$$\gamma_{\max} = \frac{kV_0}{2\sqrt{2}}\left(\frac{\omega_H}{\omega_L}\right)^{1/2}.$$

and the condition $|\gamma_{\max}| \ll \omega_1$ can be rewritten in the form

$$\frac{V_0^2}{c^2} \ll \frac{\omega_1}{\omega_L} \ll 1,$$

which indicates that an instability occurs for weak external fields. Similarly, from (4) we can obtain the growth rates for the H_- waves. Here the following condition should hold:

$$\omega_0 = \omega_2' - \omega_1' + \Delta', \quad |\Delta'| \ll |\omega_1'|, \tag{9}$$

where $\omega'_1 = -\omega_1$ and $\omega'_2 = \omega_2$ satisfy the equation

$$\Psi_-(\omega_0 + \omega_1') = \Psi_-(\omega_2') = 0.$$

Condition (9) implies that the expressions for the external frequency coincide when the H_+ and H_- modes are excited. This means that both waves can be excited simultaneously.

The physical picture of the instability can be represented as follows. When an electron moves in the field of the low-frequency helical wave under consideration it is acted on by a force $(e/c)\,[\mathbf{V}_0\mathbf{H}]$, where $\mathbf{V}_0$ is the electron velocity in the external high-frequency field and H is the magnetic component of one of the high-frequency circularly polarized waves. When the decay condition

$$\omega_0 - \omega_1 = \omega_2 \tag{10}$$

holds in the system associated with the moving electron, a constant force that accelerates the electron appears. This force results in the development of an instability in the low-frequency helical waves.

To determine the threshold value of the external high-frequency field we must take account of damping of the helical waves. In the limit of a cold completely ionized plasma the absorption is due basically to electron–ion collisions. Allowance for this mechanism leads to the appearance of the following additional term in (5):

$$\delta\Psi_\pm = i\nu\frac{\omega\omega_L^2}{(\omega \mp \omega_H)^2}.$$

Here, ν is the electron–ion collision frequency. For weakly damped low-frequency helical waves,[4] $\nu \ll \omega_H$.

Calculations similar to those above (allowing for the term $\delta\Psi_\pm$) for $\Delta = 0$ yield the following expression for the threshold value E_{thr}:

$$\frac{E_{\text{thr}}^2}{8\pi n_0 mc^2} = \frac{2\nu^2}{\omega_H\omega_L}.$$

Obviously, the results are valid if the wave-vector components $k_\parallel$ and $k_\perp$ (longitudinal and transverse with respect to the magnetic field) satisfy

$$k_\perp^2 \ll k_\parallel^2 \sim k^2.$$

Here, the pump field can be regarded as uniform only for

$$k_0^2 = \frac{(\omega_0^2 - \omega_L^2)}{c^2 \ll k_\perp^2 \ll k^2}.$$

Allowing for (10) and the definition of ω_2 in (7), the condition for the field of the pump wave to be uniform becomes

$$\left|k^2 - \frac{|\omega_H|\,\omega_L}{c^2}\right| \ll k^2.$$

It is obvious that this inequality can be satisfied.

Method for optical modulation of an electron beam

V. I. Sotnikov

Moscow Physicotechnical Institute

(Submitted February 11, 1974)
Zh. Tekh. Fiz., 44, 2436-2438 (November 1974)

It is proposed to modulate an electron beam by nonlinear transformation of an electromagnetic wave into a charge-density wave. Expressions are obtained for the modulation depth for a modified decay relation and the usual decay relation.

According to ref. 1, preliminary modulation of a relativistic beam at the plasma frequency results in a marked decrease in the relaxation length of the beams and makes collective relaxation in a D−T target possible. In considering modulation of a high-current relativistic beam at a resonant frequency corresponding to a high plasma density ($n > 10^{19}$), the most promising method involves the use of a high-power laser. In this paper we study one possible mechanism for optical modulation of an electron beam; this is based on the nonlinear transformation of an electromagnetic wave into a charge-density wave. This mechanism provides fairly good modulation depth $\Delta n/n = 10^{-2}$ even at laser powers $P \sim 3 \cdot 10^{12}$ W.

Consider an electromagnetic pump wave that propagates along a monochromatic relativistic electron beam moving along the z axis with velocity v_0; the electromagnetic wave decays into an electromagnetic wave and a plasma wave ($t_0 \to t_1 + l$). The nonlinearity which saturates the wave amplitude is associated with the feedback reaction of the pump wave on the perturbation. When the amplitude of the plasma wave is high enough the electron density in the beam is modulated.

We consider two cases.

1. In the first case, the instability growth rate $\nu \ll \omega_b \Gamma^{-3/2}$, where $\omega_b = \sqrt{4\pi e^2 n_0/m}$, n_0 is the electron density beam, and $\Gamma = (1 - v_0^2/c^2)^{-1/2}$. This corresponds to ordinary decay. In this case we have a system of equations that describes the decay of the electromagnetic pump wave $E_0(z, t)$ into an electromagnetic wave and a plasma wave $E_1(z, t)$ and $E_2(z, t)$, where

$$\left.\begin{aligned} &E_j(z, t) = E_j(t)\, e^{i(k_j z - \omega_j t + \alpha_j(t))} \quad j = 0, 1, 2, \\ &\frac{d}{dt}\left(E_0 e^{i\alpha_0}\right) = \frac{ek_2}{4m\omega_1\Gamma} E_1 E_2 e^{i(\alpha_1+\alpha_2)}, \\ &\frac{d}{dt}\left(E_1 e^{i\alpha_1}\right) = -\frac{ek_2}{4m\omega_0\Gamma} E_0 E_2 e^{i(\alpha_0-\alpha_2)}, \\ &\frac{d}{dt}\left(E_2 e^{i\alpha_2}\right) = -\frac{ek_2\omega_b}{4m\omega_0\omega_1\Gamma^{3/2}} E_0 E_1 e^{i(\alpha_0-\alpha_1)}. \end{aligned}\right\} \tag{1}$$

In deriving this system we assume that the following resonance conditions hold:

$$\omega_0 = \omega_1 + \omega_2; \quad k_0 = k_1 + k_2; \tag{2}$$

using these, we obtain

$$k_2 = \frac{\omega_b}{(c - v_0)\Gamma^{3/2}}. \tag{3}$$

In the specified pump-wave approximation, we obtain a linear growth rate:

$$\nu = \frac{ek_2\mathcal{E}_0}{4m\omega_0}\sqrt{\frac{\omega_b}{\omega_1\Gamma^{3/2}}}, \tag{4}$$

where $\mathcal{E}_0 = E_0(t = 0)$.

From the solutions[2] of nonlinear system (1), we can find the beam modulation depth:

$$\frac{\Delta n}{n_0} = \frac{ek_2\mathcal{E}_0}{m\omega_b^2}\sqrt{\frac{\omega_b}{\omega_0\Gamma^{3/2}}}. \tag{5}$$

Using (4) we find that decay occurs at pump-wave amplitudes

$$\mathcal{E}_0 < \mathcal{E}_0^* = \frac{4m\omega_0\Gamma^{3/4}}{ek_2}\sqrt{\omega_b\omega_1},$$

which corresponds to a laser power

$$P^* = \frac{4m^2 c\omega_0^2\omega_1\omega_b\Gamma^{3/2}}{\pi e^2 k_2^2}.$$

2. Now let us consider the case $\nu_{\text{mod}} \gg \omega_b \Gamma^{-3/2}$; this corresponds to "modified" decay and an aperiodic growth with time.[3] In this case the system describing the decay of the electromagnetic pump wave has the form

$$\frac{d}{dt}\left(E_0 e^{i\alpha_0}\right) = \frac{R(\omega_1 + k_2 v_0)}{2\delta^2} E_1 E_2 e^{i(\alpha_1+\alpha_2+\delta t)}, \tag{6}$$

$$\frac{d}{dt}\left(E_1 e^{i\alpha_1}\right) = -\frac{R(\omega_0 - k_2 v_0)}{2\delta^2} E_0 E_2 e^{i(\alpha_0-\alpha_2-\delta t)}, \tag{7}$$

$$\frac{d^2}{dt^2}\left(E_2 e^{i\alpha_2}\right) + \frac{\omega_b^2}{\Gamma^3} E_2 e^{i\alpha_2} = iRE_0 E_1 e^{i(\alpha_0-\alpha_1-\delta t)}, \tag{8}$$

where $\delta = \omega_0 - \omega_1 - k_2 v_0$, $R = e\omega_b^2 k_2/2m\omega_0\omega_1\Gamma^4$, the field of the plasma wave being specified in the form

$$E_2(z, t) = E_2(t)\, e^{i(k_2 z - k_2 v_0 t + \alpha_2(t))}.$$

In the specified-pump-wave approximation, setting $E_2 e^{i\alpha_2} \sim e^{i\varkappa t}$, we obtain the linear dispersion relation from (7) and (8); if we use dimensionless variables this becomes

$$(\varkappa + \Delta_1)(\varkappa^2 - B) = 1, \tag{9}$$

where

$$\Delta_1 = \frac{\delta}{\xi}, \quad B = \frac{\omega_b^2}{\xi^2\Gamma^3}, \quad \xi = (2\delta)^{-2/3} R^{2/3}\mathcal{E}_0^{2/3}(\omega_0 - k_2 v_0)^{1/3}.$$

As $B \to 0$, an instability develops for all $\Delta_1 < 3/2^{2/3}$. An analytic solution of the nonlinear problems can be obtained for $|\Delta_1| \gg 1$. The fact that

$$k_2=\frac{\Delta_1\xi}{c-v_0}<0 \qquad (10)$$

for $\Delta_1 < 0$ implies that the process occurs with a higher frequency ω_1. Since $|\Delta_1|\xi \gg \nu_{\text{mod}} \sim \xi/\sqrt{\Delta_1}$, (10) implies that k_2 increases compared to (3) and can correspond to wavelengths in the visible range. For $|\Delta_1| \gg 1$ the wave amplitude varies much more slowly than the phase. Allowing for this fact, we can obtain the following equation for the amplitude of the plasma wave (in dimensionless variables):

$$\left(\frac{du_2}{d\tau}\right)^2=\left(\frac{du_{20}}{d\tau}\right)^2+\sqrt{\frac{\Delta_1^2}{4}+u_2^2}-\sqrt{\frac{\Delta_1^2}{4}+u_{20}^2}-B\left(u_2^2-u_{20}^2\right), \qquad (11)$$

where

$$u_{20}=u_2(\tau=0);\quad \frac{du_{20}}{d\tau}=\left.\frac{du_2}{d\tau}\right|_{\tau=0};\quad \tau=\xi t,$$

$$E_2=\frac{2\beta^2\xi}{(\omega_1+k_2v_0)^{1/2}(\omega_0-k_2v_0)^{1/2}R}u_2.$$

Equation (11) has a periodic solution with period $\tau_0 = 2\pi/\sqrt{B} + \sqrt{\Delta_1}K(k)$, where K(k) is a complete elliptic integral of the first kind; $k = 1 - |a|/\Delta_1$; $a = u_{20}^2/\Delta_1 - [(du_{20}\cdot d\tau)^{-1}]^2$; u_2 varies from its minimum value $u_{2\min} = \sqrt{a\Delta_1}\cdot$ ($u_{2\min} = 0$ for $a < 0$) to its maximum value[4] $u_{2\max} = (1/B)$. The modulation depth is

$$\frac{\Delta n}{n_0}=\frac{k_2^2e^2\mathcal{E}_0^2}{2m^2\omega_0\omega_1\omega_2^2\Gamma}. \qquad (12)$$

For an amplitude

$$\mathcal{E}_0=\frac{2m\omega_1\Gamma^{1/2}}{k_2e}\sqrt{\omega_2\omega_0}\sim\mathcal{E}_0^*,$$

Eq. (5) becomes Eq. (12).

The author is grateful to V. D. Shapiro for proposing the topic and for guidance.

Liquid metal droplet with high surface tension in an axially-symmetric electromagnetic field (strong skin effect)

A. N. Tverdokhlebov and A. L. Shuster

(Submitted February 4, 1974)
Zh. Tekh. Fiz., 44, 2438-2441 (November 1974)

The stable equilibrium, total potential energy, dissipated power, and aspherical corrections for the second and third terms of the Legendre polynomial expansion are obtained for a liquid-metal droplet with high surface tension suspended in an arbitrary axially-symmetric magnetic field. The expressions are obtained for the case of a strong skin effect.

In refs. 1 and 2 the generalized results are obtained for the potential energy, dissipated power, and shape of a liquid-metal droplet with a high surface tension σ in an arbitrary magnetic field, for the case of a strong skin effect.

In the experimental work, as, for instance, in vacuum melting,[3] kinetics of interaction between the gas flow and a levitating drop[4], axially-symmetric magnetic fields are of the most practical interest; these are produced by the coaxial currents. In this case simple expressions are obtained for the stability of a levitated metal droplet, its shape, etc. In the present work several relevant expressions are derived.

Conditions for a stable equilibrium position of a sphere. Let the magnetic field $\mathbf{H}(\mathbf{r})$ be produced by a system of n coaxial rings of radius R_k in which currents $\varepsilon_k I_k \exp(-i\omega t)$ flow, where $\varepsilon_k = \pm 1$, I_k is the effective value of the alternating current with frequency ω in the k-th ring; k = 1, 2, . . ., n. In the spherical system of coordinates (r, θ, φ) the nonzero component of the vector potential $\mathbf{A}(\mathbf{r})$ is given by [omitting the multiplier $\exp(-i\omega t)$]

$$A_\varphi = \sum_{l=1}^{\infty} \frac{1}{l(l+1)} r^l P_l^1(\cos\theta)\, \psi_l, \tag{1}$$

$$\psi_l = \sum_{k=1}^{n} \frac{2\pi}{c} \varepsilon_k I_k (R_k)^{-l} (\sin\alpha_k)^{l+1} P_l^1(\cos\alpha_k), \tag{2}$$

where $P_l^\mu(z)$ is the associated Legendre polynomial, while $2\alpha_k$ is the angle subtended by the diameter of the k-th ring at the origin.

In the zeroth approximation in $1/\sigma$, the drop is a sphere. The potential energy $U(\mathbf{r})$ of the sphere with radius a calculated according to expressions given in ref. 1 is

$$U(\mathbf{r}) = \frac{1}{4\pi} \int\limits_{|\mathbf{r}-\mathbf{r}'|<a} d^3r' \frac{|\mathbf{r}-\mathbf{r}'|}{a} \mathbf{H}^2(\mathbf{r}')$$

$$\equiv \frac{1}{2} a^3 \sum_{m=0}^{\infty} \frac{a^{2m}}{(m+2)(2m+1)!} \Delta^{(m)} \mathbf{H}^2(\mathbf{r}), \tag{3}$$

where a is the radius of the sphere of equivalent volume to the liquid-metal droplet, $\Delta^{(m)}$ is the Laplace operator taken m times, $\mathbf{H}(\mathbf{r})$ is the magnetic field in the absence of the sphere.

Let the center of the sphere be located at the origin. To obtain the necessary and sufficient conditions for a stable equilibrium of a sphere we expand the potential energy $U(\mathbf{r})$ in r about the origin to second order. Expression (3) for $U(\mathbf{r})$, with $\mathbf{H}$ from (1) and (2), gives

$$U(\mathbf{r}) - U(0) = \frac{1}{4} a^3 \sum_{m=1}^{\infty} a^{2m} \left\{ \frac{2}{m+1} \psi_m \psi_{m+1} (r\cos\theta) \right.$$
$$\left. + \left(\frac{m}{m+1} \psi_{m+1}^2 + \psi_m \psi_{m+2} \right) (r\cos\theta)^2 + \frac{1}{2} \left(\frac{m^2}{(m+1)^2} \psi_{m+1}^2 - \psi_m \psi_{m+2} \right) (r\sin\theta)^2 \right\}. \tag{4}$$

By considering the gravitational energy $U_g(\mathbf{r}) = (4/3)\pi a^3 d(\mathbf{g}\mathbf{r})$, where $\mathbf{g}$ is the gravitational acceleration and d is the specific weight, we obtain the necessary and sufficient conditions for stable equilibrium:

$$\frac{4}{3}\pi d = -\frac{1}{2} \sum_{m=1}^{\infty} \frac{1}{m+1} a^{2(m-1)} \psi_m \psi_{m+1}, \tag{5}$$

$$\left. \begin{aligned} &\sum_{m=1}^{\infty} a^{2(m-1)} \left[\frac{m}{m+1} \psi_{m+1}^2 + \psi_m \psi_{m+2} \right] > 0, \\ &\sum_{m=1}^{\infty} a^{2(m-1)} \left[\left(\frac{m}{m+1} \right)^2 \psi_{m+1}^2 - \psi_m \psi_{m+2} \right] > 0. \end{aligned} \right\} \tag{6}$$

To calculate the total potential energy according to Eq. (3) we reduce the expression for $\Delta^{(m)}\mathbf{H}^2(\mathbf{r})$, derived from (1) and (2), to

$$\Delta^{(m)}\mathbf{H}^2 = \sum_{l=0}^{\infty} (2l+1) P_l(\sin\theta) \sum_{l_1, l_2=1}^{\infty} r^{l_1+l_2-2-2m} \psi_{l_1} \psi_{l_2} b_{ll_1l_2}^m, \quad m = 0, 1, 2, \ldots, \tag{7}$$

where

$$b_{ll_1l_2}^m = \frac{1}{2l_1l_2} \frac{(L-l)!\,(2L+1)!\,(L-m-1)!}{(L-l-m-1)!\,L!\,(2L-2m-1)!} \begin{pmatrix} l & l_1 & l_2 \\ 0 & 0 & 0 \end{pmatrix}^2,$$
$$2L = l + l_1 + l_2,$$

$\begin{pmatrix} l & l_1 & l_2 \\ 0 & 0 & 0 \end{pmatrix}$ is the 3j Wigner symbol, identically equal to zero, when the triplet l, l_1, l_2 does not satisfy the triangle condition $|l_1 - l_2| \le l \le |l_1 + l_2|$ or when $l_1 + l_2 + l$ is an odd number. For all other cases

$$\begin{pmatrix} l & l_1 & l_2 \\ 0 & 0 & 0 \end{pmatrix} = (-1)^L \sqrt{\frac{(2L-2l_1)!\,(2L-2l_2)!\,(2L-2l)!}{(2L+1)!}}$$
$$\times \frac{L!}{(L-l_1)!\,(L-l_2)!\,(L-l)!}.$$

To derive the equation (7) the following relations are used:

$$P_{l_1}(\cos\theta) P_{l_2}(\cos\theta) = \sum_l (2l+1) \begin{pmatrix} l & l_1 & l_2 \\ 0 & 0 & 0 \end{pmatrix}^2 P_l(\cos\theta),$$

$$P_{l_1}^1(\cos\theta) P_{l_2}^1(\cos\theta) = \frac{1}{2} \sum_l (2l+1) [l_1(l_1+1) + l_2(l_2+1) - l(l+1)]$$
$$\times \begin{pmatrix} l & l_1 & l_2 \\ 0 & 0 & 0 \end{pmatrix}^2 P_l(\cos\theta).$$

Power dissipated in the sphere. To calculate the dissipated power W we use the equation (5.2) from ref. 1 in the first approximation in the skin depth δ:

$$W=\omega\delta\left\{\frac{1}{4\pi}\oint dS\mathbf{H}^2-\frac{1}{4\pi a}\int\limits_{r<a}d^3r\left(\frac{r}{a}\right)\mathbf{H}^2\right\}.$$

Using the same approach as in the preceding section, we obtain the following expansion for the case of an axially-symmetric field:

$$W=\frac{\omega\delta}{2}a^2\sum_{m=0}^{\infty}\frac{2m+3}{(m+1)(m+2)}a^{2m}\psi_{m+1}^2. \tag{8}$$

Corrections for the shape of a liquid metal drop. As follows from ref. 2, to the first order in $1/\sigma$ the shape of a drop is given by the equation

$$r=a\left(1+\frac{1}{\sigma}\sum_{l=2}^{\infty}u_l(\theta,\varphi)\right), \tag{9}$$

where u_l is determined from the equation ($l \geq 2$)

$$(1-l)(2+l)u_l=aG_l,$$

while G_l is the expansion in spherical harmonics of the surface pressure exerted by the magnetic forces p_{mag} on the sphere. The pressure p_{mag} is determined from the equation

$$p_{\text{mag}}=-\frac{1}{2}\pi\delta^2(\mathbf{j}\mathbf{j}^*),$$

where $\mathbf{j}$ is the surface current density on the sphere. The surface current density is calculated from Eq. (2.9) in ref. 1 in terms of the magnetic field $\mathbf{H}(\mathbf{r})$, as given in the absence of the sphere:

$$\mathbf{j}=\frac{1-i}{4\pi a\delta}\frac{1}{a}\int\limits_0^a dr\left(2r\frac{\partial}{\partial r}+1\right)[\mathbf{r}\mathbf{H}(\mathbf{r})].$$

In our case of axial symmetry with the magnetic field given by (1), (2), we have

$$j_\varphi=\frac{1-i}{4\pi a\delta}\sum_{l=1}^{\infty}\frac{2l+1}{l(l+1)}a^l\psi_l P_l^1(\cos\theta).$$

Expanding p_{mag} into Legendre polynomials, we obtain G_l:

$$G_l=\frac{1}{32\pi}(2l+1)P_l(\cos\theta)\sum_{l_1,l_2=1}^{\infty}\frac{(2l_1+1)(2l_2+1)}{l_1l_2(l_1+1)(l_2+1)}[l_1(l_1+1)$$
$$+l_2(l_2+1)-l(l+1)]\begin{pmatrix}l & l_1 & l_2\\ 0 & 0 & 0\end{pmatrix}^2 a^{l_1+l_2-2}\psi_{l_1}\psi_{l_2}.$$

We reduce the expressions for u_2 and u_3

$$u_2=-\frac{5}{64\pi}\sum_{m=1}^{\infty}\left\{\frac{(2m+1)(m^2+m-3)}{(2m+3)(m+1)m(2m-1)}a^{2m-1}\psi_m^2\right.$$
$$\left.+\frac{3}{2m+3}a^{2m+1}\psi_m\psi_{m+2}\right\},$$

$$u_3=-\frac{7}{32\pi}\sum_{m=1}^{\infty}\left\{\frac{3}{5}\frac{m^2+2m-5}{(2m+5)(m+1)(2m-1)}a^{2m}\psi_m\psi_{m+2}+\right.$$
$$\left.+\frac{m+2}{(2m+5)(2m+3)}a^{2m+2}\psi_m\psi_{m+3}\right\}.$$

The surface (9), for instance in the case of a "counter-current induction coil" (two rings with current phase shifted by 180°) gives the "pear-shaped" drop that is observed experimentally.

Solution of the Stefan problem

A. M. Tsybin

B. E. Vedenov All-Union Scientific Research Institute of Hydraulic Engineering, Leningrad

(Submitted January 18, 1974)
Zh. Tekh. Fiz., 44, 2441-2444 (November 1974)

It is shown that the solution of the Stefan problem can be constructed if the trajectory of the zero isotherm is known. The desired function is written as a series of harmonic functions.

Consider the following problem:

$$\frac{\partial U}{\partial \tau} = a\frac{\partial^2 U}{\partial x^2} \quad (0 < x < S(\tau)),$$
$$U(0, \tau) = f(\tau) < 0, \quad U(S(\tau), \tau) = 0, \quad S(0) = 0,$$
$$\lambda \frac{\partial U}{\partial x}(S(\tau), \tau) = A\frac{\partial S}{\partial \tau}.$$

We use the transformation introduced in ref. 1,

$$J(p, \tau) = \int_0^{S(\tau)} U(x, \tau)\,\mathrm{sh}\sqrt{p}\,x\,dx, \quad \mathrm{Re}\,p > 0. \tag{1}$$

Then, as shown there, we have

$$J(p, \tau) = \frac{aA}{\lambda\sqrt{p}} e^{ap\tau}\left[e^{-ap\tau}\,\mathrm{ch}\left(\sqrt{p}\,S(\tau)\right) - 1 + ap\int_0^{\tau} e^{-apz}\,\mathrm{ch}\left(\sqrt{p}\,S(z)\right)dz\right] + a\sqrt{p}\,e^{ap\tau}\int_0^{\tau} f(z)\,e^{-apz}dz, \tag{2}$$

where S(τ) satisfies the integral equation

$$\int_0^{\infty} \mathrm{ch}\left(\sqrt{p}\,S(z)\right)e^{-apz}dz = \frac{1}{ap} - \bar{f}(ap)\frac{\lambda}{Aa}, \tag{3}$$

where

$$\bar{f}(ap) = \int_0^{\infty} f(\tau)\,e^{-ap\tau}d\tau.$$

We will seek U(x, τ) in the form

$$U(x, \tau) = \sum_{k=1}^{\infty} a_k(\tau)\sin\frac{k\pi x}{S(\tau)}. \tag{4}$$

Substituting (4) into (1), we obtain

$$\sum_{k=1}^{\infty} \frac{k a_k(\tau)(-1)^{k+1}}{p + \frac{k^2\pi^2}{S^2(\tau)}} = \frac{J(p, \tau)\,S(\tau)}{\pi\,\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)}. \tag{5}$$

The left part of this expression is regular everywhere except for poles on the negative semiaxis:

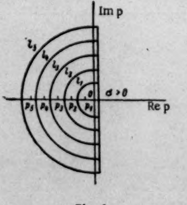

Fig. 1

$$p_k = -\frac{k^2\pi^2}{S^2(\tau)}, \text{ where } k = 1, 2, \ldots. \tag{6}$$

We integrate both sides of (5) successively over the contours $l_1, l_2, \ldots, l_k, \ldots$ (see Fig. 1). The contour l_k consists of the vertical line $\sigma > 0$, $\mathrm{Im}\,\sigma = 0$, a semicircle radius $[\pi^2/2S^2(\tau)](2k^2+2k+1)$, whose center is the coordinate origin, and the two horizontal lines $y = [\pm\pi^2/2S^2(\tau)](2k^2+2k+1)$. Then,

$$\left.\begin{aligned} a_1(\tau) &= \frac{S(\tau)}{2\pi^2 i}\int_{l_1}\frac{J(p, \tau)\,dp}{\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)}, \\ a_k(\tau) &= \frac{(-1)^{k+1}S(\tau)}{\pi k}\left[\frac{1}{2\pi i}\int_{l_k}\frac{J(p, \tau)\,dp}{\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)} - \frac{1}{2\pi i}\int_{l_{k-1}}\frac{J(p, \tau)\,dp}{\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)}\right] \quad (k = 2, 3, \ldots). \end{aligned}\right\} \tag{7}$$

From an analysis of the integrand

$$\frac{J(p, \tau)}{\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)} = \frac{aA\,\mathrm{ch}\left(\sqrt{p}\,S(\tau)\right)}{\lambda\sqrt{p}\,\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)} - \frac{aAe^{ap\tau}}{\lambda\sqrt{p}\,\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)} + \frac{a^2A}{\lambda}\frac{\sqrt{p}\,e^{ap\tau}\int_0^{\tau}e^{-apz}\,\mathrm{ch}\left(\sqrt{p}\,S(z)\right)dz}{\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)} + \frac{a\sqrt{p}\,e^{ap\tau}\int_0^{\tau}f(z)\,e^{-apz}dz}{\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)} \tag{8}$$

it is clear that the first two terms in (8) are regular everywhere except for the poles p = 0 and p = p_k (6). Therefore we have

$$a_k(\tau) = \frac{2(-1)^{k+1}aA}{\pi k\lambda}\left[1 + (-1)^{k+1}e^{-a\frac{k^2\pi^2}{S^2(\tau)}\tau}\right] + \frac{(-1)^{k+1}aS(\tau)}{\pi k}\left[\frac{1}{2\pi i}\int_{l_k}V(p, \tau)\,dp - \frac{1}{2\pi i}\int_{l_{k-1}}V(p, \tau)\,dp\right] \quad (k = 1, 2, \ldots), \tag{9}$$

where

$$V(p, \tau) = \frac{e^{ap\tau}\sqrt{p}}{\mathrm{sh}\left(\sqrt{p}\,S(\tau)\right)}\left[\frac{aA}{\lambda}\int_0^{\tau}e^{-apz}\,\mathrm{ch}\left(\sqrt{p}\,S(z)\right)dz + \int_0^{\tau}f(z)\,e^{-apz}dz\right]. \tag{10}$$

Thus, if S(τ) is determined from integral equation (3) and the coefficient $a_k(\tau)$ is computed from (9), we can construct a solution for the initial problem and write it in form of (4).

We will show that for $f(\tau) = N = \text{const} < 0$ the resultant solution becomes the familiar self-similar solution

$$W = N + \frac{A\beta}{2\lambda}\sqrt{\pi a}\,e^{\beta^2/4a}\,\mathrm{erf}\left(\frac{x}{2\sqrt{a\tau}}\right), \tag{11}$$

where β is determined from the solution of the transcendental equation

$$-\frac{2N\lambda}{A\sqrt{\pi a}} = e^{\beta^2/4a}\,\mathrm{erf}\left(\frac{\beta}{2\sqrt{a}}\right)\beta. \tag{12}$$

We have $S(\tau) = \beta\sqrt{\tau}$, in this case, where β [as follows from (3)] is given by the equation

$$\int_0^{\infty}\mathrm{ch}\left(\beta\sqrt{t}\right)e^{-at}dt = \frac{1}{a}\left(1 - \frac{\lambda N}{aA}\right). \tag{13}$$

Making the change of variable t = z^2 and using ref. 2, we obtain

$$\int_0^\infty \operatorname{ch}(\beta\sqrt{t})\, e^{-at}dt = 2\int_0^\infty \operatorname{ch}(\beta z)\, e^{-az^2}z\,dz = \frac{\beta}{2a}\sqrt{\frac{\pi}{a}}\, e^{\beta^2/4a}\operatorname{erf}\left(\frac{\beta}{2\sqrt{a}}\right) + \frac{1}{a},$$

i.e., β is exactly the same as in the self-similar solution. In this case the integrals in (9) can be readily evaluated and

$$a_k(\tau) = a_k = \frac{2Aa}{\lambda\pi k}\left[(-1)^{k+1} + e^{-a\frac{k^2\pi^2}{\beta^2}} + a e^{-a\frac{k^2\pi^2}{\beta^2}} \int_0^{\frac{k^2\pi^2}{\beta^2}} \cos\beta\sqrt{t}\, e^{at}dt\right] + \frac{2N}{\pi k}\left(1 - e^{-a\frac{k^2\pi^2}{\beta^2}}\right) = \text{const} \quad (k = 1, 2, 3, \ldots). \tag{14}$$

Again making the substitution t = z^2 and performing the necessary calculations, we find

$$a_k = \frac{2Aa\beta}{\lambda\pi k} e^{-a\frac{k^2\pi^2}{\beta^2}} \int_0^{\frac{k\pi}{\beta}} e^{az^2} \sin\beta z\,dz + \frac{2N}{\pi k}\left(1 - e^{-a\frac{k^2\pi^2}{\beta^2}}\right) \quad (k = 1, 2, 3, \ldots). \tag{15}$$

Expanding sin βz in a power series, we have

$$a_k = \frac{A\beta^2}{\lambda\pi k}\left(1 - e^{-a\frac{k^2\pi^2}{\beta^2}}\right)\sum_{i=0}^\infty \frac{\beta^{2i}\, i!}{a^i(2i+1)!} + \frac{2N}{\pi k}\left(1 - e^{-a\frac{k^2\pi^2}{\beta^2}}\right)$$

$$+ \frac{A\beta^2}{\lambda\pi k}\sum_{i=1}^\infty \frac{\left(\frac{a\pi^2}{\beta^2}\right)^i k^{2i}(-1)^i}{i!}\sum_{j=1}^\infty \frac{\left(\frac{\beta^2}{a}\right)^j j!}{(2j+1)!} \quad (k = 1, 2, 3, \ldots).$$

It can be shown that

$$\sqrt{\pi a}\, e^{\frac{\beta^2}{4a}} \operatorname{erf}\left(\frac{\beta}{2\sqrt{a}}\right) = \sum_{i=0}^\infty \frac{\beta^{2i+1}\, i!}{a^i(2i+1)!}. \tag{16}$$

This result is understandable if we represent erf as an integral and then integrate successively by parts, setting U = e^{-z^2} each time. Then, using (12), we obtain

$$a_k = \frac{A\beta^2}{\lambda\pi k}\sum_{i=1}^\infty \frac{(-1)^i k^{2i}\pi^{2i}}{i!}\left(\frac{a}{\beta^2}\right)^i \sum_{j=1}^\infty \frac{\left(\frac{\beta^2}{a}\right)^j j!}{(2j+1)!} \quad (k = 1, 2, \ldots). \tag{17}$$

On the other hand, if

$$b_k = \int_0^{\frac{x}{\beta\sqrt{\tau}}} W \sin\frac{k\pi x}{\beta\sqrt{\tau}}\, dx, \tag{18}$$

where W is given by (11), after a number of operations we can write

$$b_k = \frac{A\beta^2}{2\lambda\pi k} e^{\frac{\beta^2}{4a}} \sum_{i=1}^\infty \frac{(-1)^i k^{2i}\pi^{2i}}{(2i)!}\int_0^1 e^{-\frac{\beta^2 z^2}{4a}} z^{2i}dz \quad (k = 1, 2, \ldots). \tag{19}$$

Reasoning in exactly the same way as in deriving (16), we find that $b_k = a_k$ (k = 1, 2, ...), i.e., solution (9) does indeed become the familiar self-similar solution for $f(\tau)$ = N = const < 0.

Stigmatic sectored magnetic analyzer for a multiple-beam mass spectrometer

G. Kh. Chedzhemov

I. Franko State University, L'vov

Zh. Tekh. Fiz., 44, 2444-2446 (November 1974)

A method of design is presented for a stigmatic analyzer for a multiple-beam mass spectrometer with a homogeneous sectored magnetic field and straight magnet edges. Relations that determine the variable parameters are derived. Attention is drawn to mass discrimination in the absence of stigmatic focusing.

The simultaneous focusing of ion beams in the horizontal and vertical plane makes it possible to increase the optical power and sensitivity of mass spectrometers. Stigmatic focusing in single-beam mass spectrometers has been considered in various papers,[1-6] but no attention has been paid to the problem of stigmatic focusing in multiple-beam mass spectrometers. It is desirable to carry out measurements of isotopic abundance in multiple-beam mass spectrometers, since the comparison of ion currents under stable conditions yields high accuracy. Conditions of stigmatic focusing in single beam mass spectrometers are well understood, but not directly applicable to multiple-beam devices. The introduction of two or more collectors with focusing only in the horizontal plane leads to different optical powers of the collectors, causes mass discrimination and possible errors in isotopic abundance ratios. This fact has not received attention until now. In this paper we describe the design of a sectored analyzer of a multiple-beam mass spectrometer with homogeneous magnetic field and straight edges, permitting the simultaneous stigmatic focusing of ion beams with different masses without beam scanning.

We express all distances in absolute units and label all parameters that depend on mass with an appropriate superscript i (i = 1, i = 2, etc. according to collector number), thus

$$l_{2H}^{i}=r^{i}\cos\varepsilon_2^{i}\,\frac{\sin\varphi^{i}+\dfrac{l_1\cos(\varphi^{i}-\varepsilon_1)}{r^{i}\cos\varepsilon_1}}{\dfrac{l_1\sin(\varphi^{i}-\varepsilon_1-\varepsilon_2^{i})}{r^{i}\cos\varepsilon_1}-\cos(\varphi^{i}-\varepsilon_2^{i})},\qquad(1)$$

$$l_{2V}^{i}=r^{i}\,\frac{\varphi^{i}+\dfrac{l_1}{r^{i}}(1-\varphi^{i}\,\mathrm{tg}\,\varepsilon_1)}{\dfrac{l_1}{r^{i}}[\mathrm{tg}\,\varepsilon_1+(1-\varphi^{i}\,\mathrm{tg}\,\varepsilon_1)\,\mathrm{tg}\,\varepsilon_2^{i}]-(1-\varphi^{i}\,\mathrm{tg}\,\varepsilon_2^{i})},\qquad(2)$$

where l^{i}_{2H} and l^{i}_{2V} are the distances between the point of emergence from the field and the image in the horizontal and vertical plane, r^{i} and φ^{i} are the radii and deflection angles of ion trajectories in the magnetic field, ε_1 and ε_2^{i} are the entry and exit angles of the beams, l_1 is the distance from the source to the point of entry into the magnetic field. Denoting by r'' the radius corresponding to ions of mass m'', all other radii are determined by

$$r^{i}=r''\sqrt{\frac{m^{i}}{m''}},\qquad(3)$$

as the accelerating voltage and magnetic field are common to all ions. If φ'' = 90°, all other angles φ^{i} can be easily determined from the relation

$$\varphi^{i}=90^{\circ}+\varepsilon_2^{i}-\varepsilon_2''.\qquad(4)$$

The angles ε_2^{i} can be found from

$$\varepsilon_2^{i}=\arcsin\frac{[(r''-r^{i})+r''\,\mathrm{tg}\,\varepsilon_2'']\cos\varepsilon_2''}{r^{i}}.\qquad(5)$$

Three independent variables (l_1, ε_1, ε''_2) remain in equations (1) and (2); the choice of these, subject to the condition

$$l_{2H}^{i}=l_{2V}^{i},\qquad(6)$$

TABLE 1. Parameters of Sectored Magnetic Analyzers

continued

Analyzer No.	$\sum_{i='}^{i='''}(l^{i}_{2H}-l^{i}_{2V})$, mm	Dispersion coefficient	Magnification		Resolution with S_1 = 0.2 mm	Percentage ion efficiency
			plane H	plane V		
1	29.6	5.144*r*	2.30	0.81	220	55
2	11.7	4.581*r*	1.72	0.69	260	45
3	6.0	3.846*r*	1.05	0.54	330	31
4	104.2	2.549*r*	0.68	2.51	380	51

determines the required stigmatic analyzer of the multiple-beam mass spectrometer.

In particular, with $\varphi = 90°$ and $\varepsilon_2 = -45°$ the condition of stigmatic focusing simplifies as $\varepsilon'_2 = \varepsilon''_2 = \varepsilon'''_2 = \varepsilon$ and $\varphi' = \varphi'' = \varphi''' = \varphi$ and the beams entering the device are parallel. The equality of the angles ε_2^i and φ^i and the parallel entry of the beams is maintained for arbitrary ε_1 provided the straight line representing the continuation of the exit edge of the magnet passes through the point at which the ion beam enters the analyzer. The resolution is low in this case even with $\varphi = 180°$.

The choice of the independent variable parameters is accomplished with the aid of a MIR-1 computer by minimization of the sum of differences $\sum_{i='}^{i='''} (l^i_{2H} - l^i_{2V})$. Data pertaining to several versions of analyzers with r" = 180 mm and $\varphi'' = 90°$ computed for masses m' = 36, m" = 38, m''' = 40 are given in Table 1.

A comparative estimate of resolution (see refs. 2 and 5) and ion efficiency makes it possible to select analyzer No. 2 (see Table 1). The vertical crossovers of the ion beams in this analyzer are very close to the collector slits, which are located in accordance with horizontal focusing requirements.

Computations on a series of analyzers with minor variations of the independent variables have shown that tolerances in the manufacture of the analyzers are determined mainly by the condition of horizontal focusing, the latter being six times more stringent than the conditions of vertical focusing. In addition, if the linear dimensions are maintained to tenths of a millimeter, the angles should be satisfied to an accuracy of one minute.

The author thanks B. I. Smirnov for computations carried out on the MIR-1 computer.

Rotation of Poynting vector for ultralow-frequency ion waves in an inhomogeneous plasma

Ya. L. Al'pert and R. N. Kaufman

Institute of Terrestrial Magnetism, Ionosphere, and Radiowave Propagation, Academy of Sciences of the USSR

(Submitted October 23, 1973; resubmitted March 15, 1974)
Zh. Tekh. Fiz., 44, 2449-2453 (December 1974)

A theoretical study is made of the region in which the Poynting vector S of ultralow-frequency ion waves incident upon the planar boundary (xy plane) of a magnetoactive inhomogeneous plasma turns is rotated in the direction of the static magnetic field H_0. The frequency of the investigated waves varies in the range $0 < \omega \lesssim \omega_L$ (ω_L is the lower hybrid frequency). The solution is found in the quasilongitudinal approximation. The Poynting vector S is shown to turn rapidly at the plasma surface, the angle ψ between S and H_0 reaching the limiting value ψ_∞ ($z \to \infty$) at distances (z) of 20-30 km from the boundary. The dependence of ψ_∞ on frequency is investigated allowing for the collision frequency ν.

INTRODUCTION

In a previous paper[1] we have investigated the rotation of the Poynting vector in low-frequency electron (lf) waves ($\omega_L \ll \omega \lessdot \omega_H$ is the lower hybrid frequency, ω_H is the electron gyrofrequency, ω is the wave frequency) normally incident on the planar boundary of a one-dimensionally inhomogeneous magnetoactive plasma. The problem is solved in ref. 1 for two models of the inhomogeneous plasma [see (10) below] in the quasilongitudinal approximation ignoring the effect of ions, as is permissible for lf waves.

Allowing for the effect of ions greatly complicates the problem, especially in the case of superlow frequencies (slf): $\Omega_H < \omega \sim \omega_L$ (Ω_H is the gyrofrequency). Mathematically this is connected with the complexity of the expression for the refractive index n and of the corresponding differential equations, and physically with the fact that slf waves can propagate at any angle to the static magnetic field H_0. They are coupled by the external static magnetic field only under certain conditions. The solution of this problem for slf waves is undoubtedly of great interest, but the attendant mathematical difficulties have still to be overcome. However, in an analysis of the problem it is found that a rigorous solution allowing for the effect of the ions can be obtained for ultralow-frequency (ulf) waves (corresponding to the frequency range $0 < \omega \sim \Omega_H$) subject to certain conditions that are frequently met in practice, particularly in the near-earth plasma. In this work we present a solution of this problem. The equations obtained for n and the differential equations and their solutions are analogous to those obtained previously[1] for lf electron waves; accordingly, we omit here some of the mathematical details of the computations and refer the reader to ref. 1.

1. INITIAL EQUATIONS. FORMULATION OF THE PROBLEM AND ITS SOLUTION

We consider a magnetoactive plasma consisting of electrons and a single ion species which is inhomogeneous with respect to the coordinate z and upon the planar boundary (xy plane) of which there is normally incident a plane wave of frequency ω in the range

$$0 < \omega \ll \omega_L \simeq \sqrt{\omega_H \Omega_H}, \tag{1}$$

the time dependence being of the form $\exp\{i\omega t\}$. The vector external magnetic field H_0 lies in the yx plane and the vector $-H_0$ makes an acute angle θ with the wave vector of the incident wave $\mathbf{k}_0$, which is parallel to the positive z direction.

In the frequency range defined by (1) two waves can exist in the plasma. One of them is the ordinary wave, which is cut off at a frequency $\omega \simeq \Omega_H$; the other is the extraordinary wave. The latter propagates with small damping even when $\omega > \Omega_H$, and is cut off at frequency $\omega \simeq \omega_H$.

Let $\nu = \nu_{ei}$ be the frequency of electron–ion collisions; $\gamma_0 = m/M$ is the ratio of electron mass to ion mass; $\Omega_0^2 = (4\pi e^2/M)N(z)$ is the square of the ion plasma frequency; N(z) is the electron density. Then, (1) is satisfied and, in addition, if everywhere in the plasma

$$\alpha_0 = \omega\nu\gamma_0 \ll \Omega_0^2(z), \quad \Omega_H^2 \ll \Omega_0^2(z), \tag{2}$$

we obtain from the general equation for the refractive index (see ref. 2) the following comparatively simple expression for n^2:

$$n_\pm^2 = 1 + \frac{2\Omega_0^2}{2\Omega_H^2\cos^2\theta + \Omega_H^2\sin^2\theta + 2i\alpha_0 \pm \sqrt{\Omega_H^4\sin^4\theta + 4\omega^2\Omega_H^2\cos^2\theta}}, \tag{3}$$

where the plus and minus signs pertain respectively to the extraordinary and ordinary waves. It is readily seen that expression (3) is similar in structure to the well-known Appleton–Hartree equation for the refractive index of electron waves when the effect of the ions is ignored (see refs. 3 and 4). It is reasonable therefore to expect that the subsequent simplification and solution of the present problem in the frequency range (1) should lead mathematically to equations similar to those obtained previously[1] for lf electron waves at $\omega \gg \omega_L$.

Considering Eq. (3) in the quasilongitudinal approximation, the condition for which in the present case has the form

$$\left|\frac{\sin^2\theta}{\cos\theta}\right| \ll 2\frac{\omega}{\Omega_H}, \tag{4}$$

we find that

$$n_\pm^2 = \frac{\Omega_0^2}{\Omega_H\cos\theta(\Omega_H\cos\theta \pm \omega) + i\alpha_0}. \tag{5}$$

Equation (5) is similar in structure to the equation for n^2 in the case of lf electron waves [see Eq. (3) in ref. 1].

We note that the second of conditions (2) enables us to drop the unity from (3), which has in fact been done in Eq. (5).

The components of the electric field of the wave are denoted by E_x, E_y, E_z. Utilizing inequality (4), the expressions for the components of the tensor dielectric constant, and Maxwell's equations (see refs. 2-5), we obtain the following simple equations for the polarization of the electric field:

$$\rho_\pm = \frac{E_y}{E_x} = \pm i, \tag{6}$$

$$\frac{E_z}{E_x} = q_\pm \operatorname{tg}\theta, \tag{7}$$

where

$$q_\pm = -\frac{\Omega_H\left[a_0\omega + i\gamma_0\omega^2 + \rho_\pm\Omega_H\cos\theta\left(\omega^2 - \Omega_H^2 - ia_0\right)\right]}{\cos\theta\left[\left(\Omega_H^2 + ia_0\right)^2 - \omega^2\omega_H^2\right]}. \tag{8}$$

For the present case of normal incidence, the Maxwell equations yield two equations of the second order in E_x and E_y, the coefficients of which are expressed through the refractive index and the polarization ρ of the two normal waves in the plasma (Sec. 18.5 of ref. 4). For n^2 and ρ described by Eqs. (5) and (6) we eventually obtain the following wave equation:

$$\frac{d^2(E_x \pm iE_y)}{dz^2} + \frac{\omega^2}{c^2} n_\mp^2 (E_x \pm iE_y) = 0. \tag{9}$$

This equation reduces to a Whittaker equation if ν = const and if we use the height dependences of the electron density utilized in ref. 1 augmented by the addition of certain constant terms to secure fulfillment of the second of inequalities (2), i.e., if

$$\left.\begin{aligned} N(z) &= N_0 + N_1(1 + be^{-\alpha z})(1 - e^{-\alpha z}) \text{ for model ,} \\ N(z) &= N_0 + N_1(1 - e^{-\alpha z})^2 \text{ for model 2.} \end{aligned}\right\} \tag{10}$$

Denoting by $n_{\infty,\pm}$ the value of the refractive index at $z \to \infty$ (it corresponds to the value $N = N_\infty = N_0 + N_1$), we obtain the solution of Eq. (9) in the form

$$E_x \mp iE_y = \exp\left\{i\frac{\omega}{c}(n_{\infty,\pm})z\right\} f(z), \tag{11}$$

where

$$f(z) = \exp\{-a_\pm e^{-\alpha z}\}\,\Phi(\beta_\pm, \gamma_\pm, 2a_\pm e^{-\alpha z}). \tag{12}$$

Here $\Phi(\beta_\pm, \gamma_\pm, 2a_\pm e^{-\alpha z})$ is the degenerate hypergeometric function[6] with argument $2a_\pm e^{-\alpha z}$ and parameters $\beta_\pm$, $\gamma_\pm$, equal to

$$\beta_\pm = \frac{1}{2} - P_\pm - S_\pm, \quad \gamma_\pm = 1 - 2P_\pm,$$

where for model 1 we have

$$a_\pm = \alpha^{-1}\frac{\omega}{c}\sqrt{b}\,(n_\pm)_{N=N_1}; \quad P_\pm = i\alpha^{-1}\frac{\omega}{c} n_{\infty,\pm}; \quad S_\pm = \frac{1}{2}\frac{b-1}{b}a_\pm,$$

and for model 2

$$a_\pm = S_\pm = i\alpha^{-1}\frac{\omega}{c}(n_\pm)_{N=N_1}; \quad P_\pm = i\alpha^{-1}\frac{\omega}{c} n_{\infty,\pm}.$$

[Here $(n_\pm)_{N=N_1}$ is the value of the refractive index $n_\pm$ at $N = N_1$.]

Subsequent calculations similar to those made previously[1] lead to the following expression for the angle $\psi_\pm(z)$ between the wave vector $\mathbf{k}_0$ and the time-averaged Poynting vector $\mathbf{S}_\pm$:

$$\operatorname{tg}\psi_\pm(z) = -\frac{\operatorname{tg}\theta}{2}\,|q_\pm|\,\frac{|F(z)|}{\operatorname{Re}F(z)}, \tag{13}$$

where

$$F(z) = n_{\infty,\pm} - i\frac{c}{\omega}\frac{d}{dz}\ln f(z),$$

and $q_\pm$ is defined by Eq. (8). We note that in the limit $z \to \infty$ and $\nu = 0$, we have

$$\operatorname{tg}\psi_{\infty,\pm} \simeq -\frac{\operatorname{tg}\theta}{2}. \tag{14}$$

Expression (14) coincides with the expression for $\tan\psi$ determined from the general equation for $\tan\psi$ in a homogeneous medium:

$$\operatorname{tg}\psi = \frac{\sin\theta}{n}\,\frac{\partial n}{\partial(\cos\theta)}, \tag{15}$$

obtained in ref. 7 for $\nu = 0$. In the calculation of $\tan\psi$ from expression (15) it is necessary here when taking the derivative $\partial n/\partial(\cos\theta)$ to utilize Eq. (3) for the refractive index and then make recourse to the quasilongitudinal approximation.

It can be seen from (14) that in the quasilongitudinal approximation in a collisionless homogeneous plasma, the angles $\psi_{\infty,\pm}$ for both ulf waves coincide and do not depend on frequency. In the following section it will be shown how these angles for the two waves vary with frequency when allowance is made for the frequency of collisions ($\nu \neq 0$). The variation of the angles $\psi_\pm(z)$ with height z is also found.

2. RESULTS OF THE CALCULATIONS

In order to calculate the variation with height of the angle $\psi_\pm(z)$ between the Poynting vector $\mathbf{S}_\pm$ and the z axis through Eq. (3), the values of the degenerate hypergeometric function Φ appearing in the expression for $f(z)$ [see Eq. (12)] are computed on a BÉSM-6 high-speed computer as the sums of the corresponding series.[6] The numerical calculations are performed for model 2 for $N_1 = 10^4$ cm^{-3}, $N_0 = 10$ cm^{-3}, $\alpha = 0.03$ km^{-1}. The values of the remaining parameters are as follows: $\theta = 15°$; ion gyrofrequency $\Omega_H = 150$ Hz; frequency of collisions $\nu = 10^6$ sec^{-1}. For the ordinary wave the function $\psi_\pm(z)$ is calculated for ratios $\omega/\Omega_H = 0.5$, 0.73, 0.91, and 1.2. For the ordinary wave, as it cuts off at a frequency $\omega \simeq \Omega_H$, the function $\psi_\pm(z)$ is calculated only for the values $\omega/\Omega_H = 0.5$, 0.73, and 0.91. Conditions (1), (2), and (4) are well satisfied everywhere in the calculations.

The angles $\psi_{\infty,\pm}$ for $\nu \neq 0$ are calculated through the

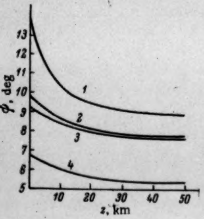

Fig. 1. Angle ψ between time-averaged Poynting vector S and z axis as function of z. 1,2) Ordinary wave (-), $\psi_{\infty -}$; 3,4) extraordinary wave (+); $\psi_{\infty +}$, 1,4) $\omega/\Omega_H = 0.92$; 2,3) 0.5.

equation

$$\operatorname{tg}\psi_{\infty,\pm} = -\frac{\operatorname{tg}\theta}{2}|q_\pm|\frac{|n_{\infty,\pm}|}{\operatorname{Re}(n_{\infty,\pm})}. \tag{16}$$

For both waves it turns out that $\psi(z)$ is at its greatest for z = 0 (Fig. 1) and is around (1.5-5)° greater than the corresponding values of ψ_∞ in the investigated frequency range. The function $\psi(z)$ decreases monotonically for increasing z, and is close to ψ_∞ at $z \approx 20$-30 km. This behavior of $\psi(z)$ is probably due to the fact that we have assumed a nonzero electron density at the boundary of the inhomogeneous medium (z = 0) in order to comply with conditions (2). For this reason it is not possible to trace, as was done in ref. 1 for lf electron waves, the way the angle $\psi(z)$ reaches the limiting value ψ_∞ by gradually increasing from the incident-wave value of $\psi = 0$, and the vector S gradually turns towards the vector $-H_0$. The maximum of $\psi(z)$ at z = 0 is probably due, as in ref. 1 for lf waves, to the effect of the quasilongitudinal approximation. In actual fact the direction of the Poynting vector of ulf waves very rapidly reaches the limiting value ψ_∞. In this range of frequencies the turning of the Poynting vector occurs in a narrower region than for lf waves, i.e., than at frequencies $\omega_L \ll \omega \lessapprox \omega_H$.

The dependence of the limiting values $\psi_{\infty,\pm}$ on frequency ω is calculated for both waves using (16); the results are presented in Fig. 2. It can be seen that as the wave frequency approaches the ion gyrofrequency Ω_H the ordinary-wave Poynting vector S moves closer and closer to the direction of the vector $-H_0$. For the extraordinary wave the angle ψ_∞ has a minimum near $\omega \simeq \Omega_H$ and then increases with increasing frequency to a limiting value: $\tan\psi_\infty \simeq -\tan\theta/2$ in a collisionless plasma ($\nu = 0$). The features of the function $\psi_\infty(\omega)$ manifest in Fig. 2 are in fact due to the effect of ν. For $\nu = 0$, $\tan\psi_\infty \approx -\tan\theta/2$ for both waves and is quite independent of frequency. The use of the quasilongitudinal approximation prevents us from tracing how ψ_∞ varies with decreasing frequency,

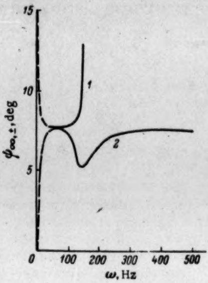

Fig. 2. Limiting value of angle ψ_∞ as function of angular frequency ω for ordinary (1) and extraordinary (2) waves.

when $\omega \to 0$. It was shown in a previous paper[8] that as $\omega \to 0$ for arbitrary θ and $\nu = 0$, then $\tan\psi_{\infty,+} \to 0$ and $\tan\psi_{\infty,-} \to -\tan\theta$ for the extraordinary and ordinary waves respectively.[1)] Approximation of the curves of $\psi_\infty(\omega)$ shown in Fig. 2 to these limiting values (the dashed curves) shows that the direction of the Poynting vector behaves in a more complex manner at frequencies $0 \lessapprox \omega \lessapprox \omega_L$ than for lf waves in the range $\omega_L \ll \omega \lessapprox \omega_H$, where $\psi_{\infty,+}$ increases monotonically with frequency. It should be noted that the approximation of $\psi_\infty(\omega)$ utilized in Fig. 2 for $\nu = 0$ is justified by the fact that the dependence of ψ_∞ on ν is determined by the parameter $\alpha_0 = \gamma_0\nu\omega$ [see Eq. (3), for example], while $\alpha_0 \to 0$ as $\omega \to 0$ and the effect of ν vanishes.

In conclusion we should like to thank G. N. Borisov, G. D. Komlev, and T. A. Londin for the numerical calculations.

[1)] The negative sign of the tan ψ for $\nu = 0$ means that the vector S lies between[8] the vectors $\mathbf{k}_0$ and $-\mathbf{H}_0$.

Anomalous resistivity of a transverse plasma current at electron-cyclotron harmonics

V. I. Aref'ev and A. A. Chernov

Moscow Physicotechnical Institute

(Submitted July 26, 1973; resubmitted November 12, 1973)
Zh. Tekh. Fiz., 44, 2454-2466 (December 1974)

Microscopic instabilities of the transverse current at electron-cyclotron harmonics (Bernstein modes) are investigated in a plasma with hot ions $T_i > T_e$. It is shown that the main problem connected with instabilities at cyclotron harmonics, which make a large contribution to the anomalous resistivity of a plasma, for example in the leading edge of a shock wave, is to explain the nonlinear mechanism that saturates the oscillation energy. For the Bernstein modes a nonlinearity is associated with the electrons. Nonlinear damping is determined from the linear theory by using a collision integral that takes account of the similarity between the usual binary collisions and the collective scattering of electrons by microscopic turbulence. The effective electron-scattering frequencies are found from the stabilization condition for different spectra. It is shown that the collective friction force produced by the instabilities does not always stabilize them; for example, stabilization does not occur for current velocities that significantly exceed the ion thermal velocity. In this case a broad spectrum of current-dissipative instabilities develops, and the collective friction force favors the development of cyclotron instabilities. Some nonlinear mechanisms that stabilize the current-dissipative instabilities are investigated. Typical examples are the development of vortical instabilities in an electron gas and the appearance of anomalous viscosity.

In connection with anomalous resistivity in the leading edge of a collisionless shock wave,[1] a recent discussion has arisen in regard to instabilities of transverse plasma currents at electron-cyclotron harmonics[2,3] (Bernstein modes); these modes have wave vectors **k** that are essentially perpendicular to the magnetic field and frequencies that are multiples of the electron-cyclotron frequency $\sim n\omega_{He}$, n = 1, 2, 3, ... These instabilities can develop in the leading edge of a shock wave for a fairly large electron current velocity $u \gg (T_e/M)^{1/2}$ and the growth rates exceed the hybrid frequency $\omega_{e,i} = (\omega_{Hi}\,\omega_{He})^{1/2}$.

In contrast to the ion-acoustic instability, which has a comparatively low current-excitation threshold[4] and which can be excited in a plasma with hot electrons $T_e > T_i$, the instability at the cyclotron harmonics can be excited in a plasma with hot ions $T_i > T_e$. The main problem connected with instabilities at cyclotron harmonics, as is noted in ref. 2, is to explain the nonlinear mechanism that restricts the growth of the energy. Nonlinear electron effects can fill this role for the Bernstein modes.[2,3] This situation has also been examined in ref. 5 in connection with the electron-acoustic instability in a plasma with hot ions, which can be regarded as an instability at the zero cyclotron harmonic.

In the present paper, as an extension of refs. 2 and 3, we use linear theory to examine new current-dissipative instabilities at the electron-cyclotron harmonics; these have a comparatively low excitation threshold and high growth rate, and it will be shown that the excitation of these instabilities, which make a large contribution to the anomalous resistivity of a plasma, is related to the drift current and to collisional processes, for example binary (Coulomb) collisions, or to collective scattering of particles by fluctuations. Stabilization of the instability through the collective friction force between the electrons and ions is then analyzed in a self-consistent nonlinear theory. It will be shown that collisional process and the scattering of particles by the waves, which is accounted for by means of the collective friction force R_f, does not always lead to stabilization of current-dissipative instabilities. This is the case because the instabilities are explosive and, as is noted in refs. 2 and 3, are negative-energy waves. Therefore, a nonlinear theory for such instabilities based on the method of successive approximations in the small parameters—the ratio of the growth rate γ_k to the frequency ω_k, $\gamma_k/\omega_k < 1$—is an incorrect formulation of the problem. An approach which takes account of the similarity between the binary collisions and the collective scattering of particles by random oscillations is necessary. This approach to the nonlinear theory of the explosive instability is proposed in refs. 2 and 3.

In contrast to ref. 3, where the approach to the nonlinear saturation of the instability exploits the similarity between binary collisions and particle scattering by the oscillations in an unstable plasma with a constant effective collision frequency ν_f, in the present paper we use a collision integral from the quasilinear theory[4] to describe the dynamics of instabilities in a weakly turbulent plasma; the effective collision frequency ν_f is then not a constant, but varies during the relaxation of the instability.

1. FORMULATION OF THE PROBLEM AND SELECTION OF THE COLLISION INTEGRAL

The stability of a transverse plasma current will be considered in the same formulation as in refs. 2, 3, 5, and 6. We treat an unbounded homogeneous plasma in quasistationary electric $\mathbf{E}_0$ and magnetic $\mathbf{H}_0$ fields with a drift current

$$\mathbf{j} = -en_e\mathbf{u} = -en_e\frac{c}{H_0^2}[\mathbf{E}_0, \mathbf{H}_0], \tag{1}$$

where **u** is the electron current velocity. We assume throughout that the external electric field is in the direction of the y axis, the magnetic field is along the z axis, and the current velocity is along the x axis.

Two types of elastic scattering of electrons will be taken into account in considering collision processes: binary (Coulomb) collisions, which can be allowed for by employing the Landau collision integral, or in simplified form by analogy with ref. 7, and collective collisions of electrons which appear in an unstable plasma. It is noted in ref. 3 that both processes can be considered by using the same collision integral and introducing the effective collision frequency ν_f, which is assumed to be constant in ref. 3.

Actually, the value of ν_f can vary during the instability relaxation process. This effect can be taken into account in the self-consistent quasilinear theory.[4] A mode of this theory will be used in which the oscillation energy is near saturation. As noted in refs. 2 and 3, the basic process restricting the amplitudes of unstable oscillations is the nonlinear damping of oscillations by electrons. In this case the momentum lost by one particle species due to Cerenkov radiation produced by the oscillations is completely transferred to the other particle species by nonlinear processes, and the linear growth rate γ_k is equal to the nonlinear damping rate γ_{nonl} (see ref. 6 for example). It should be noted that one of the possible nonlinear processes responsible for stabilization of the explosive instability can be a change in the wave dispersion.[6]

Thus, we consider a mechanism for the stabilization of an explosive instability in the quasilinear theory, which takes account of the self-consistent anomalous resistivity. The kinetic equation that describes particle scattering by the oscillations is

$$\frac{\partial f_\alpha}{\partial t}+\mathbf{v}\frac{\partial f_\alpha}{\partial \mathbf{r}}+\frac{e_\alpha}{m_\alpha}\left(\mathbf{E}+\frac{1}{c}[\mathbf{vH}]\right)\frac{\partial f_\alpha}{\partial \mathbf{v}}=\mathrm{St}_{\alpha f}, \tag{2}$$

where $\mathrm{St}_{\alpha f}$ is the collision term, which, according to ref. 4, has the following more general form:

$$\left.\begin{aligned}\mathrm{St}_{\alpha f}&=\frac{\partial}{\partial v_i}\sum_k D_{ij}(\mathbf{k},W_k)\frac{\partial f_\alpha}{\partial v_j},\\ D_{ij}&=\frac{k_ik_j|\varphi_k|^2e_\alpha^2}{m_\alpha^2}\delta(\omega_k-\mathbf{kv}).\end{aligned}\right\} \tag{3}$$

Here, we only consider scattering by electrostatic oscillations. It can be seen from (3) that the diffusion coefficient D_{ij} depends both on the shape of the spectrum and on the energy of the unstable oscillations W_k. If the energy density is

$$W_k=\frac{k^2|\varphi_k|^2}{8\pi}\omega_k\frac{\partial\varepsilon}{\partial\omega_k},$$

we can write

$$\left(\frac{\partial}{\partial t}+\frac{\partial\omega_k}{\partial\mathbf{k}}\frac{\partial}{\partial\mathbf{r}}-\frac{\partial\omega_k}{\partial\mathbf{r}}\frac{\partial}{\partial\mathbf{k}}\right)\ln W_k=2\left(\gamma_k^{(i)}+\gamma_k^{(e)}\right), \tag{4}$$

where $\gamma_k^{(i)}$ and $\gamma_k^{(e)}$ are the ion and electron parts of the growth rate (damping rate) of the instability; these include both linear mechanisms for the instability – Cerenkov radiation-absorption by oscillating resonance particles – and nonlinear processes restricting the amplitudes of unstable oscillations. Saturation is described by

$$\gamma_k^{(i)}+\gamma_k^{(e)}=0.$$

The effect of stabilization by means of the collective friction force R_f acting on the electrons becomes clearer if, retaining (2), we employ a hydrodynamic description of the electron component with the aid of two equations: the continuity equation and the momentum balance equation:

$$\left.\begin{aligned}&\frac{\partial n_e}{\partial t}+\operatorname{div}(n_e\mathbf{v}_e)=0,\\ &mn_e\left(\frac{\partial\mathbf{v}_e}{\partial t}+(\mathbf{v}_e\nabla)\mathbf{v}_e\right)=-en_e\mathbf{E}-\frac{en_e}{c}[\mathbf{v}_e\mathbf{H}]-\mathbf{R}_f;\\ &\mathbf{R}_f=\sum_k\frac{\mathbf{k}}{\omega_k}\gamma W_k,\end{aligned}\right\} \tag{5}$$

where the collective friction force R_f is determined in the usual manner (see ref. 6, for example). In this notation the collective friction force will generally appear in the growth rate γ_k as an arbitrary function of the drift current $\gamma_k(\mathbf{u})$.

In the present paper, the approach to the stabilization problem and to the investigation of the nonlinear process restricting the oscillation amplitudes is based on perturbation theory for the self-consistent system of equations of type (4) and (5) and the supplementary equations for the ion component and the potential φ. Therefore, to find the variation in the collective friction force, which depends on the drift current and the other mean plasma parameters, for example in the form $\delta R_f = \delta u(\partial R_f/\partial u) + \delta n_e(\partial R_f/\partial n) + \ldots$, we introduce the following definition of the effective frequencies of elastic scattering of electrons by the oscillations:

$$\nu=\frac{1}{mn_eu}R_f,\quad \nu_f=\frac{1}{mn_e}\frac{\partial R_f}{\partial u}. \tag{6}$$

Using these effective frequencies we can, by analogy with (3), introduce the anomalous conductivity of the plasma:

$$\sigma_f=\frac{ne^2}{m\nu_f},\quad \sigma=\frac{ne^2}{m\nu}. \tag{7}$$

In the present paper, the method for finding the effective frequencies ν and ν_f, as in ref. 3, is based on the stability condition, i.e., $\gamma_k^{(i)} + \gamma_k^{(e)} = 0$. In contrast to ref. 3, however, it is important for us to find not only the maximum value of ν_f but also to establish its dependence on the drift current $\nu_f(u)$. This approach to the nonlinear processes, which is based on a self-consistent system of equations like (4) and (5), can be used, for example, for the electron-acoustic instability considered in ref. 6, which can arbitrarily be considered an instability at the zero cyclotron harmonic.

The hydrodynamic approximation is not applicable to an instability at electron-cyclotron harmonics; therefore, it is necessary to apply perturbation theory to a more general kinetic equation of type (2). For this reason, we simplify the collision integral by using the similarity between the usual binary collisions and the collective scattering of particles by oscillations. We consider only the approximation in which the following two laws are satisfied: the conservation of the number of particles and the conservation of momentum in the form of (5).

Also, we note the following property, well known in the quasilinear theory,[4] of the distribution function, which varies due to unstable oscillations. In the quasilinear relaxation, the derivative of the distribution function, and not the function itself, has the greatest variation. This property can be used to simplify the collision integral.

Consider a Maxwellian distribution function f_0 in the zeroth approximation. The interaction between the resonance particles and the random oscillations produced by the instability is described by a collisional term in the form of (3), which is taken in the most general form. Let the velocities of the resonance electrons, which are of the same order of magnitude as the phase velocity of the oscillations $v_{res} \simeq \omega/k$, be much smaller than their average thermal velocity $v_{res} \ll v_{Te}$. For the oscillations in question the phase velocities are of the same order of magnitude as the current velocity $\omega/k \simeq u$; therefore, the above-mentioned requirement reduces to the inequality $u \ll v_{Te}$. In this case, one can carry out expansion in powers of $(v - v_{res})/v_{Te}$ near the resonance velocities $v \simeq v_{res}$ which are related to the wave vectors **k** by the relation $\omega = \mathbf{kv}$; only the first two terms of the expansion are considered:

$$\mathrm{St}_{\alpha} f = C_1 + \mathbf{v}\mathbf{C}_2 + \ldots . \tag{8}$$

It is required that the two laws of conservation (number of particles and momentum) mentioned above follow from Eq. (2), with allowance for (8). In this case the coefficients in the expansion C_1 and C_2 can be selected by analogy with ref. 7, where the collisional term is represented as

$$\mathrm{St}_{\alpha f} = \left[\nu(f_e - \eta) - \nu_f \frac{m}{T_e}(\mathbf{vq}) f_0\right], \tag{9}$$

where we have used the notation

$$\eta = \frac{f_0}{n_0}\int f_e d\mathbf{v}, \quad \mathbf{q} = \frac{1}{n_0}\int \mathbf{v} f_e d\mathbf{v}, \tag{10}$$

f_e is the electron distribution function, and f_0 is its equilibrium value (Maxwellian distribution function).

A collisional integral in the form of (9) will be used below to investigate electrostatic instabilities of the drift current. The structure of this integral allows the contributions of the pair and collective collisions to be treated similarly. In the case of binary (Coulomb) collisions the effective elastic-scattering frequencies (6) are determined in the same manner. In collective scattering the dependence of the effective frequencies ν_f and ν on the drift current is important. Note that with this type of notation for the collision integral only perturbations with wavelengths larger than the electron Larmor radius $\lambda > \rho_{He}$ can be considered, and we will restrict ourselves to this approximation.

2. DISPERSION RELATION FOR ELECTROSTATIC OSCILLATIONS

The linearized kinetic equation for the electron component with a collision integral in the form of (9), which allows for the effect of collective friction, is

$$\frac{\partial f_e}{\partial t} + (\mathbf{v}\nabla) f_e - \frac{e}{m}\left(\mathbf{E}_0 + \frac{1}{c}[\mathbf{vH}_0]\right)\frac{\partial f_e}{\partial \mathbf{v}}$$
$$= \frac{e}{m}\left(\mathbf{E} + \frac{1}{c}[\mathbf{vH}]\right)\frac{\partial f_0}{\partial \mathbf{v}} - \left[\nu(f_e - \eta) - \nu_f \frac{m}{T_e}(\mathbf{vq}) f_0\right]. \tag{11}$$

Here, f_e is a small perturbation of the electron distribution function, **E** and **H** are small perturbations of the electric and magnetic fields, and e and m are the electron charge and mass.

Solving Eq. (4) by integration over the trajectories,[8] we obtain the expression for the tensor components

$$\varepsilon_{\alpha\beta} = \varepsilon_{\alpha\beta}^{(0)} + \varepsilon_{\alpha\beta}^{(1)}, \tag{12}$$

where $\varepsilon_{\alpha\beta}^{(0)}$ is the dielectric tensor for a collisionless current-carrying plasma, which is obtained, for example, in ref. 9; $\varepsilon_{\alpha\beta}^{(1)}$ are the collisional components of the tensor. We obtain the following expressions for $\varepsilon_{\alpha\rho}^{(1)}$:

$$\varepsilon_{\alpha\beta}^{(1)} = \frac{8\pi e n_0}{\omega}\sum_{n=-\infty}^{\infty}\left\{\begin{array}{l}\left(\frac{n\omega_{H_e}}{k_\perp} + u\right)\left(-i\frac{\sqrt{\pi}}{k_z v_{T_e}} W_n\right) I_n e^{-\mu} \\ -\frac{k_\perp T_e}{m\omega_{H_e}}\left(\frac{\sqrt{\pi}}{k_z v_{T_e}} W_n\right)(I_n - I_n')e^{-\mu} \\ -\frac{1}{k_z}\left[1 + i\sqrt{\pi}\, z_n W_n\right] I_n e^{-\mu}\end{array}\right\}$$
$$\times\left[\nu\eta^\beta + \nu_f \frac{m q_x^\beta}{T_e}\left(u + \frac{n\omega_{H_e}}{k_\perp}\right)\right]. \tag{13}$$

We introduce the notation

$$v_{T_\alpha} = \left(\frac{2T_\alpha}{m_\alpha}\right)^{1/2}, \quad \mu = \frac{k_\perp^2 \rho_{H_e}^2}{2}, \quad \rho_{H_e} = \frac{v_{T_e}}{\omega_{H_e}}, \quad \omega_{H_e} = \frac{eH_0}{mc},$$
$$z_{ne} = \frac{\tilde{\omega} - n\omega_{H_e} + i\nu}{k_z v_{T_e}}, \quad W_n(z_n) = e^{-z_n^2}\left(1 + \frac{2i}{\sqrt{\pi}}\int_0^{z_n} e^{t^2} dt\right),$$
$$\eta^\beta = \frac{\eta}{E_\beta}, \quad q_x^\beta = \frac{q_x}{E_\beta}, \quad \tilde{\omega} = \omega - \mathbf{ku},$$

$I_n(\mu)$ is the Bessel function of imaginary argument, and $\mathbf{k} = (k_\perp, 0, k_z)$. To obtain the dispersion relation describing the instabilities at cyclotron harmonics with collisional dissipation taken into account we use Eqs. (10), (12), and (13), in Maxwell's equation. As a result a homogeneous system of equations is obtained for the components of the field E_β. The dispersion relation is found from the condition for solving this system. It has the following form for the electrostatic oscillations:

$$\varepsilon = 1 + \frac{1}{k^2 d_i^2}\left[1 + i\sqrt{\pi}\, z_i W(z_i)\right]$$
$$+ \frac{1}{k^2 d_e^2}\sum_{n=-\infty}^{\infty} I_n e^{-\mu}\left[1 + i\sqrt{\pi}\frac{\tilde{\omega}}{k_z v_{T_e}} W_n(z_{ne})\right] + \varepsilon_e^{(1)} = 0,$$
$$d_\alpha^2 = \frac{v_{T\alpha}^2}{\omega_{p\alpha}^2}, \quad \omega_{p\alpha}^2 = \frac{4\pi n_0 e_\alpha^2}{m_\alpha}, \quad z_i = \frac{\omega}{k v_{T_i}}, \quad \alpha = e,\ i, \tag{14}$$

where the term $\varepsilon_e^{(1)}$ which is the collision contribution to the dispersion relation, has the form

$$\varepsilon_e^{(1)} = 2i\sum_{n=-\infty}^{\infty}\frac{\left(1 + i\sqrt{\pi}\frac{\omega}{k_z v_{T_e}} W_n\right) I_n e^{-\mu}}{\left[1 - \sum\limits_{n'=-\infty}^{\infty}\frac{4(\mathbf{ku} + n'\omega_{H_e})^2\sqrt{\pi}\,\nu_f}{k^2 v_{T_e}^2 k_z v_{T_e}} W_{n'} I_{n'} e^{-\mu}\right]}$$
$$\times\left\{\frac{\nu}{\omega}\left[1 + \frac{1}{k^2 d_i^2}\left(1 + i\sqrt{\pi}\, z_i W(z_i)\right)\right]\right.$$
$$\left. - \frac{2\nu_f(\mathbf{ku} + n\omega_{H_e})}{k^2 v_{T_e}^2}\frac{1}{k^2 d_e^2}\sum_{n'=-\infty}^{\infty}\left[\frac{i\sqrt{\pi}\,\tilde{\omega}}{k_z v_{T_e}} W_{n'} I_{n'} e^{-\mu}\frac{(n'\omega_{H_e} + \mathbf{ku})}{\omega} + \frac{\mathbf{ku}}{\omega}\right]\right\}. \tag{15}$$

3. DISSIPATIVE INSTABILITIES AT ELECTRON-CYCLOTRON HARMONICS $n\omega H_e$ FOR $\mu < 1$ AND $T_i > T_e$

We first consider pure transverse oscillations $k_z \equiv 0$.

Using (14) and (15) near the frequencies $\sim n\omega_{He}$ and $\tilde{\omega} \simeq n\omega_{He}$ for $\mu \leqslant 1$ we obtain the following dispersion relation:

$$\varepsilon = \left[1 + \frac{1}{k^2 d_i^2}\left(1 + i\sqrt{\pi}\, z_i W(z_i)\right)\right]\left[1 - 2i\,\frac{\nu}{\omega}\,\frac{(\mathbf{ku} + n\omega_{H_e})}{(\tilde{\omega} - n\omega_{H_e})}\, I_n e^{-\mu}\right] - \frac{I_n e^{-\mu} n\omega_{H_e}}{(\tilde{\omega} - n\omega_{H_e})\, k^2 d_e^2}\left[1 + \frac{4i\nu_f \tilde{\omega} I_n e^{-\mu} (\mathbf{ku} + n\omega_{H_e})^3}{k^2 v_{T_e}^2\, \omega n\omega_{H_e} (\omega - n\omega_{H_e})}\right] = 0. \quad (16)$$

Neglecting the ion motion and the collisions in (16), near the frequencies $\sim n\omega_{He}$ we have

$$\tilde{\omega}^* = n\omega_{H_e}\left[1 + I_n e^{-\mu}\frac{1}{1 + k^2 d_e^2}\right]. \quad (17)$$

The instability appears from the condition for the intersection of the branches, i.e., with inclusion of the ion motion for frequencies $\omega \ll |\mathbf{ku}|$. It is easy to be convinced of this by treating the ions as cold $\omega \gg kv_{T_i}$ in (16) and expanding in the small parameter $\omega/|\mathbf{ku}| \ll 1$.

In the zeroth approximation we have

$$\omega = i\,\frac{kv_s}{(1 + k^2 d_e^2)^{1/2}}\left(\frac{ku - n\omega_{H_e}}{\tilde{\omega}^* - ku}\right)^{1/2}, \quad v_s = \left(\frac{T_e}{M}\right)^{1/2}. \quad (18)$$

Here, $\mathbf{ku} = -ku$. The oscillations become unstable for

$$n\omega_{H_e} < ku < \tilde{\omega}^*.$$

The maximum growth rate can be found by taking account of the higher terms in the expansion in the small parameter $\omega/|\mathbf{ku}| \ll 1$. As a result we find the hydrodynamic cyclotron oscillations[3] with the maximum growth rates

$$\omega = \frac{1 + i\sqrt{3}}{2^{4/3}}\left(\frac{\omega_{pi}^2 I_n e^{-\mu} n\omega_{H_e}}{1 + k^2 d_e^2}\right)^{1/3}, \quad \frac{I_n e^{-\mu}}{(1 + k^2 d_e^2)} \ll 1. \quad (19)$$

It is evident that $\operatorname{Im}\omega < \omega_{He}$; otherwise, the cyclotron resonances are "smeared out" and the unstable oscillations have a continuous spectrum. Still considering the hydrodynamic instability, we examine the effect of collisions on the cyclotron instabilities. Using the initial dispersion relation (16), we consider those current velocities for which the expansion in the small parameters $\omega/|\mathbf{ku}| \ll 1$, $\nu_f/|\mathbf{ku}| \ll 1$ is valid. Then we obtain the spectrum of cyclotron oscillations (18) in the zeroth approximation. This relation essentially determines the values of the wave numbers **k** for which the growth rate of the hydrodynamic instability is a maximum. In the next approximation we find the equation describing the spectrum of the dissipative instabilities:

$$\omega = \frac{1 + i\sqrt{3}}{2^{4/3}}\left(\frac{\omega_{pi}^2 I_n e^{-\mu} n\omega_{H_e}}{1 + k^2 d_e^2}\right)^{1/3} \frac{\left[1 - \frac{2i\nu}{\omega}\,\frac{(n\omega_{H_e} - \mathbf{ku})\, k^2 d_e^2}{n\omega_{H_e}}\right]^{1/3}}{\left[1 + \frac{4i\nu_f \tilde{\omega}^* (n\omega_{H_e} - \mathbf{ku})^4 k^2 d_e^2}{k^2 v_{T_e}^2 \omega^2 (n\omega_{H_e})^2}\right]^{1/3}}. \quad (20)$$

It can be seen from this equation that the maximum growth rate has the same order of magnitude as for $\nu_f \equiv 0$ [Eq. (19)].

We will explain for the hydrodynamic instability how the inclusion of the collisions changes the limit of excitation of the cyclotron oscillations. For the clearest view of the expected result we simplify the problem by assuming that $I_n e^{-\mu} \ll 1$. Then, from (16)

$$\omega = i\,\frac{kv_s}{(1 + k^2 d_e^2)^{1/2}}\left\{\frac{ku - n\omega_{H_e}}{\omega^* - ku\left[1 + \frac{4i\nu_f n\omega_{H_e} (I_n e^{-\mu})^5}{\omega_{pi}^2}\left(\frac{u}{v_{T_e}}\right)^2\right]}\right\}. \quad (21)$$

From this it can be seen that the instability can be excited for two reasons. Either, as is already well known, for

$$n\omega_{H_e} < ku < \tilde{\omega}^*,$$

or, even if this condition is not satisfied, for $[(\nu_f n\omega_{He}) \cdot (\omega_{pi}^2)^{-1}] (I_n e^{-\mu})^5 < (v_{T_e}/u)^2$, i.e., for arbitrarily small current velocities only if the above condition for small $I_n e^{-\mu} \ll 1$ is satisfied. Thus, for the hydrodynamic instability the collisional dissipation removes the restriction on the current velocity threshold which is valid in the case of cold electrons.

We now consider kinetic instabilities in a plasma with hot ions $T_i < T_e$ for fairly long-wavelength perturbations $k\rho_{He} < 1$. We first consider transverse oscillations, assuming that $I_n e^{-\mu}(T_i/T_e) < 1$. Then from (16) for $\mathbf{ku} = -ku$ we find the following frequencies ω_k) and growth rates γ_k of the most unstable oscillations near the instability limit, i.e., when ($\gamma_k < \omega_k$):

$$\left.\begin{aligned} \omega_k &= \mathbf{k}(\mathbf{u}^* - \mathbf{u}), \\ u^* &= \frac{n\omega_{H_e}}{k}\left[1 + I_n e^{-\mu}\frac{T_i}{T_e}\right], \end{aligned}\right\} \quad (22)$$

$$\gamma_k = -\nu + \frac{1}{2}\, n\omega_{H_e}\left(\frac{T_i}{T_e}\right) I_n e^{-\mu}\left\{\sqrt{\pi}\, z_i \operatorname{Re} W(z_s) - \frac{4\nu_f (\mathbf{ku} - n\omega_{H_e})^3 \tilde{\omega} T_e}{k^2 v_{T_e}^2 \omega (n\omega_{H_e})^2 T_i}\right\},$$

$$z_i = \frac{u - u^*}{v_{T_i}}. \quad (23)$$

The oscillations are unstable for

$$\nu_f \leqslant \frac{\omega^2 (n\omega_{H_e})^2 k^2 v_{T_e}^2}{\tilde{\omega}(n\omega_{H_e} - \mathbf{ku})^3 kv_{T_i}}\left(\frac{T_i}{T_e}\right). \quad (24)$$

Maximizing the wavelengths of the most stable oscillations, i.e., using the conditions $k \simeq n\omega_{He}/u$, $I_n e^{-\mu}(T_i/T_e) < 1$, we obtain an estimate for the effective frequency of elastic scattering of electrons by oscillations of the given type, i.e., in complete agreement with the method proposed in ref. 2,

$$\nu_f \simeq n\omega_{e,i}\left(\frac{v_{T_e}}{u}\right)^3\left(I_n e^{-\mu}\frac{T_i}{T_e}\right)^{-3}. \quad (25)$$

We use this estimate to obtain the anomalous resistivity

$$\sigma_f = \frac{n_e e^2}{m\nu_f} \simeq \left(\frac{n_e e^2}{mn\omega_{e,i}}\right)\left(\frac{u}{v_{T_e}}\right)^3\left(I_n e^{-\mu}\frac{T_i}{T_e}\right)^3. \quad (26)$$

Note, however, that estimates (25) and (26) have a very restricted region of validity (this will be shown later). This is because, remembering the definitions of ν and ν_f in (6), it is necessary in perturbation theory to evaluate more precisely the dependence of ν and ν_f on the mean plasma parameters, for example on the current velocity.

We now investigate oblique modes $k_z/k \simeq (m/M)^{1/2}$. Thus, for example, when $k\rho_e < 1$ and $T_i > T_e$ at the zeroth cyclotron harmonic ($n = 0$), we use the dispersion relation (14) to obtain the branch of the electron-acoustic oscillations[6] with an extremely low excitation threshold $v_{T_i}\{(m/M)^{1/4}, (\nu_f/\omega_{e,i})^{1/4}\}$; the frequency ω_k and the growth rate γ_k are

$$\left.\begin{aligned} \omega_k &= \mathbf{ku} + k_z\left(\frac{T_i}{m}\right)^{1/2}\bar{a}, \quad \bar{a} = (1 + k_\perp^2\rho_e^2)^{-1/2},\\ \gamma_k &= -\frac{(k\rho_e)^2}{2}\nu_f - \frac{\sqrt{\pi}}{2}k_z\left(\frac{T_i}{m}\right)^{1/2}\bar{a}^3 z_i \operatorname{Re} W(z_i), \quad z_i = \frac{\omega}{kv_{T_i}}. \end{aligned}\right\} \quad (27)$$

These oscillations can be obtained in a simpler manner by using the system of hydrodynamic equations (5) for the electron component. In the electron-acoustic instability the contribution of nonlinear effects to stabilization is seen clearly. Damping can be due to nonlinear processes which, accordihg to Eq. (5) for the electron motion, can be formally taken into account by means of the effective elastic-scattering frequency (6)

$$\nu_f = \frac{1}{mn_e}\frac{\partial R_f}{\partial u}.$$

It will be shown below that this term can be negative, i.e., $\partial R_f/\partial u < 0$ and stabilization due to the collective friction force is impossible.

The effect of a finite k_z on the development of cyclotron instabilities can be described in the following manner. We assume that the current velocities are fairly large $u \gg v_s$. Assuming in the initial equations (14) and (15) that $|\tilde{\omega} - n\omega_{He}| \gg k_z v_{Te}$ for all numbers n except $n \neq n'$, for which $|\tilde{\omega} - n'\omega_{He}| \lessgtr k_z v_{Te}$, and assuming the ions to be cold $\omega \gg kv_{T_i}$ we have

$$\varepsilon = 1 - \frac{\omega_{pi}^2}{\omega^2} + \frac{1}{k^2 d_e^2}\left\{1 - e^{-\mu}I_0 + i\sqrt{\pi}\frac{\tilde{\omega}}{k_z v_{T_e}}e^{-\mu}I_{n'} + \frac{\frac{4\tilde{\omega}}{\omega}(I_{n'}e^{-\mu})^2\left(1 + i\sqrt{\pi}\frac{\omega}{k_z v_{T_e}}\right)\frac{\sqrt{\pi}\,\nu_f}{k_z v_{T_e}}\left(\frac{n'\omega_{H_e} + \mathbf{ku}}{kv_{T_e}}\right)^2}{\left[1 - 4\left(\frac{n'\omega_{H_e} + \mathbf{ku}}{kv_{T_e}}\right)^2\frac{\sqrt{\pi}\,\nu_f}{k_z v_{T_e}}I_{n'}e^{-\mu}\right]}\right\} = 0. \quad (28)$$

Here, we retain the negative term for the n'-th cyclotron harmonic, which is important for $|\tilde{\omega} - n'\omega_{He}| \leq k_z v_{Te}$. The other negative terms are exponentially small. Solving Eq. (28) for ω we obtain the following spectrum of unstable oscillations for $4\sqrt{\pi}(ku/k_z v_{Te})(\nu_f/n'\omega_{He})I_{n'}e^{-\mu} \ll 1$:

$$\omega = \omega_{e,i}\left\{1 + \frac{4n'\omega_{H_e}}{k_z v_{T_e}}\frac{(I_{n'}e^{-\mu})^2\sqrt{\pi}}{\mu}\left(\frac{\nu_f}{\omega_{e,i}}\right)\frac{(n'\omega_{H_e} + \mathbf{ku})^2}{k^2 v_{T_e}^2} + i\sqrt{\pi}\frac{n'\omega_{H_e}}{k_z v_{T_e}}\frac{e^{-\mu}I_{n'}}{\mu}\left[1 + \frac{I_{n'}e^{-\mu}\sqrt{\pi}\,\nu_f}{k_z v_{T_e}}\frac{(n'\omega_{H_e} + \mathbf{ku})^2}{k^2 v_{T_e}^2}\right]\right\}^{-1/2}. \quad (29)$$

This spectrum of dissipative instabilities can be excited for

$$|\mathbf{k}| \simeq \frac{n'\omega_{H_e}}{|\mathbf{u}|}, \quad \frac{m}{M} \ll \frac{k_z}{k}\frac{v_s}{u} \ll \left(\frac{m}{M}\right)^{1/2},$$

and has a discrete structure. In any case collisions due to the friction force are favorable to the development of the spectrum of oblique oscillations obtained above. Consequently, stabilization by the collective friction force is impossible.

4. VORTICAL ELECTRON OSCILLATIONS AND THE ANOMALOUS VISCOSITY EFFECT

We now show the possibility of exciting an instability of vortical oscillations $|\operatorname{curl}\mathbf{E} \neq 0|$ in an incompressible electron fluid $\operatorname{div}\mathbf{v}_e = 0$ at frequencies near $\sim \omega_{He}$ in a plasma in which $\partial R_f/\partial u < 0$. We introduce the following notation for the velocity $\mathbf{v}_e$ and the vorticity $\mathbf{\Omega}$:

$$\mathbf{v}_e = -\frac{c}{4\pi en_0}\operatorname{curl}\mathbf{H}, \quad \mathbf{\Omega} = \operatorname{curl}\mathbf{v}_e = \frac{c}{4\pi en_0}\Delta\mathbf{H}. \quad (30)$$

Applying the curl operator to the equation of electron motion (5) and using a Fourier transform for the small perturbations, which are represented by $\sim H_\sim(y)\exp(-i\omega t + ikx)$, we find the differential equation that describes unstable flow of the incompressible electron fluid:

$$(\tilde{\omega} + i\nu_f)(H''_\sim - k^2H_\sim) + \left(\mathbf{k}\mathbf{u}'' - \frac{\omega}{a^2}\right)H_\sim = i\eta_f(H^{\mathrm{IV}}_\sim - 2k^2H''_\sim + k^4H_\sim). \quad (31)$$

Here, as has already been mentioned, ν_f is the effective frequency of elastic scattering (6), $a = c/\omega_{pe}$ and $H_\sim$ is the magnetic field amplitude in the vortical oscillations, which depend on the y coordinate.

The structure of (31) is similar to that of the equation for vortical oscillations of a conventional fluid. To provide eigensolutions for Eq. (31) a kinematic electron viscosity term η_f is added which does not have a theoretical value for the problem discussed below. We consider the spectrum of unstable oscillations in the semiclassical approximation $k(d\ln H_\sim\, dy)^{-1} \gg 1$. Applying the method of "semiclassical quantization" to Eq. (31) for the limiting case $k(c/\omega_{pe}) \gg 1$ and $k|d\ln H_0/dy|^{-1} \gg 1$ we find the following values for the frequencies ω_k and the growth rate γ_k

$$\left.\begin{aligned} \omega_k &= \tilde{\mathbf{k}}\mathbf{u} + \frac{\mathbf{k}\mathbf{u}''}{(k^2 + \bar{k}_y^2)},\\ \gamma_k &= -\nu_f - k^2\eta_f, \text{ where } \bar{k}_y^2 = \left(\frac{2\pi m}{\Delta y}\right)^2, \quad m = 1, 2, 3, \ldots \end{aligned}\right\} \quad (32)$$

As in the case of electron-acoustic oscillations (27), the frequencies have a dependence on the current velocity. The oscillation frequency is a maximum in the region of short wavelengths. The instability criterion for electron vortical oscillations has the simple form

$$\nu_f = \frac{1}{mn_0}\frac{\partial R_f}{\partial u} < 0 \quad (\eta_f \to 0),$$

i.e., a decreasing dependence of the friction force on the electron current velocity.

We use the hydrodynamic equations (5) to analyze the basic nonlinear effect resulting from the development of vortical electron oscillations. In the initial hydrodynamic equation (5) we average over the random phases of the vortical oscillations. As a result, a new term is added to the total momentum balance for the electron component

$$\Pi_{yx} = mn_0 \langle v_{x\sim} v^*_{y\sim} + \text{c.c.} \rangle,$$

which physically denotes the component of the viscous stress tensor giving the mean force in the direction of the current

$$R_x = -\frac{\partial \Pi_{yx}}{\partial y}.$$

To calculate this term we multiply the equation for the vortical oscillations (31) by the complex-conjugate amplitude $H^*_{\sim}$ and subtract the complex conjugate from the equality thus obtained. As a result, for the case $k|d \ln H/dy|^{-1} \gg 1$

$$\Pi_{yx} = -\sum_k 2\pi m n_0 |\mathbf{v}_{ky}|^2 \delta(\omega_k - \mathbf{k}\mathbf{u}) \frac{\partial u}{\partial y}, \qquad (33)$$

where

$$v_{ky} = -i \frac{kc}{4\pi e n_0} H_k.$$

The appearance of the δ function denotes a resonance mechanism for the interaction between segments of the electron velocity profile u(y) and the excited vortical oscillations, for which the phase velocity is $\omega/k = u(y)$. Thus, the macroscopic effect on the vortical oscillations consists of the appearance of a friction force for the electrons which is proportional to the second derivative of the current velocity $\sim (\partial/\partial y)\eta_f(\partial u/\partial y)$. In the physical sense, this force is similar to a viscous friction force due to a viscosity

$$\eta_f = \sum_k 2\pi m n_0 |v_{ky}|^2 \delta(\omega_k - \mathbf{k}\mathbf{u}), \qquad (34)$$

which is proportional to the amplitude of the vortical oscillations $\sim |v_{ky}|^2$. The anomalous electron viscosity, which contains an unknown term $|v_{ky}|^2$, can be found from the condition that viscous friction is the principal nonlinear effect stabilizing cyclotron instabilities of type (22). To determine the anomalous electron viscosity in an instability of type (22), for example, it is necessary to make the formal substitution

$$k_y^2 \eta_f = \nu_f. \qquad (35)$$

5. CONTRIBUTION OF THE COLLECTIVE FRICTION FORCE TO STABILIZATION OF CYCLOTRON INSTABILITIES

We will analyze the basic macroscopic effects resulting from the development of turbulence near cyclotron harmonics. One of the effects has been discussed above. A basic nonlinear effect produced by the electrostatic oscillations, as has already been noted, is the appearance of a collective friction force R_f which acts on the electrons. The momentum of cyclotron oscillations is transferred to electrons by nonlinear processes so that for Cerenkov radiation due to the oscillations in question the ions suffer the major loss of moment (negative energy waves).[2] At saturation of the oscillation amplitudes the momentum lost by the ions due to Cerenkov radiation produced by the oscillations is completely absorbed by the electrons by nonlinear processes. In this case the nonlinear damping rate $\gamma_H(W_k)$ which depends on the energy w_k is equal to the linear growth rate of the instability $\gamma_k(u)$. Therefore, at saturation the collective friction force acting on the electrons is

$$\mathbf{R}_f(u) = \sum_k \gamma_k(u) \mathbf{P}_k.$$

Here, P_k is some quasistationary momentum taken over the entire spectral interval of unstable waves k. According to this definition, we assume that the friction force depends on the current velocity through the instability growth rate $\gamma_k(u)$.

This dependence will be established as for the instability with a frequency spectrum (22). Since the short-wavelength perturbations are the most unstable

$$\bar{k} = \frac{n\omega_{He}}{u}\left[1 + I_n e^{-\mu} \frac{T_i}{T_e}\right],$$

the sum over k in the expression for the friction force can be replaced by a term with the most unstable value $\bar{k}$, when $\bar{k} \simeq n\omega_{He}/u$. Then we obtain a simple expression for the effective elastic-scattering frequency ν_f which is defined in (6),

$$\nu_f = \left(\frac{P_{\bar{k}}}{mn_e}\right) \frac{\partial \gamma_{\bar{k}}}{\partial u}. \qquad (36)$$

Substituting this expression into the equation for the growth rate (22), we obtain the differential equation for $\gamma_{\bar{k}}(u)$

$$\bar{u} \frac{\partial \gamma_{\bar{k}}}{\partial u} + \gamma_{\bar{k}} = \gamma_{\max} \left(\frac{u - u^*}{v_{Ti}}\right) \exp\left\{-\left(\frac{u - u^*}{v_{Ti}}\right)^2\right\}. \qquad (37)$$

Here we set

$$\bar{u} = \left(2 \frac{T_i}{T_e} I_n e^{-\mu} \frac{u}{v_{Te}}\right)^2 \frac{P_{\bar{k}}}{mn_e},$$

$$\gamma_{\max} = n\omega_{He} \frac{v_{Ti}}{u}\left[2 \ln\left(\frac{u}{v_{Ti}} \sqrt{\pi} \frac{T_i}{T_e} I_n e^{-\mu}\right)\right]^{1/2}.$$

The solution of this equation must satisfy the requirement that the growth rate γ_k vanish at the boundary of the instability

$$\gamma_{\bar{k}} = 0 \text{ for } u = u^*.$$

The solution of (37) has the form

$$\gamma_{\bar{k}}(u) = \gamma_{\max}\left\{\int_{u^*}^{u} \frac{du'}{\bar{u}} \left(\frac{u' - u^*}{v_{Ti}}\right) \exp\left[\frac{u' - u}{\bar{u}} - \left(\frac{u' - u^*}{v_{Ti}}\right)^2\right] - \frac{u}{v_{Ti}}\left[1 - \exp\left(\frac{u^* - u}{\bar{u}}\right)\right]\right\}.$$

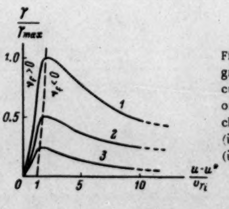

Fig. 1. Dependence of the nonlinear growth rate of the instability on the current velocity for different values of the free parameter $\bar{u}/v_{Ti}$, which characterizes the noise level. 1) $(\bar{u}/v_{Ti}) = 0$, 2) $0 < (\bar{u}/v_{Ti}) < 1$, 3) $(\bar{u}/v_{Ti}) > 1$.

It has the simplest form in the two limiting cases

$$\gamma_{\bar{k}} = \gamma_{\max} \begin{cases} \dfrac{u-u^*}{v_{Ti}} - \dfrac{\bar{u}}{v_{Ti}}\left(1 - e^{\frac{u^*-u}{\bar{u}}}\right) & \text{for } \dfrac{u-v^*}{v_{Ti}} < 1, \\ \dfrac{v_{Ti}}{u} e^{\frac{u^*-u}{\bar{u}} + \frac{v_{Ti}^2}{4\bar{u}^2}} & \text{for } \dfrac{u-u^*}{v_{Ti}} \gg 1. \end{cases} \tag{38}$$

Figure 1 illustrates the dependence of the nonlinear growth rate $\gamma_k^-(W)$ on the current velocity. It can be seen that beginning with current velocities $u > u^* + v_{Ti}$, $\gamma_k^-(u)$ falls off and ν_f becomes negative. Thus, for large current velocities $u > u^* + v_{Ti}$ the friction force has a decreasing dependence on u, and consequently the nonlinear effect of the friction force does not stabilize the instabilities in question. But when $\partial R_f/\partial u < 0$ a factor appears which excites vortical electron oscillations and a stabilizing effect of the electron viscosity type emerges. From the stability condition for an instability with a frequency spectrum (22), with allowance for (35), we find the anomalous electron viscosity

$$\eta_f \simeq \frac{\nu_f}{\bar{k}_\perp^2} \simeq \left(\frac{u^3}{n\omega_{He}}\right)\left(\frac{m}{M}\right)^{1/4}\left(\frac{v_{Te}}{u}\right)^3\left(I_n e^{-\mu}\frac{T_i}{T_e}\right)^{-3}. \tag{39}$$

Here we maximize the wavelengths of the most unstable electron-cyclotron oscillations, i.e., for $\bar{k}_\perp \simeq n\omega_{He}/u$. A similar result can be obtained for the electron-acoustic instability (27), i.e., it can be shown that the collective friction force produced by this instability also has a falling dependence on the current velocity for large current velocities $u \gg v_{Ti}$ and thus cannot stabilize the given instability.

CONCLUSIONS AND RESULTS

Thus, it has been shown that for a fairly large drift velocity u in a plasma with hot ions $T_i > T_e$, electron-cyclotron oscillations can be excited which have comparatively high growth rates $[\gamma_{\max} \simeq (m/M)^{1/4}\omega_{He}]$ and which make a large contribution to the anomalous resistivity of the plasma. An investigation of this process must consider nonlinear processes which restrict the unstable wave amplitudes and set up a quasistationary level of microscopic turbulence. A nonlinearity associated with the electrons plays such a role for electron-cyclotron oscillations (Bernstein modes). A model with a Landau collision integral has been proposed to provide a qualitative description of the basic nonlinear process: collective scattering of electrons by cyclotron oscillations excited by the instability and the stabilizing effect of the collective friction force.

The model is used in linear theory to establish a wide spectrum of current-dissipative instabilities at electron-cyclotron harmonics, which are excited, on one hand, by the flow of the drift current, and on the other by collisional processes including collective scattering of electrons by the oscillations. It has been shown that due to the collective friction force the stabilizing effect is possible only at low current velocities ($u < v_{Ti} + v_s$) near the instability limit (small supercriticality). For sufficiently large current velocities ($u > v_{Ti} + v_s$), however, long-wavelength oscillations ($\lambda > \rho_{He}$) are not stabilized by the collective friction force resulting from nonlinear scattering of electrons by the excited oscillations. Formally, this is the case because at high current velocities the collective friction force has a declining dependence on the drift current. Physically, this means that the momentum of the waves cannot be completely transferred to the electrons through the given nonlinear process. In this case part of the momentum can be carried out of the instability region and dissipated elsewhere. Secondly, the restriction on the unstable wave amplitude and the dissipation of the transferred momentum can also result from nonlinear scattering of electrons during the development of decay processes, for example the excitation of vortical electron oscillations. Assuming total absorption of the wave momentum, we have estimated the anomalous electron viscosity (39), which is a possible nonlinear process leading to stabilization of the cyclotron oscillations.

Finally, for a sufficiently high level of oscillations a change in wave dispersion can have a stabilizing effect (see ref. 6).

Anomalous ion heating in a parametrically unstable plasma

I. S. Baikov and V. P. Silin
P. N. Lebedev Institute of Physics, Academy of Sciences of the USSR, Moscow
(Submitted December 20, 1973)
Zh. Tekh. Fiz., 44. 2467-2475 (December 1974)

Anomalous ion heating is investigated in a plasma driven by an ac electric field with a frequency near the electron plasma frequency. The anomalous heating is due to the coupling between the external electric field and the plasma caused by ion-acoustic fluctuations; these grow exponentially in the parametric instability and are the cause of anomalous ion heating in a plasma with $T_e \lessdot T_i$ when strong absorption of the ion-acoustic oscillations occurs.

In recent years, the development of programs for thermonuclear research[1] and experiments in the ionosphere[2] has stimulated interest in investigations of the anomalous properties of a plasma that interacts with powerful electromagnetic radiation. Increasing attention has been paid to plasmas with $T_i \gtrsim T_e$ in which strong absorption of ion-acoustic oscillations occurs; this is of interest for problems of laser fusion since the plasma corona with hot ions $T_i \gtrsim T_e$ which is produced by the laser-material interaction can have a small reflection coefficient.[3] According to the linear theory, strong electromagnetic radiation produces oscillating two-stream and ion-acoustic decay instabilities in a plasma with $T_i \gtrsim T_e$ (see refs. 4 and 5). The phase velocities of the ion-acoustic perturbations lie near the ion thermal velocity. In this case the perturbations interact effectively with the bulk of the ions, which leads to an effective coupling between the external electric field and the plasma through the ion fluctuations.

Anomalous resistivity and heating of electrons in a highly nonisothermal plasma $T_e \gg T_i$ have been studied in several papers by numerical simulation.[6] These experiments have confirmed anomalous heating of electrons in such a plasma when the nonacoustic fluctuations saturate, and they indicate that an appreciable portion of the external-field energy is not expended in increasing the electron temperature, but in forming energy tails in the electron distribution function (fast particles). The ion distribution function retains its initial Maxwellian character although the temperature varies somewhat in time (but several orders of magnitude slower than the electron temperature). However, analytical relations have not yet been obtained for the variation in the ion temperature.

In the present paper we investigate the anomalous heating of ions in an isothermal plasma or for $T_i > T_e$. We use the quasilinear theory (see ref. 7) to describe the turbulent state resulting from the development of the parametric instability. In Sec. I, the linear theory of a parametric instability is discussed. Special attention is given to the case $T_i \gtrsim T_e$, which has not been discussed in detail in the literature. In Sec. II, the quasilinear theory is used to analyze the results of an investigation of anomalous heating of ions.

I. LINEAR THEORY

We consider a homogeneous plasma driven by an external electric field $E = E_0 \sin\omega_0 t$ with a frequency near the electron plasma frequency ω_{Le}. For fairly weak microwave fields, in which the electron oscillation amplitude in the electric field is small compared to the wavelength of the excited oscillation, we can obtain the following dispersion relation to describe the low-frequency parametric instabilities[4] ($\omega \ll \omega_{Le}$):

$$\frac{1}{\delta\varepsilon_i(\omega,\mathbf{k})} + \frac{1}{1+\delta\varepsilon_e(\omega,\mathbf{k})} = \frac{(\mathbf{k}\cdot\mathbf{r}_E)^2}{4} \times \left[\frac{\omega_{Le}^2}{\omega_{Le}^2 + 3k^2 v_{Te}^2 - (\omega+\omega_0)^2 - i\nu_e(\omega+\omega_0)} + \frac{\omega_{Le}^2}{\omega_{Le}^2 + 3k^2 v_{Te}^2 - (\omega-\omega_0)^2 - i\nu_e(\omega-\omega_0)^2}\right], \tag{1}$$

where $\delta\varepsilon_\alpha$ is the partial contribution of particles of species α to the low-frequency dielectric constant of the plasma $\varepsilon(\omega,\mathbf{k}) = 1 + \sum_{\alpha=e,i}\delta\varepsilon_\alpha$; r_E is the electron oscillation amplitude in the external field; the other notation is standard.

We are interested in the case of a collisionless plasma, in which the ion-acoustic frequency exceeds the particle collision frequency ($\nu_\alpha \ll \omega$). Considering long-wavelength oscillations $k^2 r_{D\alpha}^2 \ll 1$ where $r_{D\alpha}$ is the Debye radius for species α in the frequency range $\omega < |k| v_{Te}$ and the inequality $\omega_0 \sim \omega_{Le} \gg \omega$ we can reduce Eq. (1) to

$$\frac{T_e}{T_i}\left(1 - i\sqrt{\frac{\pi}{2}}\frac{\omega}{|k| v_{Te}}\right) + \frac{1}{1 - J_+\left(\frac{\omega}{|k| v_{Ti}}\right)} = -\frac{(\mathbf{k}\cdot\mathbf{r}_E)^2}{8k^2 r_{Di}^2}\frac{\omega_{Le}^2}{\omega_0}\left(\frac{1}{\omega+\delta+i\tilde{\gamma}} - \frac{1}{\omega-\delta+i\tilde{\gamma}}\right), \tag{2}$$

where

$$\tilde{\gamma} = \frac{\nu_e}{2}, \quad \delta = \omega_0 - \omega_{Le}\left(1 + \frac{3}{2}k^2 r_{De}^2\right) = \omega_0 - \omega_L(\mathbf{k}), \tag{3}$$

The expression (2) is a complex equation for determining the frequency and growth rate. Setting $\omega = \mathrm{Re}\,\omega + i\gamma$ and using ω for $\mathrm{Re}\,\omega$, for $\gamma < \omega$ we can write [the general case $\gamma \gtrsim \omega$, which corresponds to very large electric fields, usually requires a numerical solution of Eq. (2)]

$$\frac{1}{1 - J_+\left(\frac{\omega + i\gamma}{|k| v_{Ti}}\right)} = \frac{1}{1 - J_+(x)} + i\frac{\gamma}{|k| v_{Ti}}\frac{x^2 + (1-x^2)J_+(x)}{x[1 - J_+(x)]^2} + 0\left(\frac{\gamma^2}{k^2 v_{Ti}^2}\right),$$

where $x = \omega/|k| v_{Ti}$. Substituting this expansion into (2) and separating the real and imaginary parts, we obtain

$$\frac{T_e}{T_i}\left(1 + \sqrt{\frac{\pi}{2}}\frac{\gamma}{|k| v_{Te}}\right) + \frac{1 - \mathrm{Re}\,J_+}{(1 - \mathrm{Re}\,J_+)^2 + (\mathrm{Im}\,J_+)^2} - \frac{\gamma}{\omega}\mathrm{Im}\,J_+\frac{2x^2(1 - \mathrm{Re}\,J_+) + (1-x^2)[1 - (\mathrm{Re}\,J_+)^2 - (\mathrm{Im}\,J_+)^2]}{[(1 - \mathrm{Re}\,J_+)^2 + (\mathrm{Im}\,J_+)^2]^2} = -\frac{(\mathbf{k}\cdot\mathbf{r}_E)^2}{4k^2 r_{Di}^2}\frac{\omega_{Le}^2\delta}{\omega_0}\frac{\delta^2 - \omega^2 + (\gamma+\tilde{\gamma})^2}{[(\omega+\delta)^2 + (\gamma+\tilde{\gamma})^2][(\omega-\delta)^2 + (\gamma+\tilde{\gamma})^2]}. \tag{3a}$$

$$-\frac{T_e}{T_i}\sqrt{\frac{\pi}{2}}\frac{\omega}{|k|v_{Te}}+\frac{\mathrm{Im}\,J_+}{(1-\mathrm{Re}\,J_+)^2+(\mathrm{Im}\,J_+)^2}+\frac{\gamma}{\omega}\frac{[x^2+(1-x^2)\,\mathrm{Re}\,J_+]\,[(1-\mathrm{Re}\,J_+)^2-(\mathrm{Im}\,J_+)^2]-2\,(1-x^2)\,(\mathrm{Im}\,J_+)^2\,(1-\mathrm{Re}\,J_+)}{[(1-\mathrm{Re}\,J_+)^2+(\mathrm{Im}\,J_+)^2]^2}$$

$$=-\frac{(\mathbf{k}\cdot\mathbf{r}_E)^2}{4k^2r_{Di}^2}\frac{\omega_{Le}^2\delta}{\omega_0}\frac{2\omega\,(\gamma+\tilde{\gamma})}{[(\omega+\delta)^2+(\gamma+\tilde{\gamma})^2]\,[(\omega-\delta)^2+(\gamma+\tilde{\gamma})^2]}. \tag{3b}$$

If the pump field is close to the threshold value, the problem can be solved by successive approximations. This method gives a good description when the pump field does not produce a substantial shift in the frequencies of the characteristic plasma oscillations; this is known to be the case for moderate external fields. The growth rate can vary considerably due to the presence of the pump field. Thus, we find from (3a) in the zeroth approximation with respect to the pump field (small terms containing γ can be dropped)

$$\frac{\mathrm{Re}\,J_+(x)-1}{[1-\mathrm{Re}\,J_+(x)]^2+[\mathrm{Im}\,J_+(x)]^2}=\frac{T_e}{T_i}. \tag{4}$$

The solution of this equation is

$$\omega_1=x_0\,|k|\,v_{Ti}, \tag{5}$$

where x_0 is the root of Eq. (4), which depends only on the temperature ratio. The dependence of x_0 on $(T_e/T_i)^{1/2}$ is shown in Fig. 1. Note that the coefficient x_0 is almost constant in the region $T_i \gtrsim T_e$; in particular $x_0 = 1.3$ for $T_i \gg T_e$, $x_0 = 1.7$ for $T_e = T_i$, and $x_0 = (T_e/T_i)^{1/2}$ for $T_e \gg T_i$.

The frequency, with a correction for the external magnetic field, and the corresponding growth rate are determined by

$$\omega_1(\omega-\omega_1)=-\frac{(\mathbf{k}\cdot\mathbf{r}_E)^2}{4k^2r_{Di}^2}\frac{\omega_{Le}^2\delta\omega_1\,|k|\,v_{Ti}}{\omega_0c_1}$$

$$\times\frac{\delta^2-\omega^2+(\gamma+\tilde{\gamma})^2}{[(\omega+\delta)^2+(\gamma+\tilde{\gamma})^2]\,[(\omega-\delta)^2+(\gamma+\tilde{\gamma})^2]}, \tag{6}$$

$$\omega_1\left(\gamma+\frac{c_0}{c_1}|k|\,v_{Ti}\right)=-\frac{(\mathbf{k}\cdot\mathbf{r}_E)^2}{4k^2r_{Di}^2}\frac{\omega_{Le}^2\delta\omega_1\,|k|\,v_{Ti}}{\omega_0c_1}$$

$$\times\frac{2\omega\,(\gamma+\tilde{\gamma})}{[(\omega+\delta)^2+(\gamma+\tilde{\gamma})^2]\,[(\omega-\delta)^2+(\gamma+\tilde{\gamma})^2]}, \tag{7}$$

where

$$c_0=-\frac{T_e}{T_i}\sqrt{\frac{\pi}{2}}\frac{\omega_1}{|k|\,v_{Te}}+\frac{\mathrm{Im}\,J_+(x_0)}{[1-\mathrm{Re}\,J_+(x_0)]^2+[\mathrm{Im}\,J_+(x_0)]^2},$$

$$c_1=\frac{\partial}{\partial x}\left[\frac{1-\mathrm{Re}\,J_+}{1-\mathrm{Re}\,J_+)^2+(\mathrm{Im}\,J_+)^2}\right]_{x=x_0}=\frac{[x_0^2+(1-x_0^2)\,\mathrm{Re}\,J_+]\,[(1-\mathrm{Re}\,J_+)^2-(\mathrm{Im}\,J_+)^2]-2\,(1-x_0^2)\,(\mathrm{Im}\,J_+)^2\,(1-\mathrm{Re}\,J_+)}{x_0\,[(1-\mathrm{Re}\,J_+)^2+(\mathrm{Im}\,J_+)^2]^2}.$$

Note that the coefficients $c_1 \lesssim 0$ and $c_0 < 0$. In particular, $c_0 = -1.4$ and $c_1 = -1.53$ for $T_e \ll T_i$; for $T_e \gg T_i$ the coefficient $c_0 = (-T_e/T_i)\cdot[(\pi/2)(m/M)]^{1/2}$. It follows from (7) that the parametric decay instability ($\gamma > 0$) can exist only in the region $\delta > 0$. In the absence of an external pump field, the ion-acoustic damping is

$$\gamma_s=\frac{c_0}{c_1}|k|\,v_{Ti}. \tag{8}$$

By solving (6) and (7), we obtain the following expression for the growth rate of the parametrically unstable solution for pump fields slightly larger than the threshold value:

$$\gamma=\tilde{\gamma}\left[\frac{(\mathbf{k}\cdot\mathbf{r}_E)^2\,\omega_L(\mathbf{k})}{4\,|c_0|\,k^2r_{Di}^2\nu_e\left(1+\frac{\Delta^2}{\gamma_s^2}\right)}-1\right], \tag{9}$$

where the detuning $\Delta(\mathbf{k})$ is given by

$$\Delta=\delta-\omega_1=\omega_0-\omega_L(\mathbf{k})-\omega_1(\mathbf{k}). \tag{10}$$

Equation (9) can be written in the form

$$\gamma=\tilde{\gamma}\left[\frac{P\cos^2\theta}{1+\left(\frac{k-k_m}{\Delta k}\right)^2}-1\right], \tag{11}$$

where θ is the angle between the vectors k and $\mathbf{E}_0$; the wave number k_m is the root of $\Delta(\mathbf{k}) = 0$ and is equal to

$$3k_mr_{De}=-x_0\frac{v_{Ti}}{v_{Te}}+\left[\left(x_0\frac{v_{Ti}}{v_{Te}}\right)^2+6\left(\frac{\omega_0}{\omega_{Le}}-1\right)\right]^{1/2}, \tag{12}$$

the spread in the wave vectors Δk is

$$\Delta kr_{De}=\frac{c_0}{c_1}\frac{v_{Ti}}{v_{Te}}\left(3+\frac{v_{Ti}}{v_{Te}}\frac{x_0}{k_mr_{De}}\right)^{-1}, \tag{13}$$

and the supercriticality parameter P is

$$P(\mathbf{k})=\frac{r_E^2\omega_L(\mathbf{k})}{4\,|c_0|\,r_{Di}^2\nu_e}. \tag{14}$$

It can be seen from (12) and (13) that for typical plasma parameters $\Delta k \ll k_m \lesssim k_1$, where k_1 is the root of $\delta(k_1) = 0$ and is equal to

$$k_1r_{De}=\left[\frac{2}{3}\left(\frac{\omega_0}{\omega_{Le}}-1\right)\right]^{1/2}. \tag{15}$$

For example, in experiments in the ionosphere plasma,[8] where $T_e \sim T_i$, the spread in the wave vectors is $\Delta k \approx (k_D/3)(m/M)^{1/2}$. Here, $k_D = r_{De}^{-1}$ is the Debye wave vector, and k_mr_D varies from 0.1 to 0.3 depending on the frequency of the external pump.

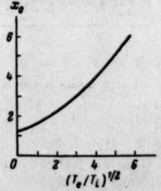

Fig. 1

II. NONLINEAR THEORY

We now consider the nonlinear theory for the instability discussed in the previous section. We are interested in how this parametric instability affects the ion distribution function. The equation for the evolution of the ion distribution in the turbulent state resulting from the imposition of an external hf field on the plasma can be written

$$\frac{\partial F(\mathbf{P},\, t)}{\partial t}=\frac{\partial}{\partial P_i}D_{ij}\frac{\partial F(\mathbf{P},\, t)}{\partial P_j}, \tag{16}$$

where the ion diffusion coefficient is

$$D_{ij}(\mathbf{P})=e^2\int\frac{d\mathbf{k}}{(2\pi)^3}k_ik_j\sum_{\mathrm{n}}|\varphi_0(\omega_{\mathrm{n}}(\mathbf{k}),\ \mathbf{k},\ t)|^2\{\pi\delta[\omega_{\mathrm{n}}(\mathbf{k})-\mathbf{k}\cdot\mathbf{v}]$$
$$-\gamma(\omega_{\mathrm{n}},\ \mathbf{k},\ t)\frac{\partial}{\partial\omega_{\mathrm{n}}}\left[\frac{P}{\omega_{\mathrm{n}}(\mathbf{k})-\mathbf{k}\cdot\mathbf{v}}\right]$$

and φ_0 is the potential of the perturbed longitudinal electric field in the plasma. The ion distribution function satisfying Eq. (16) will be sought in the form of a Maxwellian distribution with a time-dependent temperature

$$F=\frac{n}{[2\pi MT_i(t)]^{3/2}}\exp\left[-\frac{P^2}{2MT_i(t)}\right].$$

Substituting this expression into (16) and integrating over the velocities, we obtain

$$\frac{d}{dt}\left(\frac{3}{2}n_iT_i\right)=\frac{\omega_{Li}^2}{\sqrt{2\pi}}\int\frac{d\mathbf{k}}{(2\pi)^3}\frac{k^2}{4\pi}\sum_{\mathrm{n}}|\varphi_0|^2\int_{-\infty}^{\infty}dx\,x^2e^{-x^2/2}$$
$$\times\left[\pi\delta(\omega_{\mathrm{n}}-kv_{Ti}x)-\gamma\frac{\partial}{\partial\omega_{\mathrm{n}}}\left(\frac{1}{\omega_{\mathrm{n}}-kv_{Ti}x}\right)\right], \tag{17}$$

where x is the component, normalized to $v_{Ti}=(T_i/M)^{1/2}$, of the ion velocity along the vector **k**.

Below, we consider the resonant interaction, leaving only the term with the δ function in (17). This approximation is reasonable when the growth rate of the parametric instability does not exceed the rate at which ion waves are damped in the absence of a pump field.

In the resonance approximation we have the following equation for the ion temperature:

$$\frac{d}{dt}\left(\frac{3}{2}n_iT_i\right)=\sqrt{\frac{\pi}{2}}\,\omega_{Li}^2\int\frac{d\mathbf{k}}{(2\pi)^3}\frac{1}{4\pi}\sum_{\mathrm{n}}|\varphi_0|^2\frac{\omega_{\mathrm{n}}^2(\mathbf{k})}{kv_{Ti}^3}\exp\left(-\frac{\omega_{\mathrm{n}}^2}{2k^2v_{Ti}^2}\right). \tag{18}$$

The potential of the longitudinal field in the plasma is given by

$$\frac{d}{dt}\varphi_0(\omega_{\mathrm{n}},\ \mathbf{k},\ t)=\gamma(\omega_{\mathrm{n}},\ \mathbf{k},\ t)\varphi_0(\omega_{\mathrm{n}},\ \mathbf{k},\ t),$$

whose solution is written in the form

$$|\varphi_0(\mathbf{k},\ t)|^2=|\varphi_0(\mathbf{k},\ 0)|^2\exp\left[2\int_0^t\gamma(t')\,dt'\right]. \tag{19}$$

The initial value of the perturbation is determined by the thermal noise:

$$|\varphi_0(\mathbf{k},\ 0)|^2=\frac{4\pi}{k^2}(T_{e0}+T_{i0}). \tag{20}$$

The fact that the properties of the growing modes are independent of the small-scale properties of the ion distribution indicates the possibility of using in (19) the expression for γ obtained in the linear theory, but time-dependent through the macroscopic plasma parameters (the temperature). Substituting (19) and (20) and using the equations of the preceding section for ω and γ we write (18) as

$$\frac{d}{dt}(3n_iT_i)=(T_{e0}+T_{i0})\frac{\omega_{Li}^2}{\pi^{3/2}}\int_0^{k_D}kdk\frac{x_0^2}{v_{Ti}}e^{-x_0^2/2}$$
$$\times\int_0^1d\mu\exp\left[\nu_e\int_0^t\frac{P\mu^2dt'}{1+\left(\frac{k-k_m}{\Delta k}\right)^2}-\nu_et\right]. \tag{21}$$

The integral is

$$\int_0^1d\mu e^{\beta^2\mu^2}=f(\beta^2)e^{\beta^2}=\begin{cases}1+\frac{\beta^2}{3}+\dots & \text{for}\quad \beta^2\ll1,\\ \frac{1}{2\beta^2}e^{\beta^2}\left(1+\frac{1}{2\beta^2}+\dots\right) & \text{for}\quad \beta^2\gg1.\end{cases}$$

The function $f(\beta^2)$ will be approximated by the following simple expression:

$$f(\beta^2)\approx\frac{1}{1+2\beta^2}.$$

This approximation gives a good estimate for large and small values of the argument and is not very different from the true value for $\beta=1$. Then (21) reduces to

$$\frac{d}{dt}(n_iT_i)=(T_{e0}+T_{i0})\frac{\omega_{Li}^2}{3\pi\sqrt{2\pi}}\int_0^{k_D}kdk\frac{x_0^2}{v_{Ti}}e^{-x_0^2/2}f(\beta^2)\exp(\beta^2-\nu_et),$$

where

$$\beta^2=\nu_e\int_0^t\frac{Pdt'}{1+\left(\frac{k-k_m}{\Delta k}\right)^2}.$$

Since P has a fairly weak dependence on k, it can be neglected in the above equation. The dependence of $f(\beta^2)$ on k is of small importance compared to the dependence on k of the subintegrand contained in the exponent. This dependence on k in the exponent is very important since it determines the wave vector interval within which the initial thermal noise increases. Therefore, in calculating the integral over k, the function $f(\beta^2)$ can be assumed to be independent of k by setting $k=k_m$. Furthermore, we have

$$\beta^2\approx\frac{\nu_eP(t)\,t}{1+\left[\frac{k-k_m(t)}{\Delta k(t)}\right]^2}.$$

Then, the integration over k reduces to the calculation of the following integral:

$$\Psi(a,\ \Delta k,\ k_m,\ k_D)=\int_0^{k_D}kdk\exp\left[\frac{a}{1+\left(\frac{k-k_m}{\Delta k}\right)^2}\right]=\Psi_1+\Psi_2,$$

where

$$2\Psi_1=(\Delta k)^2\int_{-\frac{k_m}{\Delta k}}^{\frac{k_D-k_m}{\Delta k}}dx^2e^{\frac{a}{1+x^2}}=[(\Delta k)^2+(k_D-k_m)^2]\,e^{\frac{a(\Delta k)^2}{(\Delta k)^2+(k_D-k_m)^2}}$$

$$-[(\Delta k)^2+k_m^2]\,e^{\frac{a(\Delta k)^2}{(\Delta k)^2+k_m^2}}$$

$$+a(\Delta k)^2\left[Ei\left(\frac{a(\Delta k)^2}{(\Delta k)^2+k_m^2}\right)-Ei\left(\frac{a(\Delta k)^2}{(\Delta k)^2+(k_D-k_m)^2}\right)\right],$$

$$\Psi_2=\Delta k k_m\int\limits_{-\frac{k_m}{\Delta k}}^{\frac{k_D-k_m}{\Delta k}}dx e^{\frac{a}{1+x^2}}\approx k_m\left[k_D+\Delta k\sqrt{\frac{\pi}{a}}e^a\Phi(\sqrt{a})\right].$$

Here, Ei(x) is the exponential integral, and Φ is the error function. The second integral is estimated from an equation which gives a fairly good approximation if the limits of integration are on the order of unity. This is true in our case ($\Delta k \ll k_m < k_D$). Using the small value of Δk we obtain the following expression for Ψ:

$$\Psi\approx\frac{k_D^2}{2}+k_m\Delta k\left[\sqrt{\frac{\pi}{a}}e^a\Phi(\sqrt{a})-2\right]\quad\text{for}\quad 0<\Delta k\ll k_m<k_D.$$

As a result, the equation for the ion temperature becomes

$$\frac{dT_i}{dt}\approx(T_{e0}+T_{i0})\frac{x_0^2e^{-\frac{x_0^2}{2}}}{6\pi\sqrt{2\pi}}\frac{\omega_{Li}^2}{nv_{Ti}r_{De}^2}f(\nu_e Pt)e^{-\nu_e t}$$

$$\times\left\{1+2\frac{k_m(t)\Delta k(t)}{k_D^2}\left[\frac{\pi^{1/2}}{(\nu_e Pt)^{1/2}}\Phi\langle(\nu_e Pt)^{1/2}\rangle e^{\nu_e Pt}-2\right]\right\}. \tag{22}$$

The variation in the ion temperature depends on the characteristic parameter

$$\nu_e t_p=\frac{\nu_e}{\omega_{Li}}nr_{De}^3\left(\frac{T_{i0}}{T_{e0}}\right)^{1/2}\approx L\left(\frac{MT_{i0}}{mT_{e0}}\right)^{1/2}\gg 1,$$

where L is the Coulomb logarithm. In view of the large value of this parameter, marked temperature changes can be expected only for large times, when $\nu_e t \gg 1$. For such times we have

$$\frac{dT_i}{dt}\approx(T_{e0}+T_{i0})\frac{x_0^2}{6\pi}e^{-\frac{x_0^2}{2}}\frac{\omega_{Li}^2}{nv_{Ti}}\frac{k_m\Delta k}{(2\nu_e Pt)^{3/2}}e^{\nu_e(P-1)t}. \tag{23}$$

This equation describes the anomalous heating of ions due to the parametric instability and the exponential increase in the initial thermal noise in the region of wave vectors mentioned above. From this equation we obtain the following estimate of the characteristic time of change in the ion temperature due to the parametric instability:

$$t_T\sim\frac{1}{\nu_e(P_0-1)}\left[\frac{T_{e0}}{2T_{i0}}+8+\ln(\nu_e t_p)\right]. \tag{24}$$

It follows from this estimate that anomalous heating of ions due to the mechanism in question for the same initial supercriticality P_0 occurs much faster in a plasma with $T_{e0} \lesssim T_{i0}$ than in a strongly nonisothermal plasma with $T_{e0} \gg T_{i0}$, where the ion sound is weakly absorbed by the plasma.

Note that the case $T_{e0} \gg T_{i0}$ generally requires a more detailed analysis since we must allow for the time variation of the electron temperature, which in this limit has a significant effect on the properties of the exponential ion-acoustic fluctuations (the frequency and growth rate of the parametric instability in this limit are determined by the electron temperature).

It is also useful to point out that the ratio of the energy of the noise increasing exponentially in the initial stage to the total plasma energy at time t_T is approximately ν_e/ω_{Le}. This means that the rms electric-field fluctuation in the parametrically unstable plasma increases for a time t_T (or somewhat larger) almost to the pump-field amplitude. In this stage the fluctuations can be saturated by nonlinear effects related to interaction with the noise and scattering or beating by the ion fluctuations. If the parametric instability is not stabilized for such times due to some other processes (for example, heating of the plasma), and the ratio of noise to the total plasma energy remains constant, then

$$\frac{d}{dt}(nT_i)\sim\frac{\omega_{Li}}{k_m r_{Di}}W,$$

where W is the total noise energy. It follows that the characteristic time for a change in the ion temperature at saturation is proportional to ν_e^{-1} (it is assumed that the pump amplitude is slightly above threshold). However, these problems are beyond the scope of the present paper. Therefore, we will consider in more detail the initial stage of ion heating, when the noise level is not very large and nonlinear interaction with the noise can be neglected.

Taking the above into account, we consider the case $T_e \leq T_i$. The equation for the ion temperature is written

$$\frac{d\ln T_i}{d\tau}=\frac{c}{\tau^{3/2}}k_m\Delta k r_{De0}^2\exp\left[\tau\left(\frac{P_0T_{i0}}{T_i}-I\right)\right],\quad \tau\gg 1, \tag{25}$$

where

$$c=\frac{\omega_{Li}}{\nu_0}\frac{\left(1+\frac{T_{e0}}{T_{i0}}\right)x_0^2\exp\left(-\frac{x_0^2}{2}\right)}{12\pi\sqrt{2}nr_{Di0}r_{De0}^2}\approx\frac{1}{50\nu_0 t_p},$$

$\tau = t\nu_0$ is the dimensionless time, $I = \nu_e[T_e(t)]/\nu_0$, $\nu_0 = \nu_e(T_{e0})$, and the zero subscript denotes the initial value of the quantity. It can be seen from the equation that the time dependence of the right-hand side is determined primarily by the exponent.

If the variation in the electron temperature is neglected for time t_T, then $I(T_e) = 1$, and it follows from (25) that the ion temperature for fairly large times must reach a steady-state value due to stabilization of the ion-acoustic parametric instability by ion heating. As a result we find the maximum ion temperature which can be attained by the process in question while the electron temperature has not yet changed

$$(T_i)_{\max}=P_0T_{i0}. \tag{26}$$

In the case of small supercriticality $1 < P_0 \lesssim 2$ for $(P_0-1)\tau \gg 1$, when a marked increase in the fluctuations in the plasma is to be expected, the solution of (25) is written

$$\frac{T(\tau)}{T_{0i}}\approx 1+\frac{ck_m\Delta k r_{De0}^2}{(P_0-1)}\left(\frac{1}{\tau}+\frac{1}{\tau_{Ti}}\right)^{1/2}\exp\left[(P_0-1)\frac{\tau\tau_{Ti}}{\tau+\tau_{Ti}}\right]. \tag{27}$$

The characteristic time for a change in the ion temperature τ_{Ti} is determined by the stability condition (26) for large times $\tau \gg \tau_{Ti}$; as a result, we have

$$(P_0-1)^3\tau_{Ti}^{3/2}=ck_m\Delta k r_{De0}^2 \exp[\tau_{Ti}(P_0-1)]. \tag{28}$$

Note that the times for the characteristic change in the ion temperature obtained from (24) and (28) are of the same order of magnitude.

In the case of large supercriticality, $P_0 > 2$, Eqs. (27) and (28) still describe qualitatively the change in the ion temperature. In the initial stage the ion temperature increases exponentially, and for time τ_{Ti} the temperature increase is comparable to the initial value; then the temperature increases almost linearly ($\sim \tau/\tau_{Ti}$) and reaches a plateau fairly quickly.

In a realistic plasma with a parametric instability the electrons will also be heated after a time. This is apparent from Eq. (26). The situation is completely different for weakly and fully ionized plasmas. In a weakly ionized plasma the electron heating accelerates the stabilization process for the ion-acoustic parametric instability since $I_{\text{weak}}(T_e) = [T_e(t)/T_{e0}]^{1/2}$ increases as the electron temperature increases. The stabilization time is determined by the characteristic time of heating in a hf field of the lighter electrons, and not by the time for anomalous ion heating τ_{Ti} obtained above, although the latter is evidently a characteristic time for the change in ion temperature. The maximum ion temperature to which a relatively weak hf field (P_0 is small) heats ions in a weakly ionized plasma can be obtained from the following considerations. Since Eq. (25) is applicable when $T_i \gg T_e$ and the electrons are generally heated more rapidly than the ions, in the final analysis the electron temperature is comparable to the ion temperature (since P_0 is assumed not very large, the discontinuity in the initial values of the ion and electron temperatures should not be too large). Then the condition for reaching a plateau becomes

$$(T_i)_{\max} \sim \frac{4\pi e^2 n r_E^{4/3}}{\left[\frac{32}{3}\sqrt{2\pi}\,|c_0|\,a^2 N\right]^{2/3}} \approx \left[\frac{eE_0^2}{28\pi\,|c_0|\,n^{1/2}a^2 N}\right]^{2/3},$$

where a is the effective radius of the electron–neutral interaction ($a \sim 10^{-8}$ cm), n is the electron density, and N is the neutral density. It can be seen that the maximum attainable ion temperature in the anomalous heating process under consideration increases with the increase in the pump amplitude as $E_0^{4/3}$.

In a fully ionized plasma, heating of the electrons broadens the region with the ion-acoustic instability since $I_{\text{inst}}(T_e) = [T_{0e}/T_e(t)]^{3/2}$ declines as t increases. In view of the more rapid heating of the electrons, the parametric instability will obtain during the entire ion heating process; in this case the ion temperature will not reach a plateau. In the initial stage of the heating the characteristic time for a change in the ion temperature is determined, as before, by Eq. (24), and stabilization of the instability due to ion heating does not occur.

The transformation of a slow nonlinear acoustic wave into a fast acoustic wave in a slightly inhomogeneous plasma is analyzed. The transformation coefficient is calculated for the case in which the nonlinearity can be assumed slight.

INTRODUCTION

The existing theory for a wave transformation in an inhomogeneous medium (see, e.g., the reviews in refs. 1,2) is valid only for small amplitudes of the interacting waves. In this work we treat the transformation of weakly nonlinear stationary waves that propagate in a weakly inhomogeneous medium. Problems of this type are usually treated by various methods[3–6] in the adiabatic approximation, i.e., in the approximation that the deviation from conservation of the adiabatic invariant of the wave is exponentially small in the weakly inhomogeneous medium. Nevertheless, slight nonadiabatic corrections can be important if they alter the physical nature of the process. In this work we take account of nonadiabatic effects and the resulting transformation of essentially nonlinear waves. This method is analogous to that used in ref. 7 in a study of the reflection of nonlinear waves from a smooth inhomogeneity.

1. GENERAL STATEMENT OF THE PROBLEM

We briefly review the conditions for linear wave transformation. We assume that a medium supports two independent wavelike motions with dispersion relations $D_1(\omega, k) = 0$ and $D_2(\omega, k) = 0$, where ω is the frequency and k is the wave vector. When these waves are weakly coupled the wave motion is described by a new dispersion relation $D(\omega, k)$, which has two solutions; for weak coupling these are approximately equal to the solutions $k_1 = k_1(\omega)$ and $k_2 = k_2(\omega)$ of the original dispersion relations.

If the medium is inhomogeneous, the wave vectors are functions of the coordinate, and a linear wave transformation occurs because solutions "intersect" i.e., $k_1(\omega, x_0) = k_2(\omega, x_0)$. We have an analogous situation in the nonlinear case. The system of weakly coupled nonlinear equations describing nonlinear waves leads to the nonlinear dispersion relation $D(\omega, k, A)$, where $k \equiv \omega/u$, $u = u(A)$, is the velocity of the nonlinear wave, and A is a parameter which serves as a measure of the nonlinearity. Let us assume that this dispersion relation has the system of solutions $k_1 = k_1(\omega, A)$, $k_2 = k_2(\omega, A)$. In the case of weak coupling each of these solutions is approximately equal to the corresponding nonlinear uncoupled-wave solution. In an inhomogeneous medium we have $k_{1,2} = k_{1,2}(\omega, A(x), x)$, and there can be an intersection of the roots, i.e., regions in which two solution branches exist simultaneously. This leads to transformation of the nonlinear waves. If the transformation coefficient is small and if one of the waves, corresponding to the solution with wave vector k_2 vanishes at $x=-\infty$, while the wave corresponding to the first solution has a wave vector A_1 and an amplitude k_1, the transformation coefficient will obviously be a function of k_1 and A_1. The amplitude of the second wave (which results from the transformation) is determined by the transformation coefficient, and its wave vector is unambiguously governed by the properties of the medium and of the first wave in accordance with the nonlinear dispersion relation.

2. EQUATIONS FOR THE INTERACTION OF NONLINEAR MHD WAVES

Let us consider, for example, the interaction of nonlinear MHD waves, specifically, the fast and slow acoustic waves. We assume an inhomogeneous plasma in which the gradient of the inhomogeneity is along the oz axis; the plasma is in a fixed magnetic field $\mathbf{H}_0$, which makes a small angle ($\theta \ll 1$) with the oz axis and lies in the zy plane. We assume that MHD waves propagate parallel to the gradient of the inhomogeneity. Here the angle θ is the linear-coupling parameter: At small values of θ, the coupling is weak; for very small angles ($\theta \to 0$), on the other hand, the slow acoustic wave becomes the ion-acoustic wave, while the fast acoustic wave becomes the Alfvén wave. Accordingly, at small values of θ it is reasonable to incorporate the dispersion for the slow acoustic wave by analogy with the ion-acoustic wave.

The interaction of fast and slow acoustic waves has been analyzed thoroughly in the linear approximation.[8,9] The system of equations describing the MHD motion is

$$\left.\begin{aligned} m_i\left[\frac{\partial \mathbf{v}_i}{\partial t}+(\mathbf{v}_i\nabla)\mathbf{v}_i\right] &= e\mathbf{E}+\frac{e}{c}[\mathbf{v}_i\times\mathbf{B}],\\ m_e\left[\frac{\partial \mathbf{v}_e}{\partial t}+(\mathbf{v}_e\nabla)\mathbf{v}_e\right] &= -e\mathbf{E}-\frac{\nabla P_e}{N_e}-\frac{e}{c}[\mathbf{v}_e\times\mathbf{B}],\\ \frac{\partial N_{i,e}}{\partial t}+\operatorname{div}(N_{i,e}\mathbf{v}_{i,e}) &= 0;\ \operatorname{curl}\mathbf{B}=\frac{4\pi e}{c}(N_i\mathbf{v}_i-N_e\mathbf{v}_e),\\ \operatorname{div}\mathbf{E} &= 4\pi e(N_i-N_e);\ \operatorname{curl}\mathbf{E}=-\frac{1}{c}\frac{\partial\mathbf{B}}{\partial t};\quad \operatorname{div}\mathbf{B}=0. \end{aligned}\right\} \qquad (1)$$

We neglect the thermal motion of the ions. The plasma inhomogeneity is maintained by external conditions (e.g., an external gravitational field) and is assumed to be smooth, $[(1/N_0)/(\partial N_0/\partial z)]^{-1} \gg \lambda$, where λ is the characteristic wavelength. Neglecting the electron inertia in the longitudinal motion for the slow acoustic wave, to second order in the perturbation, we can write[10]

$$\frac{\partial^2 v_{zi}}{\partial t^2}+\frac{\partial^2}{\partial z\partial t}(v_{zi}^2)-c_s^2\frac{\partial^2 v_{zi}}{\partial z^2}-r_g^2c_s^2\frac{\partial^4 v_{zi}}{\partial z^4}=-\frac{1}{2}v_A^2\frac{\partial^2 h^2}{\partial z\partial t}-\sin\theta v_A^2\frac{\partial^2 h}{\partial z\partial t}, \qquad (2)$$

where $h = H_y/H_0$; $c_s^2 = T_e/M$; $r_g = (T_e/4\pi e^2N_0)^{1/2}$ is the Debye length, $v_A = H_0/\sqrt{4\pi m_e N_0}$ is the Alfvén velocity, and N_0 is the unperturbed density of the inhomogeneous plasma. The derivation of (2) is based on the assumption

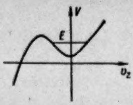

Fig. 1

that the dispersion is weak, so that the dispersion is incorporated only in the linear terms. In accordance with the discussion above, we now assume the angle θ to be small: $\theta \sim \sin\theta < 1$. In particular, we omit the nonlinear terms which are proportional to θ. For the fast acoustic waves we can write, to second order,

$$\left.\begin{aligned} &\frac{\partial h}{\partial t} = \cos\theta\frac{\partial v_{yt}}{\partial z} - \sin\theta\frac{\partial v_{zt}}{\partial z} - \frac{\partial}{\partial z}(hv_{zt}),\\ &\frac{\partial v_y}{\partial t} = v_A^2\cos\theta\frac{\partial h}{\partial z}\left(1 - \frac{\tilde{N}}{N_0}\right) - v_z\frac{\partial v_y}{\partial z},\\ &\frac{1}{N_0}\frac{\partial \tilde{N}}{\partial t} + \frac{1}{N_0}\frac{\partial}{\partial z}(\tilde{N}v_{zt}) + \frac{\partial v_{zt}}{\partial z} = 0. \end{aligned}\right\} \qquad (3)$$

In contrast with (2), the equation for the fast acoustic wave, (3) contains no nonlinear terms which refer to a wave of one type only. All the nonlinear terms in (3) are cross terms, because of the smallness of the angle θ. It should be noted that at very small angles θ the fast sound can have nonlinear "self-effect" terms only in third order in the perturbation;[11] these terms are not included in (3). Accordingly, in the absence of longitudinal motion, $v_z \simeq 0$, the fast acoustic wave (at $\theta \ll 1$) is a packet of noninteracting harmonics. An interaction among them is possible only in the presence of longitudinal motion (slow sound).

3. STEADY-STATE SOLUTIONS IN THE HOMOGENEOUS CASE

We first consider the interaction of waves in a homogeneous plasma, writing the solution as $\sim f(z - ut)$, where u is the velocity of the steady-state nonlinear wave. From (2) and (3) we find the energy integral:

$$\frac{1}{2}r_g^2(v_z')^2 + \frac{1}{2}\left(1 - \frac{u^2}{c_s^2}\right)v_z^2 + \frac{u}{3c_s^2}v_z^3 - \frac{uv_A^2}{2c_s^2}\sin^2\theta\, v_z$$
$$- \frac{uv_A}{2c_s^2}\frac{\left[\sin\theta\left(-u + \dfrac{v_A^2}{u}\cos^2\theta\right) + A\cos\theta\right]^2}{v_z - u + \dfrac{v_A^2\cos^2\theta}{u}} = E = \text{const}, \qquad (4)$$

which describes the family of possible trajectories in the phase plane, where A and E are the constants of integration. Equation (4) describes two coupled nonlinear waves. At small values of θ and of $u \gtrsim c_s$ and of $u \gtrsim v_A$ we obtain a wave which is approximately a slow or fast acoustic wave, respectively. We consider two limiting cases: a) $c_s \gg v_A$; b) $v_A \gg c_s$. In case a) we first assume $u \gtrsim c_s$; then the last term in (4) reduces to a constant increment, and the equation corresponds to the oscillation of a nonlinear oscillator describing a nonlinear slow acoustic wave. The potential is

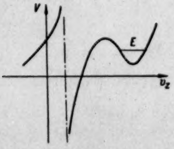

Fig. 2

$$V = \left(1 - \frac{u}{c_s}\right)v_z^2 + \frac{v_z^3}{3c_s} - \frac{v_A^2\sin\theta}{2c_s}v_z + \frac{v_A}{2c_s^2}[-u\sin\theta + A\cos\theta]^2,$$

and the potential well is shown in Fig. 1.

At $u \gtrsim v_A$ and at small values of θ, the last term in (4) becomes important. The structure of the potential well is different (Fig. 2), and the potential is

$$V = \frac{v_z^2}{2} + \frac{v_A}{3c_s^2}v_z^3 - \frac{v_A^3}{2c_s^2}\sin\theta\, v_z - \frac{v_A^2}{2c_s^2}\frac{[A\cos\theta - v_A\sin^2\theta]^2}{v_z - v_A\sin^2\theta}.$$

The solution in this case corresponds to fast sound.

In case b) the structure of the potential wells is slightly different. The structure can be easily determined by analyzing Eq. (4) for the cases $u \gtrsim v_A$ and $u \gtrsim c_s$.

Figure 3 shows the shape of the potential wells for the case $c_s \simeq v_A$. We see that both the nonlinear solutions, for slow and fast sound, exist simultaneously, and the waves propagate at the same velocity c_s. Accordingly, they interact strongly. Then even in the homogeneous case we see that as the ratio v_A/c_s changes from a very small value to a large value the structure of the solution changes. It is also easy to see that in an inhomogeneous plasma in the case $v_A \sim c_s$ we should find a new characteristic mode, i.e., there should be a transformation of one type of wave into another.

4. WAVE-TRANSFORMATION COEFFICIENT IN AN INHOMOGENEOUS PLASMA

We consider nonlinear waves which are periodic in time (with frequency ω) and which propagate in a weakly inhomogeneous plasma. To determine the coefficient of the transformation between these waves we expand (2) and (3) in a Fourier series, finding

$$\left.\begin{aligned} &\frac{d^2v_{zn}}{dz^2} + \frac{n^2\omega^2}{c_s^2}v_{zn} + r_g^2\frac{d^4v_{zn}}{dz^4} - \frac{i\omega_n}{c_s^2}\\ &\times\sum_{(k,\,m)}\frac{d}{dz}(v_{zm}v_{zk})\,\delta(n - k - m) = -\theta\frac{\omega^2n^2}{c_s^2}v_{ny},\\ &\frac{d^2v_{yn}}{dz^2} + \frac{\omega^2n^2(c_s^2 + \theta^2v_A^2)}{v_A^2c_s^2}v_{ny} = -\theta\frac{n^2\omega^2}{c_s^2}v_{zn}\\ &-\sum_{(k,\,m)}\frac{d^2}{dz^2}\left[\frac{1}{i\omega_k}\frac{dv_{yk}}{dz}v_{mz}\right]\delta(n - m - k), \end{aligned}\right\} \qquad (5)$$

where

$$v_{z,y} = \sum_n (v_{z,y;n}e^{i\omega_nt} + v^*_{z,y;n}e^{-i\omega_nt}).$$

In particular, for slow sound with N_0 = const and $\theta \ll 1$ (ref. 7), we have $v_{zn} = a_ne^{-ink_sz}$, where k_s is the wave vector of the first harmonic, and a_n is independent of z and t, being given by

$$a_n = \begin{cases} \text{const}, & n \leqslant N_*,\\ e^{-n/N_*}, & n \geqslant N_*, \end{cases}$$

where N∗, the number the harmonics whose amplitudes

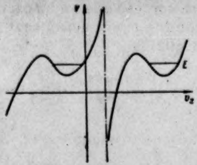

Fig. 3

are of the order of the first harmonic, is governed by the extent of the nonlinearity. In a weakly inhomogeneous plasma, we seek a solution of (5) in the form

$$\left.\begin{aligned} v_{zn}^{(\pm)} &= B_n^{(\pm)} \exp\left\{ \mp in \int^{z} k_s^{(\pm)}(z')\,dz' \right\}, \\ v_{yn}^{(\pm)} &= A_n^{(\pm)} \exp\left\{ \mp in \int^{z} k_A^{(\pm)}(z')\,dz' \right\}, \end{aligned}\right\} \quad (6)$$

where $u_{nz}^{(+)}$ and $v_{ny}^{(+)}$ are the harmonics of the incident wave $v_z^{(+)} = \sum_n v_{zn}^{(+)} e^{in\omega t}$ and $v_y^{(+)} = \sum_n v_{yn}^{(+)} e^{in\omega t}$, and $v_{n;\,y,z}^{(-)}$ are those of the reflected waves $v_{y,\,z}^{(-)} = \sum_n v_{z,y;\,n}^{(-)} e^{-in\omega t}$; k_s and k_A are the wave numbers of the slow and fast acoustic waves at the first harmonic.

Substituting (6) into (5), we see that in the first approximation $v_{nz}^{(+)}$ and $v_{ny}^{(+)}$ satisfy the equations

$$\left.\begin{aligned} \frac{d^2 v_{zn}}{dz^2} + n^2 k_s^2(z) v_{nz} &= -\alpha v_{yn}, \\ \frac{d^2 v_{yn}}{dz^2} + n^2 k_A^2(z) v_{ny} &= -\alpha v_{zn}, \end{aligned}\right\} \quad (7)$$

where $k_A(z)$ and $k_s(z)$ are functions of z and of the parameter, through $N_0(z)$; and where $\alpha \equiv \theta n^2 \omega^2 / c_s^2$. We assume for the moment that we are solving system (7) separately for each pair v_{zn} and v_{yn}, neglecting the interaction between harmonics. Then the process of finding the transformation coefficient for system (7) reduces to the linear case for each harmonic n, and the relationship between the amplitudes on different sides of the interaction region is[12]

$$\left.\begin{aligned} A'_n &= e^{-n\delta} A_n + \sqrt{1 - e^{-2n\delta}}\, B_n, \\ B'_n &= \sqrt{1 - e^{-2n\delta}}\, A_n - e^{-n\delta} B_n, \end{aligned}\right\} \quad (8)$$

where

$$\delta = -\frac{i}{4} \oint_{c} (k_A - k_s)\,dz'. \quad (9)$$

The integral is evaluated along a closed contour in the complex plane encompassing points at which $k_A^2(z) = k_s^2(z)$. Since $\delta \gg 1$, in a first approximation it is sufficient to consider a transformation effect of order $e^{-\delta}$, i.e., the transformation of the first harmonic, and to neglect the transformation of the higher harmonics. We have derived Eqs. (8) without taking account of the coupling between harmonics. Now we assume a weak coupling, due to the nonlinear terms, and we seek the solution in the form

$$v_{zn}^{(\pm)} = \left[\mp \frac{B_n^{(\pm)}(z)}{ik_s^{(\pm)}(z)\,n} + b_n^{(\pm)}(z) \right] e^{\mp in \int^{z} k_s^{\pm}(z')\,dz'},$$

$$v_{yn}^{(\pm)} = \left[\mp \frac{A_n^{(\pm)}(z)}{ik_A^{(\pm)}(z)\,n} + a_n^{(\pm)}(z) \right] e^{\mp in \int^{z} k_A^{\pm}(z')\,dz'}, \quad (10)$$

where $B_n^{(\pm)}$ and $A_n^{(\pm)}$ are slowly varying functions of z, and $b_n^{(\pm)}$ and $a_n^{(\pm)}$ are rapidly varying functions. Substituting (10) into system (5), and omitting the second derivatives of the slowly varying functions, we find

$$\frac{dB_n}{dz} = -i\,\frac{k_s n}{c_s}\, B_n A_0, \quad (11)$$

$$\frac{dA_n}{dz} = i\,\frac{k_A n}{c_s}\, A_n B_0 \quad (12)$$

where

$$\Delta k_s \simeq \frac{k_s}{c_s} A_0; \quad \Delta k_A \simeq \frac{k_A}{c_s} B_0.$$

That is, the phase corrections to the wave number due to the nonlinear terms are governed by the zeroth wave harmonics in the first approximation,[8] i.e.,

$$k_A(z) \simeq \frac{\omega}{v_A(z)(1 + \alpha_A)} \text{ and } k_s = \frac{\omega}{c_s(1 + \alpha_s)},$$

where α_s and α_A are given by (12) ($\alpha_s, \alpha_A \ll 1$). Since $\alpha_s, \alpha_A \ll 1$, we can neglect the functional dependences of these quantities on z. Then the analytic properties of k_A and k_s are independent of the wave amplitude and are determined as in the linear case.

Substituting the expressions for k_A and k_s into (9), we find

$$\delta = -\frac{i}{4} \oint (k_A - k_s)\,dz' \simeq \frac{\pi}{2} \theta^2 \frac{\omega L}{c_s(1 + \alpha_s)}. \quad (13)$$

We see from (13) that, generally speaking, the nonlinearity leads to a reduction of δ and thus an increase in the efficiency of the transformation between normal modes.[2] If, as x → −∞, we have

$$v_z(z - ut) = \sum_n B_n^{(+)} \exp\left\{ in \left[\omega t - \int^{z} k_s(z')\,dz' \right] \right\},$$

then as x → + ∞ we find

$$v_z(z - u_s t) = \sum_n B_n^{(+)} \exp\left\{ in \left[\omega t - \int^{z} k_s(z')\,dz' \right] \right\};$$

in addition, we find

$$v_y = B_1^{(+)} e^{-\delta} \sin\left[\omega t - \int^{z} k_A(z')\,dz' + \varphi \right],$$

where φ is the phase.

CONCLUSION

We have analyzed the effect of nonlinearity in the case in which there is a "super-barrier intersection of solutions" in the linear approximation.[2] Generally speaking, a nonlinear stationary wave is destroyed in the transformation, and a many-stream mode should arise.[8] These arguments are plausible since the phase and amplitude relations between the harmonics of a stationary wave are maintained very closely, and these relations can be violated in the transformation. In this problem, however, the higher harmonics of the resulting wave are exponentially small in comparison with the first harmonic, so that a single-stream mode is "generated" in the first approximation. On the other hand, we can cite at least two examples in which the flow is of a many-stream nature: first, reflection of a nonlinear stationary wave from a δ-shaped singularity[8] (in general, reflection and transformation at a sharp boundary should have the same properties); second, incidence of a nonlinear stationary wave on a region in which the refractive index for one of the harmonics has a singularity in the linear approximation.[13] In this case, despite the nonlinear dispersion relation, the first harmonic is effectively synchronized with other harmonics even in the linear approximation, so that there can be a "scattering" of the nonlinear stationary wave.[13] We note that in this case for the linear approximation the transformation in question is of an anomalous type.[2]

The authors thank N. S. Erokhin for useful discussion.

Two-stream flow in a thin plasma slab

A. V. Pashchenko and B. N. Rutkevich

(Submitted December 21, 1973)
Zh. Tekh. Fiz., 44, 2483-2488 (December 1974)

A general solution is found for the problem of two-stream hydrodynamic flow in a thin plasma slab in a strong longitudinal magnetic field. The solutions of problems with initial boundary conditions are classified, and the role of a simple wave in the general solution is indicated. The possible use of the simple-wave concept to describe the two-stream instability in a beam–plasma system is discussed.

INTRODUCTION

Various cases of two-stream flow in plasma have been treated in a long series of papers, beginning with refs. 1 and 2. In particular, there has been an analysis of the beam–plasma system, in which the beam electrons and the plasma execute certain types of motion against a fixed ion background. The electromagnetic fields which arise must be small for the analysis to hold.

In this work we find a general solution for the problem of two-stream hydrodynamic flow in a thin plasma slab. We determine the nature of the wave motion in the two-stream system for specified initial or boundary conditions. The results are obtained without the assumption that the field amplitudes are small, and the results can be extended to both electron–electron and electron–ion flow.

1. EQUATIONS OF A THIN PLASMA SLAB

The model of a thin plasma slab for the case of single-stream electron flow is described in detail in refs. 3, 7; we treat two-stream flows on the basis of this model.

We consider a slab of cold plasma of thickness of 2d, arranged symmetrically with respect to the x = 0 plane between two conducting planes at x = ± D, held at ground potential. We assume the system to be homogeneous in the y direction. Along the z axis is a magnetic field, which we assume to be so strong that we need take into account only the longitudinal motion of the particles.

Two-stream electron–electron flow in the slab is described by

$$\frac{\partial v_j}{\partial t}+v_j\frac{\partial v_j}{\partial z}=-\frac{e_j}{m_j}\frac{\partial \varphi}{\partial z}, \tag{1}$$

$$\frac{\partial n_j}{\partial t}+\frac{\partial (n_j v_j)}{\partial z}=0, \quad j=1,\ 2, \tag{2}$$

$$\frac{\partial^2 \varphi}{\partial x^2}+\frac{\partial^2 \varphi}{\partial z^2}=\begin{cases}-4\pi\sum\limits_{l=1}^{3} e_l n_l, & |x|<d,\\ 0, & d<|x|<D;\end{cases} \tag{3}$$

where the notation is standard. In Eq. (3), $e_1 = e_2 = -e$, $e_3 = e$, and $n_3 = n_0$ is the density of the ion background.

As in the single-stream case,[3,7] we find that, under the conditions d ≪ D ≪ L (where L is the scale length of the perturbation), the Poisson equation, Eq. (3), reduces to

$$\varphi=\begin{cases}4\pi\sum\limits_{l=1}^{3} e_l n_l\left(1-\frac{d}{2D}-\frac{x^2}{2dD}\right)dD, & |x|\leqslant d,\\ 4\pi\sum\limits_{l=1}^{3} e_l n_l\left(1-\frac{|x|}{D}\right)dD, & d\leqslant|x|\leqslant D.\end{cases}$$

Since d ≪ D, within the slab we can write, to order O(d/D),

$$\varphi=4\pi dD\sum_{l=1}^{3} e_l n_l. \tag{4}$$

Substituting (4) into (1), we find

$$\frac{\partial v_j}{\partial t}+v_j\frac{\partial v_j}{\partial z}+\lambda\sum_{l=1}^{2}\frac{\partial n_l}{\partial z}=0, \tag{5}$$

where

$$\lambda=\frac{4\pi e^2 dD}{m}.$$

2. GENERAL SOLUTION

Equations (2) and (5) give v_j and n_j as functions of z and t. We seek a solution of this system of equations by the method of characteristics.[4] In vector and matrix notation, we can write this system as

$$L_j[u]=a_{ij}\frac{\partial u^i}{\partial t}+b_{ij}\frac{\partial u^i}{\partial z}=0 \quad (j=1,\ 2,\ 3,\ 4), \tag{6}$$

where u is a vector having the components $u^1 = v_1$, $u^2 = v_2$, $u^3 = n_1$, $u^4 = n_2$; a_{ij} and b_{ij} are the elements of matrices A and B;

$$B=\begin{pmatrix} v_1 & 0 & \lambda & \lambda\\ 0 & v_2 & \lambda & \lambda\\ n_1 & 0 & v_1 & 0\\ 0 & n_2 & 0 & v_2\end{pmatrix}; \tag{7}$$

and A = E is the unit diagonal matrix. To find the characteristic curves of system (6), we must solve the equation

$$|B-\tau A|=0 \tag{8}$$

or, equivalently, the equation

$$\frac{\lambda n_1}{(v_1-\tau)^2}+\frac{\lambda n_2}{(v_2-\tau)^2}=1 \tag{9}$$

(which becomes the familiar dispersion relation in the linear limit) for τ. The characteristic curves are described by

$$\frac{dz}{dt}=\tau. \tag{10}$$

On these curves we solve the following system of linear homogeneous equations for the vector l, with components l_1, l_2, l_3, l_4:

$$l_j(b_{ij}-\tau a_{ij})=0, \quad j=1,\ 2,\ 3,\ 4.$$

We find

$$l_2=\frac{n_2(v_1-\tau)^2}{n_1(v_2-\tau)^2}l_1,\quad l_3=-\frac{v_1-\tau}{n_1}l_1,\quad l_4=-\frac{(v_1-\tau)^2}{n_1(v_2-\tau)}l_1. \quad (11)$$

Now using the linear combination $\sum_{j=1}^{4} l_j L_j[u]$, we can write the original system of equations in characteristic canonical form:

$$\left(\frac{\partial}{\partial t}+\tau_j\frac{\partial}{\partial z}\right)\left(\frac{\tau_j}{\lambda}-\frac{n_1}{v_1-\tau_j}-\frac{n_1}{v_2-\tau_j}\right)=0,\quad j=1,2,3,4. \quad (12)$$

The differentiation in (12) is carried out along the direction of the characteristic curve corresponding to the root τ_j. After integrating (12), we find a system of algebraic equations:

$$\frac{\tau_j}{\lambda}-\frac{n_1}{v_1-\tau_j}-\frac{n_2}{v_2-\tau_j}=F_j\left(t-\int_0^z\frac{dz}{\tau_j}\right),\quad j=1,2,3,4, \quad (13)$$

where F_j is some arbitrary function.

Equations (9) and (13), with specified F_j, give v_1, v_2, n_1, and n_2 as functions of t and z. The functions F_j are determined from system (13) if, at z = 0, we specify v_1, v_2, n_1, and n_2 as functions of the time or if these quantities are specified as functions of the coordinate at t = 0. Below we treat the first case in its general form.

3. PROBLEM WITH A BOUNDARY CONDITION

We assume that the u^j are specified as functions of the time at z = 0. Without any loss of generality we can assume

$$u^j(t_0)=c_{1j}+g_j(t_0)\,1(t_0), \quad (14)$$

where

$$1(s)=\begin{cases}1, & \operatorname{Re}s>0,\\ 0, & \operatorname{Re}s<0,\end{cases} \quad (15)$$

and c_{ij} is a constant, i.e., we are assuming that before time $t_0 = 0$ the variable component of u^j is zero. Then from (9) and (13) we find

$$F_j(t_0)=c_{2j}+f_j(t_0)\,1(t_0), \quad (16)$$

and system (13) becomes

$$\frac{\tau_j}{\lambda}-\frac{n_1}{v_1-\tau_j}-\frac{n_2}{v_2-\tau_j}=c_{2j}+f_j\left(t-\int_0^z\frac{z}{\tau_j}\right)1$$
$$\times\left(t-\int_0^z\frac{dz}{\tau_j}\right),\quad j=1,2,3,4. \quad (17)$$

To classify the solutions of this problem on the basis of (9) and (17), we write Eq. (9) as the system of equations

$$\left.\begin{aligned}y=\frac{\lambda n_1}{(v_1-\tau)^3}+\frac{\lambda n_2}{(v_2-\tau)^3},\\ y=1.\end{aligned}\right\} \quad (18)$$

The solution is shown qualitatively in Fig. 1 by the abscissas of the points A_1, A_2, A_3, and A_4. As long as the ordinate of point M satisfies $y_M < 1$, the roots τ_1, τ_2, τ_3, and τ_4 are real and different. They represent "phase" velocities of the waves propagating in the slab. Below we refer to the wave corresponding to τ_j as "wave j."

Waves 1 and 2 are "coupled" with stream 1, and waves 3 and 4 are coupled with stream 2. In the case $v_{10} = 0$, $v_{20} \neq 0$, the former are the "backward" and "forward" plasma waves, while the latter are "slow" and "fast" beam waves.

The ordinate of point N can be either larger than or smaller than unity, depending on the values of v_1, n_1, n_2, and v_2. If it is smaller than unity we have $\tau_1 > 0$, and we find that all the waves propagate in the same direction.

When $y_M = 1$ the quantities τ_2 and τ_3 are equal; when $y_M > 1$ they are complex. This corresponds to instability. The threshold for the instability is determined from

$$\left.\begin{aligned}y=1,\\ \frac{dy}{d\tau}=0,\end{aligned}\right\} \quad (19)$$

so that the condition relating the parameters at the boundary and in the instability region is

$$\lambda^{1/3}(n_1^{1/3}+n_2^{1/3})\geqslant(v_2-v_1)^{2/3}. \quad (20)$$

At the boundary we have

$$\tau_2=\tau_3=\alpha_0=v_2-[\lambda n_2(v_2-v_1)]^{1/3}=v_1-[\lambda n_1(v_1-v_2)]^{1/3}, \quad (21)$$

$$\tau_{1,4}=(v_1+v_2-\alpha_0)\left\{1\mp\left[1+\frac{\alpha_0(v_1+v_2)-3v_1v_2}{(v_1+v_2-\alpha_0)^2}\right]^{1/2}\right\}. \quad (22)$$

If $\tau_j = \alpha_j + i\beta_j$ in the instability region, then $\beta_j = 0$ at the boundary.

Let us find the "phase" velocities of waves 2 and 3 in the unstable case. We see from (17) that the phases are given by

$$t-\int_0^z\frac{dz}{\tau_j}=t-\int_0^z\frac{\alpha_j dz}{\alpha_j^2+\beta_j^2}+i\int_0^z\frac{\beta_j dz}{\alpha_j^2+\beta_j^2},$$

so that

$$v_p^{(j)}=z\left(\int_0^z\frac{\alpha_j dz}{\alpha_j^2+\beta_j^2}\right)^{-1}. \quad (23)$$

Since τ_2 and τ_3 are complex conjugates, we have $v_p^{(2)} = v_p^{(3)}$.

Because of the unit functions on the right-hand side of (17), we can classify the solutions of this problem. In accordance with the definition of the unit function, (15), we conclude that in the case $[t - z/v_p^{(j)}] < 0$ we are left with only the constant term on the right-hand side of (17). Since, on the other hand, the phase velocities of the waves are related by

$$v_p^{(1)}<v_p^{(2)}\leqslant v_p^{(3)}<v_p^{(4)},$$

we find that in the {z, t} plane there are four distinct regions of nonvanishing solutions ($v_p^{(2)} < v_p^{(3)}$, correspond-

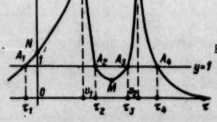

Fig. 1. Graphical solution of the characteristic equation.

ing to stability) or three such regions ($v_p^{(2)} = v_p^{(3)}$, corresponding to instability), and we can replace (17) for each by the equivalent system

$$\frac{\tau_i}{\lambda} - \frac{n_1}{v_1 - \tau_i} - \frac{n_2}{v_2 - \tau_i} = c_{2i}, \quad i = 0, 1, \ldots, k, \tag{24}$$

$$\frac{\tau_j}{\lambda} - \frac{n_1}{v_1 - \tau_j} - \frac{n_2}{v_2 - \tau_j} = c_{2j} + f_j\left(t - \int_0^z \frac{dz}{\tau_j}\right),$$

$$j = (k+1), \ldots, 4, \tag{25}$$

where $0 \leq k \leq 3$.

In the case k = 3 the solution of system (9), (24), and (25) is a simple wave. In fact, Eqs. (9) and (24), in correspondence with the theorem for the existence of implicit functions,[5] give any three quantities in the set n_1, n_2, v_1, v_2 as a function of the fourth. The Jacobian used in this existence theorem turns out to be nonvanishing in all cases in which we can speak of two streams ($n_2 \neq 0$, $v_1 \neq v_2$). Substituting the quantities determined in this manner into (25), we find an equation which gives the fourth quantity as a function of the coordinates and the time.

The simple wave describes the part of the propagation region of the fast wave of the second beam not yet reached by the slow wave of the same beam and, in the case $\tau_1 < 0$, the backward wave of the first beam. The simple wave delineates the region of a "common solution," on the one hand, and the unperturbed region on the other, in accordance with the theorem of ref. 6. The boundaries of the region occupied by the simple wave are described by the inequalities

$$v_p^{(3)} < \frac{z}{t} < v_p^{(4)} \tag{26}$$

($\tau_1 < 0$),

$$z < 0. \tag{26a}$$

In the case k = 0 we can, in principle, determine from system (9), (24) any two quantities as functions of the other two; system (25) then gives these remaining quantities as functions of the time and the coordinate. This solution describes the region in which the fast and slow waves of the second beam interact in the stable regime. If the parameters are such that both $\tau_1 < 0$ and $\tau_2 < 0$ (oppositely directed beams), the interaction of waves 1 and 2 is also covered in this case. The boundaries of the region are given by the inequalities

$$v_p^{(2)} < \frac{z}{t} < v_p^{(3)}, \tag{27}$$

and, in the case $\tau_1 < 0$, $\tau_2 < 0$, by the inequalities

$$0 < \frac{z}{t} < v_p^{(3)}, \tag{27a}$$

$$v_p^{(2)} < \frac{z}{t} < 0. \tag{27b}$$

The case k = 1 leads to three equations of system (25), which describe the region in which the second, third, and fourth waves interact. The boundaries of this region are given by

$$v_p^{(2)} > \frac{z}{t} > \begin{cases} v_p^{(1)}, & v_p^{(1)} > 0, \\ 0, & v_p^{(1)} > 0. \end{cases} \tag{28}$$

The solution with k = 0 holds only in the case $v_p^{(1)} > 0$ and describes the region in which all four waves interact ($0 < z/t < v_p^{(1)}$). The solutions match up in a natural manner at the boundary of the regions if we choose the $u^j(t_0)$ to be continuous functions satisfying $u^j(0) = 0$. This latter condition is a natural condition and does not restrict the generality of the discussion, if we exclude the propagation of discontinuities from this analysis.

In a study of the two-stream instability a case of particular interest is the case k = 1, which describes the region z > 0 in the beam–plasma system for large values of t. The region z < 0 is described by a simple wave here. The simple-wave concept has been used previously[3] to describe the two-stream instability in the k = 1 region; this procedure is valid only in a certain approximation. Let us examine the meaning of this approximation.

As mentioned earlier, in the case k = 1 the solution follows from a system of three equations like (25), while the simple wave is described by a single equation of this type. Accordingly, in two of the equations the f_j must be assumed equal to zero. Let us see whether there is a justification for this assumption.

We can treat the solution with k = 1 as the result of an interaction between unstable waves 2 and 3 propagating against the background of wave 4 and interacting with this background. Since one of the waves (2 or 3) decays while the second grows, at a sufficiently high amplitude of the growing wave the amplitudes of the other waves are negligible in comparison with the amplitude of the growing wave, so that we can neglect them. In this approximation an unstable growing wave delineates the region of unperturbed plasma and is described by a single equation like (25), i.e., it is in fact a simple wave.

We have thus found a general solution for the problem of electron–electron flow in a thin plasma slab. The entire solution can be easily generalized to the case of ion–electron flow.

The initial-condition problem can be solved in similar fashion; a fundamental difference in this case is that we can introduce unit functions over some interval of the z axis only if the functions f_j vanish on this interval. In general, on the other hand, the solution of the problem at any point z and at any time is the result of the interaction of all four waves and is described by a system of equations analogous to (9), (25) in the case k = 0.

Energy balance in Tokamaks in the "plateau–banana" transition region

Yu. N. Dnestrovskii and D. P. Kostomarov

Physics Faculty, M. V. Lomonosov Moscow State University

(Submitted December 14, 1973)
Zh. Tekh. Fiz., 44, 2489-2492 (December 1974)

The transition to a collisionless regime at large currents in modern Tokamaks is investigated by numercial integration of the energy-balance equations. It is shown that the presence of cold neutrals can reduce significantly the plasma ion temperature and impede the transition from the plateau regime to the banana regime.

Theoretical investigations yield significantly different values and scaling of the thermal conductivity, χ_i, for different collision frequencies.[1-3] If the collision frequency is small, i.e.,

$$\tilde{\nu}=\frac{\nu_j}{\nu_B}=20\frac{Rn}{T_j^2}\left(\frac{R}{r}\right)^{3/2}\ll 1 \tag{1}$$

(this is the region of banana orbits for trapped particles; ν_B is the bounce frequency in the banana), then

$$\chi_j\sim\frac{a^2n}{H^2\sqrt{T_j}}, \tag{1a}$$

if

$$\tilde{\nu}_j\gg 1 \tag{2}$$

(plateau region), then

$$\chi_j\sim\frac{T_j^{3/2}q}{H^2}. \tag{2a}$$

Here, R is the major radius of the torus, n is the plasma density in 10^{13} cm^{-3}, T_j is the temperature of the j-th species in eV, and q is the safety factor with respect to MHD stability. At present a number of machines are operating in which the transformation from region (2) to region (1) is possible for the ions. Experimental confirmation of the existence of a banana region and of the scaling in Eq. (1a) will evidently be one of the basic goals of Tokamak research in the next few years. In addition, the complex dependence of all variables on the coordinates and the presence of a series of poorly controllable factors which increase losses (cold neutrals, impurities) require that detailed calculations be carried out in order to compare the results of theory with experiment. Some results of these kinds of calculations (without considering the effect of impurities) are presented in this note.

The following system of equations[4] is used to describe the energy balance:

$$\left.\begin{aligned}\frac{\partial T_i}{\partial t}&=\frac{1}{xn}\frac{\partial}{\partial x}\left(xn\chi_i\frac{\partial T_i}{\partial x}\right)+Q_{ei}-Q_{in},\\ \frac{\partial T_e}{\partial t}&=\frac{1}{xn}\frac{\partial}{\partial x}\left(xn7\gamma\chi_e\frac{\partial T_e}{\partial x}\right)-Q_{ei}-Q_{en}+Q_{\text{joul}},\\ \frac{\partial\mu}{\partial t}&=\frac{A}{x}\frac{\partial}{\partial x}\left[\frac{\gamma}{T_e^{3/2}}\frac{1}{x}\frac{\partial}{\partial x}(x^2\mu)\right].\end{aligned}\right\} \tag{3}$$

Here $x = r/a$, a is the semiminor axis of the torus, t is the time in msec, $\mu = 1/q = RH_\vartheta/rH$, H is the longitudinal magnetic field in kOe, $n = n_0(1 - 0.8x^2)$ $A = 6.1\cdot 10^3/a^2$, $Q_{ei} = Cn/T_e^{3/2}(T_e - T_i)$ is the Coulomb heat exchange between the electrons and ions, Q_{in} and Q_{en} are the thermal losses through the cold neutrals, $Q_{\text{joul}} = (B\gamma/nT_e^{3/2})\cdot[(1/x)(\partial/\partial x)(x^2\mu)]^2$ is the Joule heat, $C = 470/p$, $B = 2\cdot 10^7H^2/R^2$, p is the reduced mass of the plasma ions, γ is the anomalous resistance factor as compared with the classical value, and

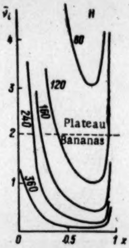

Fig. 1

$$\left.\begin{aligned}\chi_j&=300F_j\frac{nq^2}{a^2H^2\sqrt{T_j}}\left(\frac{R}{r}\right)^{3/2}J(\tilde{\nu}_j),\\ J(\nu)&=0.3\int_0^\infty\frac{e^{-z}z^2dz}{\sqrt{z+\nu^2}},\quad F_i=\sqrt{p},\quad F_e=5\left(\frac{m_e}{m_i}\right)^{1/2}.\end{aligned}\right\} \tag{4}$$

The model kinetic equation of refs. 5 and 6 is used to describe the neutrals in the plasma and to calculate Q_{in} and Q_{en}.

As an example the results of an energy balance calculation for the T-4 device,[7] with parameters R = 90 cm, a = 17 cm, n_0 = 5, and H = 40 kOe, are presented in the figures. Figures 1 and 2 refer to a hydrogen plasma without neutrals. Figure 1 shows the dependence of the ion collision frequency, ν_i, on the spatial coordinate for various plasma currents, I = 80, 120, 160, 240, and 360 kA. The dotted line separates regions (1) and (2). For currents I < 100 kA the curves lie within region (2). The current range 100 < I < 200 kA corresponds to a transition region. For I > 200 kA the major part of the plasma cross section is

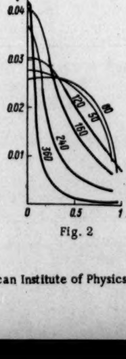

Fig. 2

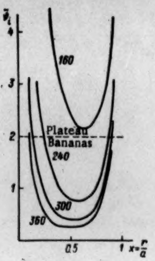

Fig. 3

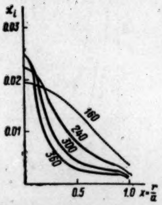

Fig. 4

in region (1) and only in the center of the plasma is $\tilde{\nu}_i$ large.

Figure 2 shows the dependence of the coefficients of ion thermal conductivity, χ_i (Eq. 4), on x for the same parameter ranges. The thick parts of the curves correspond to region (1). For small currents [region (2)] χ_i increases with current. In this case $T_i \sim I$, $\chi_i \sim I^{1/2}$ (Eq. 2a). In the transition to regime (1), χ_i begins to fall off rapidly as the current increases; however, this reduction is not uniform over the plasma cross section. For currents, $I \sim 150$ kA, χ_i is as large as before over the bulk of the plasma and only the peripheral region of the plasma forms a thermally insulating layer. In the transition region for the current, regime (1) still does not hold for the ring as a whole. For currents $I > 200$ kA the thickness of the thermally insulating shell becomes comparable to the plasma radius and the discharge goes over to region (1).

The presence of cold neutrals impedes the transition to a banana regime. Figures 3 and 4 show the analogous distributions of $\tilde{\nu}_i$ and χ_i with respect to radius for various currents for a reasonable vacuum value of the neutral density, $N = 5 \cdot 10^9$ cm^{-3}. It is clear that only at large currents, $I > 300$ kA, can we expect a transition into regime (1). Even larger currents are required for a deuterium plasma to enter the banana regime. Figure 5 shows the dependence of the maximum ion temperature, $T_{i\max}$, on the current for hydrogen (H) and deuterium (D) plasmas for the cases N = 0 and $5 \cdot 10^9$ cm^{-3} (curves 1 and 2, respectively). The behavior of the curves for N = 0 corresponds to the above noted features of the transition from regime (2) to regime (1). For a hydrogen plasma at $I < 120$ kA, $T_{i\max}$ shows a linear dependence on the current. Artsimovich's formula, $T_i \sim I^{1/3}$, for a density of $n_0 = 5$ applies poorly since the ratio $\delta = (T_e - T_i/T_e)$ is small (for a hydrogen plasma at I = 100 kA, $\delta \sim 0.2$). For currents, $I > 150$, kA $T_{i\max}$ increases more rapidly than linearly, which agrees with the estimate for regime (1): $T_i \sim 0.01\ (I^2/p^{3/2})\ (R/a)^{1/2}$.

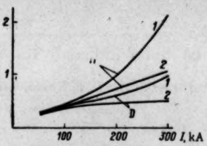

Fig. 5

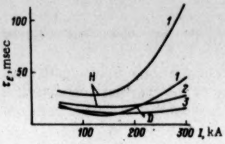

Fig. 6

For a neutral density $N \sim 5 \cdot 10^9$ cm^{-3} the linear behavior of $T_{i\max}$ as a function of the current, I is maintained up to $I \sim 300$ kA, and it is difficult to define the transition into the banana regime in terms of the ion temperature alone in this case.

The dependence of the energy lifetime, τ_E, on the current for the same discharge parameters is shown in Fig. 6. At low neutral densities experimental measurements in regime (1) are complicated by the large values of τ_E. For $I \sim 300$ kA, $\tau_E \sim 100$ msec, and in order to establish a stationary regime it is necessary to keep the current constant over 200-300 msec.

Thus, the transition to the banana regime is possible in T-4 devices; however, experimental confirmation of such a transition requires large currents ($I \sim 300$ kA), a high vacuum ($N \leqslant 10^9$ cm^{-3}), and a long discharge. We note that when the plasma density is increased and the torus radius is small the effect of the remaining gas on the energy balance decreases. In this case the transition to a banana regime may be easier.

The present work was done at the suggestion of the late Academician L. A. Artsimovich.

Anisotropic plasma heating near the lower hybrid frequency

V. M. Glagolev, V. V. Martynenko, and Yu. V. Skosyrev

(Submitted September 6, 1973; resubmitted March 23, 1974)
Zh. Tekh. Fiz., 44, 2493-2499 (December 1974)

The ion and electron energy components associated with the transverse and longitudinal motion with respect to a fixed magnetic field are measured in the heating of a plasma with a density of 10^{12} cm^{-3} at a frequency near the lower hybrid frequency. The transverse energy of the particles is determined with a multigrid probe which measures the currents parallel to the magnetic field. The method for finding the energy is based on the effect of the magnetic field at the probe on the voltage–current characteristics of the probe. The plasma is heated by the excitation of ordinary and extraordinary waves at the plasma surface by means of a coupling loop and the subsequent transformation of these waves into plasma waves. Measurements show that the average ion energy associated with the motion across the magnetic field is equal to the total transverse energy of the plasma found from the diamagnetic signal. Thus, the transverse energy of the ion component increases in the heating process. The average ion energy, measured from the spectrum of charge-exchange neutrals over the range 0.5-3 keV, is 250 eV, in good agreement with the results obtained by the method described above. The transverse electron energy is much lower than the transverse ion energy. It is found experimentally that both transverse and longitudinal ion heating occur in a homogeneous magnetic field.

INTRODUCTION

Recent theoretical[1,2] and experimental[3-5] work has shown that one of the most promising methods for increasing the energy of plasma ions is plasma heating at a frequency near the lower hybrid frequency. The ion heating results from Cerenkov absorption of energy from the plasma waves which appear in the linear transformation of electromagnetic waves or from nonlinear effects, e.g., parametric instabilities. Since a plasma wave propagates nearly perpendicularly to the magnetic field near the lower hybrid resonance, the transverse ion energy increases. The Cerenkov absorption of electromagnetic waves by magnetized electrons tends to build up the longitudinal electron energy.

It has been reported[6] that the plasma diamagnetism increases when the plasma is subjected to a high-frequency electric field. A study of the propagation conditions for electromagnetic waves near the lower hybrid resonance is reported in ref. 7. The observed retardation and strengthening of the electric field of the ordinary (type E) wave during heating verify the suggestion that the plasma heating is due to wave transformation. On the other hand, the relative number of ions which are heated, the ratio of the longitudinal and transverse ion energies, and whether the transverse electron energy increases during the heating are not resolved.

We report here measurements of the transverse ion and electron energy in plasma heating at a frequency near the lower hybrid frequency. The idea behind these measurements is that as the magnetic field at the multigrid probe changes, there are changes in the voltage–current characteristics of the probe, since the inhomogeneity of the magnetic field affects the motion of charged particles.

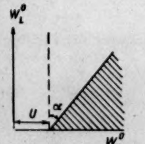

Fig. 1. Particles whose energies correspond to the hatched region strike the collector of the probe if the probe is in a relatively strong magnetic field.

A similar method for measuring the transverse ion energy is proposed in ref. 8, and a similar method for the transverse electron energy is proposed in ref. 9. The probe used in the present experiments is structurally similar to that of refs. 10 and 11. The probe has three grids and a collector; the particles enter through apertures with diameter smaller than the Debye length.

THEORY FOR THE MEASUREMENT METHOD

1. Probe in a relatively strong magnetic field. We denote by H_0 the magnetic field in the part of the plasma in which we are to determine the transverse energy of the particles, and we denote that near the probe by $(H_0 + \Delta H)$; here $\Delta H > 0$. If U is the retarding potential of the probe, the particles reach the collector when $W_\parallel^0 > W_\perp^0 \Delta H/H + U$, where $W_\parallel^0$ and $W_\perp^0$ are the longitudinal and transverse energies of the particle in the field H_0. The hatched region in Fig. 1 shows the energies of particles which reach the collector for the specified value of U; here $\tan\alpha = \Delta H/H_0$. The density of the current collected by the probe along the magnetic field is

$$j_\parallel = 2\pi \int\limits_{W_\perp=0}^{\infty} F_\perp(W_\perp)\,dW_\perp \int\limits_{U+W_\perp^0(\Delta H/H_0)}^{\infty} F_\parallel(W_\parallel)\,dW_\parallel,$$

where the distributions with respect to transverse energy, $F_\perp(W_\perp)$, and with respect to longitudinal energy, $F_\parallel(W_\parallel)$, are assumed to be Maxwellian:

$$F_\perp(W_\perp) = Ae^{-W_\perp/T_\perp};\quad F_\parallel = Be^{-W_\parallel/T_\parallel}.$$

When U = 0, ΔH = 0 the current density at the probe reaches a maximum:

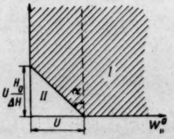

Fig. 2. The same as Fig. 1, for the case in which the probe is in a relatively weak magnetic field.

$$j_{\max}=2\pi\int_{\infty}^{\infty}F_{\perp}(W_{\perp})\,dW_{\perp}\int_{0}^{\infty}F_{\parallel}(W_{\parallel})\,dW_{\parallel}=2\pi ABT_{\parallel}T_{\perp}.$$

Then we have

$$\frac{j_{\parallel}}{j_{\max}}=\frac{1}{T_{\parallel}T_{\perp}}\int_{0}^{\infty}e^{-W_{\perp}/T_{\perp}}dW_{\perp}\int_{U+W_{\perp}(\Delta H/H_0)}^{\infty}e^{-\frac{W_{\parallel}}{T_{\parallel}}}dW_{\parallel},$$

and

$$\frac{j_{\parallel}}{j_{\max}}=e^{-U/T_{\parallel}}\frac{1}{1+\varkappa},\ \text{where}\ \ \varkappa=\frac{T_{\perp}}{T_{\parallel}}\frac{\Delta H}{H_0}.$$

Comparing this function with the function

$$j_{\parallel}=j_{\max}e^{-U/T_{\parallel}}$$

corresponding to a homogeneous magnetic field, we see that the nature of the functional dependence does not change when the field at the probe is strengthened, and the maximum current decreases.

2. Probe in a relatively weak magnetic field. If the magnetic field near the collector is weaker than that in the heating region, and if the retarding potential is zero, all the particles reach the collector, regardless of the field strength. If $U > W_{\perp}^{0}(\Delta H/H_0)$, the collector collects particles whose longitudinal energies satisfy

$$W_{\parallel}^{0}>U-W_{\perp}^{0}\frac{\Delta H}{H_0}.$$

If $W_{\perp}^{0}(\Delta H/H_0) > U$, all the particles reach the collector. Particles whose energies correspond to the hatched region in the plot of $W_{\parallel}^{0}$ vs $W_{\perp}^{0}$ in Fig. 2 reach the collector. We divide the first quadrant in Fig. 2 into two regions, I (the region in which particles do not reach the collector) and II (the region in which particles do reach the collector). The current drawn by the collector, which is due to particles in region I, is conveniently written $j_{\parallel}^{\mathrm{I}} = j_{\parallel}^{\mathrm{I+II}} - j_{\parallel}^{\mathrm{II}}$, where $j^{\mathrm{I+II}}$ is the total current which would be drawn by the collector if all the particles reached it, and $j_{\parallel}^{\mathrm{II}}$ is the current associated with the particles which are in fact prevented from reaching the collector by the retarding field:

$$j_{\parallel}^{I+II}=j_{\max}=2\pi\int_{0}^{\infty}F_{\perp}dW_{\perp}\int_{0}^{\infty}F_{\parallel}dW_{\parallel}=2\pi ABT_{\perp}T_{\parallel},$$

$$j_{\parallel}^{II}=2\pi\int_{0}^{U(H/\Delta H)}F_{\perp}dW_{\perp}^{0}\int_{W_{\parallel}=0}^{U-W_{\perp}^{0}(\Delta H/H_0)}F_{\parallel}dW_{\parallel}^{0}.$$

Assuming $F_{\perp}$ and $F_{\parallel}$ to be Maxwell distributions, as in subsection 1, we find

$$j_{\parallel}^{II}=2\pi ABT_{\parallel}\int_{0}^{U(H/\Delta H)}e^{-\frac{W_{\perp}}{T}}\left[1-e^{-\frac{U}{T_{\parallel}}+\frac{W_{\perp}^{0}}{T_{\parallel}}\frac{\Delta H}{H_0}}\right]dW_{\perp}^{0}.$$

Integrating, we find

$$j_{\parallel}^{II}=\frac{j_{\max}e^{-\frac{U}{T_{\parallel}}}}{1-\varkappa}\left(1-\varkappa e^{-\frac{U}{T_{\parallel}}\frac{1-\varkappa}{\varkappa}}\right),$$

$$j_{\parallel}^{II}=2\pi ABT_{\parallel}T_{\perp}\left\{1-\frac{e^{-\frac{U}{T_{\parallel}}}-\varkappa e^{-\frac{u}{T_{\parallel}\varkappa}}}{1-\varkappa}\right\}.$$

Let us examine some particular cases. (1) $\varkappa \ll 1$ as $\Delta H \to 0$; then $j_{\parallel}^{\mathrm{I}} = j_{\max}e^{-u/T_{\parallel}}$. (2) $\varkappa \gg 1$, $j_{\parallel}^{1} \simeq j_{\max}$ (regardless of the magnetic field, all the particles overcome the retarding potential U). (3) $\varkappa - 1 \to 0$, $j = j_{\max}e^{-u/T_{\parallel}}(1 + U/T_{\parallel})$, i.e., the collector current is rich in high-energy particles. (4) When U = 0 we have $j = j_{\max}$, regardless of the magnetic field, since all the particles reach the collector.

Accordingly, when the field is relatively weak near the probe and the particles have a Maxwellian energy distribution the collector current is rich in high-energy particles. This effect should be observed when $\varkappa \sim 1$. Since $\Delta H/H \lessdot 1$, the larger values of $\varkappa$ correspond to $T_{\perp}/T_{\parallel} \gtrdot 1$ (a pronounced anisotropy). A greater enrichment with energetic particles is found in the case $U/T_{\parallel} \gtrdot 1$. Figure 3 shows the calculated function $f(x)$ for various values of $\varkappa$, according to

$$f(x)=\frac{e^{-x}}{1-\varkappa}\left[1-\varkappa e^{-x\frac{(1-\varkappa)}{\varkappa}}\right].$$

A TEST OF THE METHOD

To test the method we use an electron beam in which the transverse and longitudinal energies can be regulated independently. The beam is produced by an electron gun having two close-space electrodes (a few Larmor radii apart): a hot cathode and anode with a small aperture, 1 mm in diameter. An external magnetic field of ~300 Oe is used for focusing. The gun is rotated around the axis perpendicular to the magnetic field in order to produce beams with different values of the ratio $v_{\perp}/v_{\parallel}$. The longitudinal beam energy is calculated from the longitudinal magnetic fields at which the beam is focused onto a screen covered with a phosphor, held a known distance from the gun. With the screen at an oblique angle with respect to the magnetic field the electron beam traces out an arc of a Larmor circle. By measuring the radius of this circle we find the transverse energy of the beam. The longitudinal and transverse beam energies found in this manner are compared with the values obtained from the voltage–current characteristics of the multigrid probe in magnetic fields which are weak and strong with respect to that at the gun. Figure 4 shows typical characteristics. This figure shows, on an arbitrary scale, the current drawn by the collector of the multigrid probe as a function of the retarding potential. The beam makes an angle of 20° with the magnetic field. Curve a is obtained in a homogeneous field, while curve b corresponds to a relative reduction of $\Delta H = 0.47H_0$ in the field at the probe position. From the retarding potential which causes the electron current to

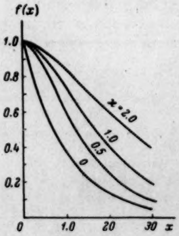

Fig. 3. The function $f(x) = e^{-x}(1-\varkappa)^{-1}[1-\varkappa e^{-x(1-\varkappa)/\varkappa}]$, which is representative of the current drawn by the probe as a function of the retarding potential.

drop to 0.5 of its maximum value (at the plateau), we find the transverse energy to be 30 eV. This result is consistent with the transverse energy corresponding to the angular position of the gun and determined from the measurements of the Larmor radius. The transverse beam energy $W_\perp^1$ in a homogeneous field is determined from

$$W_\perp^1 = (W_\parallel^1 - W_\parallel^2)\frac{H_0}{\Delta H},$$

where $W_\parallel^1$ (the longitudinal particle energy in field H_0) and $W_\parallel^2$ (the longitudinal energy of the particles in a field which is weaker than the homogeneous field by ΔH) are found from the retarding potential corresponding to a reduction by a factor of the current drawn by the collector of the multigrid probe. As the particles pass through the entrance apertures and the grids of the multigrid analyzer their energy distribution changes.[12] Experiments with electron beams show that the particle-detection efficiency decreases with increasing angle between the velocity of the particles and the magnetic field. The particle current drawn by the collector at an angle of 45° is several times smaller than that corresponding to an angle of 10°, for a given emission current. To reduce this error we use a procedure which exploits a difference between the characteristics of a probe in a homogeneous magnetic field from those of a probe in a highly inhomogeneous field. In a relatively weak field the transverse particle energy is converted into longitudinal energy in accordance with conservation of the magnetic moment, and the conditions for transmission through the grids of the probe are degraded. Then the particle distribution can be enriched by particles with large longitudinal velocities. In plasma experiments an additional source of systematic errors is the difference between the times required for particles with different energies to traverse the distance between the region in which the particles are produced and the region in which they are detected. To reduce this error we measure the current drawn by the collector of the probe at the time at which this current is a maximum. Taking these errors into account we conclude that the errors in the measurement of the transverse energy of particles by this method are ~10% in experiments with electron beams and ~20% in experiments with plasmas.

MEASUREMENT OF THE ANISOTROPY IN THE PLASMA HEATING

The experimental apparatus is shown schematically in Fig. 5; it is described in detail in ref. 6. The plasma 7, produced in a discharge on the surface of a hydrogen-saturated titanium disk 1, propagates along the lines of force of homogeneous magnetic field 2 and enters the heating region. The plasma is heated by coupling loop 3, which carries an rf current (f = 140 MHz). This coupling loop is part of a heating resonator formed by two-conductor line 4, connected to the rf oscillator. When coils 5 are activated a mirror field with a mirror ratio of 1.5 is produced in the heating region. It is shown in ref. 6 that when a plasma is heated in a mirror system the plasma energy increases to a value 1.5 to 2 times that of a plasma heated in a homogeneous field. Multigrid probe 6 is located behind the mirror coil, ~1.5 m from the heating region. The maximum magnetic field in the heating region is 3 kOe; a field of 2.2 kOe corresponds to the lower hybrid resonance of a dense plasma, i.e., to $\omega^2 = \omega_{He}\omega_{Hi}$, where $\omega = 2\pi f$, and ω_{He} and ω_{Hi} are the electron and ion gyrofrequencies. Because of the limited power supplying the magnetic-field coils we are not able to exceed a field of 1.8 kOe at the probe. The transverse energy of the particles is determined by comparing the characteristics of probes in magnetic fields of 1.7 kOe and 40 Oe. The transverse energy of the particles in the heating region, where the magnetic field is 3 kOe, is calculated from the transverse energy in a field of 1.7 kOe, with conservation of energy and the magnetic moment of the particles taken into account. As mentioned above, the total current in the fringing-field region is equal to the total current in the heating region. The current collected by the probe falls off in inverse proportion to the magnetic field; at a field of 40 Oe it is lower than the current in a field of 1.7 kOe by a factor of ~40. The difference is due to the spreading of the plasma along the lines of force of the weakened field. Since the calculated curves do not incorporate the changes in the current density in the fringing field, the probe characteristics in a field of 40 Oe are normalized so that the ion currents for a retarding potential of 100 V and the electron currents at zero potential coincide. A potential of 100 V is selected because it is near this potential that there is a break in the voltage–current characteristic due to the potential of the sheath which accelerates ions near the entrance grid of the probe.

Figure 6 shows the basic results of the measurements of the heating anisotropy. This figure shows, on an arbitrary scale, the ion current I_j and the electron current I_e drawn by the collector of the multigrid probe as a function of the potential on the retarding grid of the probe. The solid curves are experimental; curves 1 and 3 pertain to a field of 1.7 kOe, and curves 2 and 4 to a field of 40 Oe. Dashed curves a and b are calculated (they are of the same nature as the curves in Fig. 3). Curve a shows how the retarding potential affects the probe current corresponding to ions with a Maxwellian longitudinal-velocity distribution with $T_\parallel$ = 330 eV and $\varkappa$ = 0. Calculated curve b is the same, except that $\varkappa$ = 0.5. The experimental error is reduced through the use of a strong variation in the

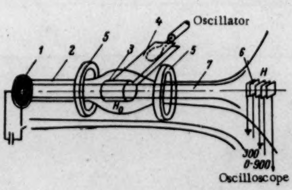

Fig. 5. The experimental apparatus.

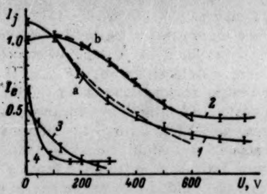

Fig. 6. Voltage–current characteristics for the ion current I_j and the electron current I_e from the heated plasma.

magnetic field ($\Delta H \simeq H$), since the differences between the experimental curves are more distinct in this case. On the other hand, since $\Delta H \simeq H$, then $\varkappa = T_\perp / T_\parallel$. The transverse ion temperature in the heating region in a magnetic field of 3 kOe is calculated to be $T^0_{\perp j} = 280$ eV with $T^0_{\parallel j} = 210$ eV under the assumption that the adiabatic invariant is conserved. Similar measurements carried out for heating in a homogeneous field reveal $T^0_{\perp j} = 150$ eV at $T^0_{\parallel j} = 250$ eV, i.e., $T_\perp / T_\parallel = 0.6$. These measurements show that the ions acquire longitudinal as well as transverse energy in the heating. The transverse energy of ions at the center of the mirror system found from measurements of the charge-exchange current is 300 eV, in agreement with measurements by the method described above. The ratio $(T^0_\perp + T^0_\parallel)/T^0_\perp = 1.75$ is comparable to the mirror ratio (1.5). Figure 6 shows, along with the ion-current characteristics, the electron current (arbitrary scale) drawn by the probe collector as a function of the retarding potential. The average electron energy calculated from curve 3, recorded in a field of 1.7 kOe, is 120 eV. Curve 4 is obtained with a magnetic field of 40 Oe at the probe; the average electron energy calculated from this curve is 40 eV. The decrease in the average electron energy in the fringing field is evidently due to the circumstance that the electrons are heated in the surface layer of the plasma.[6] The electron temperature is a minimum at the center of the plasma. In the fringing field the electrons striking the probe come from the central region and the average electron energy decreases. We can thus assume that the transverse energy of the electrons is low. This conclusion is supported by the argument[6] that the plasma diamagnetism is due to the ion component. We can summarize the experimental results as follows:

(1) The "transverse" ion temperature, determined from the charge-exchange spectrum at energies 0.5-3 keV, agrees with the temperature measured by the procedure of this paper.

(2) The average energy of the plasma ions is raised by heating.

(3) The ion energy spectrum becomes enriched with high-energy ions in comparison with a Maxwellian spectrum.

(4) The transverse plasma energy is concentrated in the ion component ($T_{\perp j} \gg T_{\perp e}$).

(5) $T_{\perp j} \simeq 1.5\, T_{\parallel j}$ for heating in a mirror field; $T_{\perp j} = 0.6\, T_{\parallel j} = 150$ eV for heating in a homogeneous field.

DISCUSSION OF RESULTS

The experimentally demonstrated low transverse electron energy can be explained under the assumption that for these experimental conditions, i.e., $\omega_{Hi} < \omega < \omega_{He}$, the electrons are magnetized and do not absorb energy in the propagation of the ordinary wave launched by the coupling loop. The observed "longitudinal" heating of the electrons can be attributed to a Cerenkov interaction due to oblique propagation with the wave. The electromagnetic wave is transformed into plasma waves, which propagate nearly perpendicularly to the magnetic field. When $\omega \gg \omega_{Hi}$ the magnetic field has little effect on the ion motion, so that the Cerenkov interaction should lead to a transverse heating of the ion component, as observed experimentally. However, this mechanism for the determination of the ion energies does not explain the observed longitudinal ion heating. Further experiments are necessary to clarify the heating mechanism.

In conclusion the authors thank N. A. Krivov for assistance in the experiments.

Interaction of a hollow electron beam with a plasma

N. M. Zemlyanskii, A. K. Berezin, Ya. B. Fainberg, L. I. Bolotin, and S. S. Krivulya

(Submitted September 12, 1973; resubmitted March 4, 1974)
Zh. Tekh. Fiz., 44, 2500-2503 (December 1974)

An experimental study has been made of the intereaction of a high-current electron beam with a plasma in a longitudinal magnetic field. When the plasma density is lower than the beam density instabilities are excited by the Cerenkov effect.

Instabilities in a beam–plasma system can be caused by the anomalous and normal Doppler effects, and by the Cerenkov effect. When an electron beam interacts with a plasma whose density n_p is lower than the beam density n_b, instabilities are excited because of the anomalous Doppler effect.[1-3] The excitation conditions and frequency spectra are examined in ref. 3; the frequencies are

$$\omega_m = \frac{\pi v_0 m}{L(1+\alpha^{-1/2})}, \tag{1}$$

where $\alpha = n_p/n_b$; L is the interaction length; n = 1, 2, 3, ... ; and v_0 is the beam velocity.

It follows from (1) that a) harmonics are excited and b) the frequency is a linear function of the beam velocity. If $n_p > n_b$, instabilities are excited because of the Cerenkov effect. The instability condition is the equality of the beam velocity v_0 and the slow-wave phase velocity in a hollow plasma waveguide, v_h. In a strong magnetic field ($\omega < \omega_0 < \omega_{He}$) we can write this condition, by analogy with refs. 2 and 4, in the following form:

$$v_0 \simeq v_h = c\left[1 + \frac{(1+|\varepsilon_\parallel|)\lambda_p^2 c^2}{|\varepsilon_\parallel|\omega_0^2 a^2}\right]^{-1/2}, \tag{2}$$

where $|\varepsilon_\parallel| = [(\omega_0^2/\omega^2) - 1]$, c is the speed of light in vacuum, ω is the frequency, ω_{He} is the electron gyrofrequency, ω_p is the electron plasma frequency, a is the waveguide radius, and λ_p is a constant governed by the boundary conditions.[5] From this equation we can determine the critical plasma density n_p^* for the onset of the Cerenkov instability. If the beam electrons have a velocity $v_0 = 0.5c$ and if $\omega = 3 \cdot 10^9$ sec^{-1} we find $n_p^* = 6 \cdot 10^{10}$ cm^{-3}.

Figure 1 shows a block diagram of the experimental apparatus, described in ref. 6. The electron beam interacts with the plasma in a cylindrical chamber 7 cm in diameter and 100 cm long, in a homogeneous external magnetic field from 500 to 1200 G. Probes to detect the E_r and H_φ components of the electromagnetic field are located along the chamber. The plasma density is measured by the "open-resonator" method.[7]

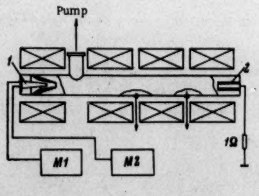

Fig. 1. The experimental apparatus.

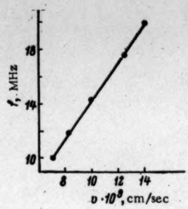

Fig. 2. Frequency of the oscillations as a function of the velocity of the beam electrons ($n_b > n_p$).

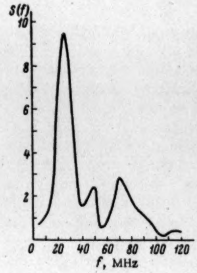

Fig. 3. Frequency spectrum $n_b > n_p$.

The electron beam is produced by magnetron gun 1, which produces a 100 A beam at a voltage of 100 kV. It has an annular cross section, an inside diameter of 2.5 cm, and an outside diameter of 3.5 cm. The gun is fed by two modulators; modulator M-1 produces a voltage pulse 120 μsec long, while M-2 produces a pulse 2.5 μsec long. The first current pulse (15 A and 20 keV) produces plasma as it passes through the working gas (hydrogen); the primary beam (100 A and 100 keV) interacts with this

plasma. The delay between the ignition and primary pulses can be adjusted from 0 to 2 msec, so that the interaction of the electron beam with plasmas of various densities can be studied. The energy lost by the beam as it passes through the plasma is measured by a thermal probe – a platinum foil 10 × 20 mm in area and 50 μ thick, located behind a radial slit cut in collector 2 in such a manner that about 1/10 of the beam electrons reach the foil. Because of this radial slit the electron current drawn by the thermal probe remains constant as the diameter of the current tube is changed. After the beam passes through the plasma its profile is recorded by x-ray photography, and the x-ray image is studied photometrically. The frequency spectra excited in the system are determined with a computer. In a beam–plasma interaction with $n_p < n_b$ the oscillations excited in the plasma are due to the anomalous Doppler effect, at the frequencies given in (1). Figure 2 shows the frequency as a function of the velocity of the beam electrons. Figure 3 shows a typical spectrum obtained with $v_0 = 1.5 \cdot 10^{10}$ cm/sec, $\alpha = 0.2$, and L = 100 cm. Figure 4 shows the power associated with these oscillations as a function of the gas pressure for various beam power levels. We see that the oscillation power increases with the beam power. In this case the efficiency of the beam–plasma interaction does not exceed 4%. As the beam passes through a plasma with density higher than n^*_p, an instability occurs as a result of the Cerenkov effect. The spectrum is much broader than that in the case $n_p < n_b$ and is shifted toward higher frequencies (Fig. 5). It follows from measurements of the beam profile that the beam narrows after passing through the plasma (Fig. 6). Figure 7 shows the relative energy loss of the beam as a function of the beam power for the case of the oscillations resulting from the Cerenkov effect. The interaction is most efficiency in a narrow pressure range (2.10^{-5}–$7 \cdot 10^{-5}$ torr). Similar results are reported in ref. 8.

Accordingly, in this study of the collective interaction of an intense hollow electron beam with a plasma we have found that the interaction is due to the anomalous Doppler effect in the case $n_p < n_b$. The corresponding efficiency is less than 4%. In the case $n_b < n_p$, the oscillations which are excited are due to the Cerenkov effect, and the efficiency reaches 28%.

Low-pressure self-maintained discharge with suppressed electron drift. I

V. K. Kalashnikov and Yu. V. Sanochkin

(Submitted January 8, 1973; resubmitted July 8, 1973)
Zh. Tekh. Fiz., 44, 2504-2511 (December 1974)

The structure of the anode sheath in a low-pressure, high-voltage discharge with a suppressed Hall current is analyzed in the diffusion approximation. "Weak effects," e.g., the functional dependence of the ionization coefficient on the electron energy, the inelastic energy loss, and the existence of an electron-depleted region, are shown to have a significant influence on the discharge characteristics. It is shown that the properties of the sheath are essentially independent of the choice of initial conditions (over certain ranges of these conditions).

Discharges in strong transverse magnetic fields with suppressed electron drift have been studied in Penning cells and straight or inverted magnetrons (see, e.g., refs. 1 and 2). The recently intensified interest in such discharges stems from their important applications in producing and accelerating intense ion beams.[3] Because of the low conductivity across the magnetic field, at pressures $p < 10^{-3}$ torr, the discharge current does not exceed a few milliamperes per square centimeter while the density of the Hall current is several orders of magnitude higher (by a factor of $\omega_e \tau_e$), for typical discharge voltages φ_0 at the kilovolt level. For typical magnetic fields $H \leqslant 1$ kOe the electron density is of the order of $n_e \leqslant 10^{10}$ cm^{-3} and is independent of the pressure. Under these conditions the discharge is highly inhomogeneous. A sheath of negative space charge forms near the anode; this consists of magnetized electrons and the thickness is of the order of the Larmor radius of electrons with energy $e\varphi_0$. The entire discharge voltage appears in the voltage drop across this sheath. A one-dimensional theory for the low-pressure anode sheath is derived in refs. 2, 4, and 5 (for a system homogeneous in the direction of the magnetic field and in the electron-drift direction). Several factors are not incorporated in this derivation, e.g., the calculations involved in an analysis of the structure of the sheath are simplified by neglecting the electron energy equation. The electrons at ~1 eV formed in each cross section of the sheath in the ionization of atoms acquire, as they move toward the anode, an energy sufficient to excite and ionize neutrals. It is therefore worthwhile to examine the effect of the inelastic electron energy loss on the discharge characteristics. Since the electron energies in the sheath span a broad range, it is also necessary to take account of the dependence of the ionization rate on the electron energy. In weak electric fields (the beginning of the sheath), where there is a flux of fast ions and the average electron energy is low, a possible contribution of ionization by ions must be taken into account. Finally, sensitivity of the discharge characteristics to the part of the sheath near the anode which is deficient in electrons (the electron-depleted region) is neglected in refs. 4 and 5. The finite size of the region must be taken into account in an analysis of electron heating. We show below that a small parameter can be associated with each of these effects, so that we refer to these effects as "weak effects" for brevity. The primary purpose in Part I of this work is to study systematically the influence of these weak effects on the discharge characteristics and to estimate the influence of each effect on the structure of the sheath.

We also take note of the following circumstance: Homogeneous boundary conditions on the electric field and the electron current ($E_0 = j_0 = 0$) are assumed at the beginning of the sheath in refs. 2, 4, and 5. Actually, in this case the quantities must assume certain finite values, which are governed by relations similar to the familiar Bohm criterion.[6] These relations make possible the formation of an anode sheath with monotonic distributions of the appropriate parameters so that the solutions in the sheath and in the plasma can be matched. In the present work the derivation of these criteria is not given and we restrict the study to the influence of changes in the boundary conditions, within certain allowed ranges, on the sheath structure.

In the second part of this paper we treat the influence of two-dimensional effects on the structure of the discharge, primarily the two-dimensional effect of the loss of electrons along the magnetic field to the cathodes. While the electron Larmor radius serves as the mean free path across the magnetic field, the motion of electrons along the magnetic field is collisionless in the pressure range under consideration. The fastest electrons overcome the potential barrier and escape to the walls; the corresponding leakage current can in fact become comparable to the discharge current. The two-dimensional nature of the model requires a specification of the geometry, the conditions at the walls bounding the system, and the conditions in the plasma adjacent to the sheath. We adopt a model for the discharge corresponding to an inverted magnetron or to a Hall-current accelerator with a short acceleration zone.[3] The problem of an ion beam propagating between equipotential electrodes, with the space charge balanced by ionization of residual gas, is solved. This problem is of some independent interest, but for our purposes we need the solution to establish certain approximate boundary conditions for the sheath.

STATEMENT OF THE PROBLEM

Instruments in which the electron drift is suppressed are axisymmetric. As in refs. 4 and 5 we treat the planar problem for simplicity; the x axis is across the sheath, the z axis is along the magnetic field, the Hall current is along the y axis, and the circuit is closed at infinity. The discharge chamber is bounded by the cathodes ($z = \pm h$) and the anode ($x = x_0$, $|z| \leq A < h$, $A \gg x_0$). The electron-depleted region is $x_{ed} < x < x_0$. Figure 1 gives an idea of the two-dimensional distribution of the potential $\Phi(x, z)$ in such a system. By definition, the voltage drop along z for a given x consists of the drop near the wall, $\Delta\varphi_{ed}(x)$, and the change in the core of the discharge, $\Delta\varphi \simeq [\delta(x)/e]W(x)$ [$W(x)$ is the average electron energy at cross section x, and $\delta(x) \leqslant 1$ is some function]. These potential drops satisfy

$$\varphi(x) + \Delta\varphi_0 = \frac{\delta(x)}{e} W(x) + \Delta\varphi_{ed}(x),$$

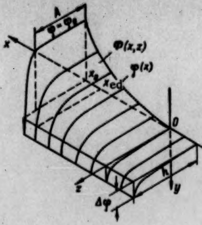

Fig. 1

where $\varphi(x)$ is the potential distribution in the $(z = 0)$ symmetry plane, and $\Delta\varphi_0$ is the total potential drop toward the wall in the initial cross section (Fig. 1).

We can partition the space along the x axis somewhat arbitrarily into three regions: a quasineutral plasma $(x \to -\infty)$, a transition region $(x < 0)$, and a sheath $(0 \le x \le x_0)$. Of course it is not possible to unambiguously define the boundary or the thickness of the sheath. Although the sheath boundary is at a potential extremely close to the plasma potential, the shielding of the plasma from the anode field is incomplete. This simplified approach is based on the fact that the field in the transition region is weak in comparison with that in the sheath, so that the changes in the potential over distances of the order of the sheath thickness are negligible. Accordingly, for $x < 0$ we can assume $\varphi(x) = \varphi_b = \text{const}$. We arbitrarily assume $\varphi_b = 0$, since we can always redetermine the reference point for the potential from the known solution if necessary. The field $E_0 = \varphi'(0)$ cannot be neglected, even though it is weak, since it determines j_0 and perhaps the initial electron energy W_0. Strictly speaking, with weak electric fields the sheath solution must be matched with the solution of the corresponding problem for the transition region. This procedure would help us define the sheath and the transition region and would permit an unambiguous determination of the boundary conditions at the sheath.

The problem is solved under the following assumptions: The electrons are magnetized, and the ions are not magnetized over distances $\sim x_0$ $(\rho_i \gg x_0 \gg \rho_e)$. Charge exchange, recombination, and secondary ionization are negligible, as are secondary processes at the walls. We assume discharge conditions such that

$$\frac{m\omega_e\nu_i}{4\pi e^2 n_n}\sqrt{\frac{e\varphi_0}{mv_n^2}\frac{\nu_i}{\nu_0}} < 1, \quad \beta = \sqrt{\frac{M}{2m}\frac{\nu_i\nu_0}{\omega_e^2}} \ll 1. \tag{1}$$

Here, ω_e is the electron gyrofrequency; $\nu_i = \langle\sigma_{ie}v_e\rangle n_n$ is the rate of ionization collisions of electrons; $\nu_0 = \langle\sigma_0 v_e\rangle n_n$ is the rate of electron collisions involving a loss of directed momentum; v_e, σ_{ei}, σ_0 are the electron thermal velocity and the corresponding cross sections; and n_n, v_n are the density and velocity of the neutrals. If the first of these inequalities holds we can neglect the "burn up" of neutrals in the sheath and assume[5] $n_n = \text{const}$. The second condition means that the density of the ion space charge in the sheath is negligible. When $\langle\sigma_{ie}v_e\rangle \simeq 10^{-7}$ cm^3/sec, $\nu_0/\nu_i \simeq 3$, and $v_n \simeq 3 \cdot 10^4$ cm/sec the first inequality holds for $H\sqrt{\varphi_0} < 10^6$ eV$^{1/2}$. With $H \simeq 10^3$ Oe the second condition holds for $n_n < 10^{12}$-10^{13} cm^{-3}.

To estimate the size of the region we note that the lifetime of en electron in the sheath is of order $\tau_e = \nu_0^{-1}$. In a time of order ω_e^{-1} electrons move without collisions from the cutoff region to the anode, i.e., the electron lifetime is shorter than that in the sheath by a factor $\omega_e\tau_e$. We can thus use the crude assumption that the electron density vanishes in the electron-depleted region. An electron whose velocity components in the plane $x = x_{ed}$ are v_x, v_y traverses the following distance to the turning point:

$$d = \frac{1}{\omega_e}\left[\frac{cE}{H} - v_y + \sqrt{v_x^2 + \left(\frac{cE}{H} - v_y\right)^2}\right].$$

Averaging this quantity over the electron distribution

$$f \sim \exp\left\{-\frac{m}{2W}\left[v_x^2 + \left(\frac{cE}{H} - v_y\right)^2\right]\right\},$$

we find

$$\bar{d} = \frac{1}{\omega_e}\sqrt{\frac{\pi}{2m}W}\ . \tag{2}$$

Accordingly, the size of the electron-depleted region, $x_0 - x_{ed}$, is equal to the electron Larmor radius in the plane x_{ed}, within a coefficient of order unity. In this region the average electric field is approximately homogeneous, and the electron energy and potential vary linearly with the coordinate x.

To describe the distributions of the unknown quantities over most of the sheath we use

$$\frac{\partial j_x}{\partial x} + \frac{\partial j_z}{\partial z} = \langle\sigma_{ie}v_e\rangle n_n n_e + \langle\sigma_{ii}v_i\rangle n_n n_1, \tag{3}$$

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_z}{\partial z} = -ej_x E_x - ej_z E_z - \mathcal{E}_i\langle\sigma_{ie}v_e\rangle n_n n_e, \tag{4}$$

$$\frac{\partial E_x}{\partial x} + \frac{\partial E_z}{\partial z} = -4\pi e n_e \quad (\mathbf{E} = -\nabla\Phi), \tag{5}$$

$$j_x = b_\perp n_e \frac{\partial\Phi}{\partial x} \quad \left(b_\perp = \frac{e}{m\tau_e}\frac{1}{\omega_e^2}\right). \tag{6}$$

Here j_x, j_z, q_x, and q_z are the corresponding components of the electron current density and of the energy carried by electrons; n_1 is the density of the fast ions, which are efficient in causing ionization; σ_{ii} and v_i are the cross section for ionization collisions and the velocity of the ions; $b_\perp$ is the transverse electron mobility; and $\mathcal{E}_i$ is the "effective cost" of an ion. The second term on the right side of (3) can make an appreciable contribution only at the beginning of the sheath, where W_0 is small and where $\langle\sigma_{ie}v_e\rangle \to 0$. We deliberately overestimate its value, setting it equal to the constant $n_n\langle\sigma_{ii}v_i\rangle n_{10}$, where n_{10} is the density of fast ions in the initial cross section. Conflicting arguments have been advanced regarding the mechanism for the electron transport to the anode, so that this mechanism is in doubt; we work on the basis of refs. 1 and 7, where it was shown that classical transverse mobility is the predominant mechanism at low pressures. The function dependence of the ionization rate by electron impact on electron energy can be approximated by

$$\langle\sigma_{ie}v_e\rangle = \langle\sigma_{ie}v_e\rangle_0 \nu\left(\frac{W}{eV_i}\right), \tag{7}$$

where

$$\nu = -\frac{1}{0.57}\sqrt{\frac{eV_i}{W}}\,\mathrm{Ei}\left(-\frac{eV_i}{W}\right), \quad \langle\sigma_{ie}v_e\rangle_0 = \frac{1.14}{\sqrt{\pi}}\sqrt{\frac{2eV_i}{m}}\,\sigma_{i0},$$

V_i is the ionization potential, σ_{i0} is the characteristic cross section for the given material, and Ei(x) is the exponential integral function.[8] With $W \leqslant eV_i$ and $\nu \ll 1$, the maximum value $\nu \simeq 1$ is reached at $W \simeq (3\text{-}6)eV_i$. The energy expenditure per ionization event includes the inelastic and elastic loss and is governed by the conditions in the discharge. At an electron energy $\sim eV_i$ this quantity can reach hundreds of electron volts; as the energy drops to $\sim 10^3$ eV, it drops to 30-50 eV. For a qualitative treatment we assume $\mathcal{E}_i$ = const to be a few eV_i.

AVERAGING THE SYSTEM OF EQUATIONS

Below we use averages over z of the distributions of physical quantities in the core of the sheath for $|z| < a < A$:

$$\Phi(x) = \frac{1}{a}\int_0^a \Phi(x, z)\,dz.$$

It follows from symmetry considerations that everywhere, except near the cathodes, where all quantities are strong functions of z, we can approximate the distributions of the unknown quantities by expansions like

$$\left.\begin{aligned} \Phi(x, z) = \varphi(x) - \varphi_1(x)\frac{z^2}{h^2} - \ldots, \quad n_e = n_0(x) - n_1(x)\frac{z^2}{h^2} - \ldots, \\ j_z = j_1(x)\frac{z}{h} + \ldots, \quad q_z = q_1(x)\frac{z}{h} + \ldots \text{ etc.} \end{aligned}\right\} \tag{8}$$

As a rough first approximation we only consider terms which are linear or quadratic in z. We neglect the structure of the cathode regions, and we assume the thickness to be small in comparison with h. Then we can set $\varphi_1 \simeq [\delta(x)/e]W(x)$. The quantity $n_1(x)$ can be determined from the Boltzmann distribution

$$n_e(x, z) = n_0 \exp\left\{-\frac{e}{W(x)}[\varphi(x) - \Phi(x, z)]\right\}.$$

Integrating system (3)-(6) over z within the framework of approximation (8), we find the quasi-one-dimensional equations

$$\frac{d}{dx}J_x = \langle\sigma_{ie}v_e\rangle n_n\bar{n}_e + \langle\sigma_{ii}v_i\rangle n_n n_{10} - \frac{1}{h}j_1(x),$$

$$\frac{d}{dx}q_x = -e\overline{j_xE_x} - \frac{2}{3}\delta\frac{a^2}{h^2}\frac{W}{h}j_1 - \frac{1}{h}q_1(x) - \mathcal{E}_i\langle\sigma_{ie}v_e\rangle n_n\bar{n}_e,$$

$$\frac{d}{dx}E_x = -4\pi e\bar{n}_e - \frac{2\delta}{h^2}\frac{W}{e},$$

$$E_x = -\frac{d}{dx}\Phi, \quad E_z = \frac{\delta}{a}\frac{W}{e}\frac{a^2}{h^2},$$

$$J_x = b_\perp\overline{n_e\frac{\partial\Phi}{\partial x}}.$$

It can be shown that the following relations hold within 10%:

$$\overline{j_xE_x} \simeq J_xE_x, \quad \overline{n_e\frac{\partial\Phi}{\partial x}} \simeq \bar{n}_e\frac{d}{dx}\Phi.$$

We introduce the dimensionless quantities

$$s = \frac{x}{l^*}, \quad n = \frac{\bar{n}_e}{n^*}, \quad n_1 = \frac{n_{10}}{n^*}, \quad \theta = \frac{W}{e\varphi_0},$$

$$\eta = \frac{\Phi + \frac{\delta_0}{3}\frac{a^2}{h^2}\frac{W_0}{e}}{\varphi_0}, \quad \Delta\eta = \frac{\Delta\varphi_0}{\varphi_0}, \quad j = \frac{J_x}{j^*},$$

where

$$l^* = \sqrt{\frac{e\varphi_0}{m\omega_e^2}\frac{\nu_0}{\nu_{i0}}}, \quad n^* = \frac{m\omega_e^2}{4\pi e^2}\frac{\nu_{i0}}{\nu_0}, \quad j^* = \nu_{i0}n^*l^* \quad (\nu_{i0} = n_n\langle\sigma_{ie}v_e\rangle_0).$$

Assuming $\bar{\bar{q}}_z = W\bar{j}_x$ and using the Boltzmann approximation for the electron flux to the wall, we can write the system of equations for the averages in final form:

$$\frac{dj}{ds} = \nu(\theta)n + In_1 - \Lambda j_w, \tag{9}$$

$$j = n\frac{d\eta}{ds}, \tag{10}$$

$$\frac{d^2\eta}{ds^2} = n + 2\delta\Lambda^2\theta, \tag{11}$$

$$\frac{d}{ds}(j\theta) = j\frac{d\eta}{ds} - \Lambda\left(1 + \frac{2}{3}\delta\alpha^2\Lambda^2\right)\theta j_w - \mathcal{E}\nu(\theta)n, \tag{12}$$

$$j_w = Qn\sqrt{\theta}\exp\left(-\frac{\eta + \Delta\eta}{\theta}\right), \tag{13}$$

$$\nu(\theta) = -\frac{1}{0.57}\frac{1}{\sqrt{K\theta}}E_i\left(-\frac{1}{K\theta}\right). \tag{14}$$

Here we obtain

$$I = \frac{\langle\sigma_{ii}v_i\rangle}{\langle\sigma_{ie}v_e\rangle_0}, \quad \Lambda = \frac{l^*}{h}, \quad \alpha = \frac{a}{l^*}, \quad Q = \frac{\sqrt{2}}{4}\frac{\omega_e}{\sqrt{\nu_{i0}\nu_0}},$$

$$\mathcal{E} = \frac{\mathcal{E}_i}{e\varphi_0}, \quad K = \frac{\varphi_0}{V_i}.$$

The initial conditions are $s = 0$, $\eta = 0$, $d\eta/ds = E_0$, $j = j_0$, and $\theta = \theta_0$.

To determine the coordinate of the electron-depleted region, $s = s_{ed}$ we use

$$\eta(s_{ed}) + \frac{1}{3}\delta(s_{ed})\alpha^2\Lambda^2\theta(s_{ed}) = 1 - d(s_{ed})\left[\eta'(s_{ed}) + \frac{1}{3}\delta(s_{ed})\alpha^2\Lambda^2\theta'(s_{ed})\right],$$

where $d(x) = \bar{d}/l^*$.

ONE-DIMENSIONAL TREATMENT.

If we set $h = \infty\,(\Lambda = 0)$ in (9)-(12), we find that E_z, j_z, and q_z vanish, and we find the equations of the one-dimensional problem. We solve it, adding various physical effects in succession.

If we neglect the electron-depleted region and set $\nu(\theta) = 1$, and $I = 0$, we can write the solution of (9)-(12) as

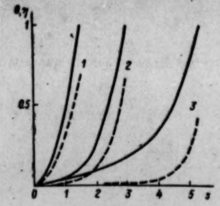

Fig. 2

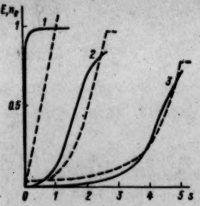

Fig. 3

$$
\left.\begin{aligned}
s&=(E-E_0)-(j_0-E_0)\ln\left(1+\frac{E-E_0}{j_0}\right),\\
\eta&=\frac{1}{2}(E^2-E_0^2)-(j_0-E_0)(E-E_0)\\
&\quad+(j_0-E_0)^2\ln\left(1+\frac{E-E_0}{j_0}\right),\\
\theta&=\frac{1}{E-E_0+j_0}\left[\theta_0 j_0+\frac{1}{3}(E^3-E_0^3)-\mathcal{E}(E-E_0)\right],\\
j&=j_0+(E-E_0).
\end{aligned}\right\}\qquad(15)
$$

In this case the increase in the electron energy in the sheath does not affect the sheath structure. When $\mathcal{E} > 0$ at the beginning of the sheath solution (15) yields $\theta < 0$, i.e., the problem of the effect of the energy loss on the electron heating is not well posed. The solution for the sheath, (15), is very nearly the same as the solution

$$\eta=\frac{1}{2}s^2,\quad j=E=s,\quad n=1\quad (s_0=\sqrt{2}),$$

obtained for homogeneous boundary conditions.[4] For example, as E_0 and j_0 are varied over broad ranges (10^{-4}–10^{-1}), the sheath thickness varies only slightly (s_0 = 1.29–1.77), the electron energy at the anode varies only slightly (from 0.66 to 0.69), and $n(s) \simeq 1$ everywhere except in a small neighborhood of the initial cross section. Typical $\eta(s)$ and $\theta(s)$ distributions according to (15) are shown in Fig. 2 (the solid curve and dashed curve 1, respectively). Figure 3 shows the corresponding functions n(s) and E(s), and Fig. 4 shows the j(s) and $j_i(s)$ distributions (the solid and dashed curves, respectively). As noted above, as $E_0 \to 0$ and $j_0 \to 0$, solution (15) goes over to the similar solution of ref. 4. The situation is different if we take weak effects into account; in this case solutions of the sheath type do not exist for E_0 and j_0 for homogeneous boundary conditions. This result is evident from the linear conditions for the growth of the electron density and energy:

$$n_0<\nu(\theta_0)+I\frac{n_1}{n_0},\quad E_0^2>(\mathcal{E}+\theta_0)\nu(\theta_0)+I\frac{n_1}{n_0}\theta_0\quad \left(n_0=\frac{j_0}{E_0}\right).$$

As is evident from the discussion below, a lower limit on n_0 (i.e., on j_0) can be estimated in accordance with our definitions of the sheath and the transition region:

$$\eta_b \leqslant 0.1,$$

where η_b is the potential in the region where the rapid increases in the field and in the electron density, current, and energy begin. A check shows that the solutions become meaningless if these conditions are violated (the check has been carried out for broad ranges of the boundary values: $n_0 = 5\cdot10^{-2}$–10^{-5}, $E_0 = 5\cdot10^{-2}$–10^{-4}, $\theta_0 \simeq 10^{-3}$–10^{-2}). As n_0 decreases, the distributions of the physical quantities become deformed in a certain specific manner: "Tails" form in the n, j, θ, and E profiles at the beginning of the sheath, where the values of the corresponding functions are on the order of the initial values, i.e., where the gradients along x are small, but where the greater part of the applied potential difference is nevertheless found. There are slow decreases in the basic properties of the sheath: $j_d = j(s_0) = j_i(0)$, $\theta_{ed} = \theta(s_{ed})$, $\theta_A = \theta(s_0)$, n_{ed}, and E_{ed}. Because of the lengthening of the tail, the formal thickness of the sheath, s_0, increases. (As $j_0 \to 0$, we have $s_0 \to \infty$, and the sheath-type solution disappears.) The conditions prevailing in the tail of the distributions are suitable for further rapid increases in the properties; these increases occur in a region ~ 2-3 units long. This region is naturally identified as the sheath proper. Accordingly, solutions displaying a large potential drop in the tails of the distributions should be treated as formal solutions resulting from an incorrect choice of initial conditions. Analysis of the solutions obtained by varying the boundary conditions over the allowed ranges shows that, within the error associated with this analysis, all properties of the sheath except the formal length s_0 remain constant.

If we take the functional dependence of the rate of ionization collisions of electrons on the electron energy into account [$\nu = \nu(\theta)$], we find that the electron heating in the sheath affects the sheath structure. In this case it is natural to expect decreases in the density, the electric field, and the discharge current. Curves 2 in Figs. 2-4 demonstrate the changes in the distributions of the corresponding quantities.

The energy losses which occur in electron collisions should lead to reductions in the average electron energy,

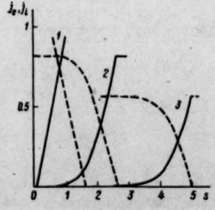

Fig. 4

and the ionization, and thus the density and currents. Curves 3 show the corresponding changes in the sheath structure. (Figures 2-4 show curves for $K = 63$, $\mathscr{E} = 0.05$, corresponding to $\varphi_0 = 1\,\text{kV}$, $\mathscr{E}_i \simeq 3\ \text{eV}_i$ for argon.) From the curves in Figs. 2-4 we see that the weak effects deform the distributions. The sheath thickness increases systematically by a factor of 2 or 3, while the profiles of the field, the potential, and the density become smoother. However, the actual thickness of the sheath, over which most of the increase in the field and electron energy, current, and density occurs, and where the ion beam is shaped, turns out to be some 2 or 3 units in all cases. In the one-dimensional theory the electron current drawn by the anode is always equal to the ion current at the beginning of the sheath (Fig. 4). The maximum electric field and currents fall off systematically by factors of 2 or more. The density attained changes relatively little (by about 30%). The energy loss strongly influences electron heating in the sheath. The energy of the electrons reaching the anode falls off by a factor of more than 1.5 (to about 0.4 unit). The cutoff region corresponds to the horizontal parts of the E(s) and j(s) distributions; although this region is relatively narrow, $s_0 - s_{ed} \simeq 0.2\text{–}0.3$ (about 10% of the effective sheath thickness), there is a voltage drop of about $(0.2\text{–}0.3)\varphi_0$ in it, and the electrons acquire in this region about half the energy brought to the anode. The quantity θ_{ed} is about 0.2, i.e., the electrons in the sheath have energies much lower than 1 unit. This circumstance offers some justification for the assumption that the term in Eq. (6) containing the gradient of the electron pressure is small.

As is shown in Part II of this work (the following paper), $n_1 \to 0$ as $h \to \infty$. To determine the effect on ionization by ions on the sheath structure we assume both $n_1 = 0$ and the limiting value $n_1 = n_0$ in the calculations ($I \nless 10^{-2}$). It turns out that ionization by fast ions, even if it is predominant at the beginning of the sheath $[\nu(\theta_0)n_0 \ll In_1]$, does not affect the characteristics of the sheath. The reason is that the increase in θ is accompanied by a very rapid increase in $\nu(\theta)$, and ionization by electrons becomes predominant.

In the one-dimensional formulation of the problem there are two dimensionless parameters, $\mathscr{E}$ and K, which are functions of φ_0 and the gas properties. Calculations show that an increase in $\mathscr{E}$ (or a decrease in K) is accompanied by monotonic decreases in the sheath properties θ_A, j_d, θ_{ed}, n_{ed}, and E_{ed}. We can thus extrapolate the available data to estimate the properties of the discharge for other values of K and $\mathscr{E}$.

In summary we can say that the weak effects, described by the small parameters ν, $\mathscr{E}$, and d/s_0, have a significant influence on the discharge characteristics.

Finally, we note that since the electron energy in the sheath is lower than $e\varphi_0$ by a factor of 4 or 5, while the effective thickness of the anode sheath is $L \simeq (2\text{–}3)\rho_e(\varphi_0)\sqrt{\nu_0/2\nu_{i0}}$, we conclude that the ratio of L to the average electron Larmor radius in the sheath, $\rho_e(\overline{W})$, is about 10. This circumstance justifies the diffusion approach.

Low-pressure self-maintained discharge with suppressed electron drift. II

Yu. V. Sanochkin and V. K. Kalashnikov

(Submitted January 8, 1973; resubmitted July 8, 1973)
Zh. Tekh. Fiz., 44, 2512-2518 (December 1974)

The influence of two-dimensional effects on the discharge characteristics is analyzed for a Hall-current accelerator or an inverted magnetron. The properties of the plasma adjacent to the anode sheath, the electron density and average energy, the electric field, and the electron and ion currents in the anode sheath are found; the loss of electrons along the magnetic field to the cathodes is taken into account. A comparison is made with the results of the one-dimensional treatment. A study is made of the influence of the pressure on the discharge characteristics. The calculated results can be used to interpret experimental data.

In Part II of this work we report an approximate analysis of the influence of two-dimensional effects on the discharge characteristics, and we compare the theoretical results with experiment. The geometry of the discharge chamber, the physical conditions, and the statement of the problem are given in Part I of this work,[1] where we also derive "quasi-one-dimensional" equations for the system [Eqs. (9)-(14)], which describe the distributions of various parameters in the axial part of the discharge for finite values of h. The quantities n_1, $\Delta\eta$, and δ in these equations are not yet determined. There is an ion beam in the beginning of the sheath;[1] it is a natural procedure to determine the missing boundary conditions by solving the problem of a neutralized parallel ion beam propagating in a plasma adjacent to the anode sheath.

NEUTRALIZED ION BEAM PARALLEL TO EQUIPOTENTIAL SURFACES

We consider the region at the exit from the system ($x \to -\infty$) where the gradients with respect to x are small, and the ion beam moves in the x direction. If the electrons are still magnetized in this region they cannot neutralize the ion beam, even partially. However, the ion space charge must be neutralized. We assume that a parallel ion beam propagates between equipotential planes $z = \pm h$ and that the ion space charge is neutralized by ionization of the residual gas (there are no thermionic cathodes). The plasma in this region consists of the "primary" ions (which enter this region as ions) and "secondary" ions and electrons (which are formed in this region).

Neglecting the initial velocity of the secondary ions, we write their density as

$$n_2 = \int_0^z \frac{\langle\sigma_{ii}v_i\rangle n_n n_1 + \langle\sigma_{ie}v_e\rangle n_n n_0 e^{\frac{e\varphi}{T_e}}}{\sqrt{\frac{2e}{M}[\varphi(z') - \varphi(z)]}}\, dz'. \qquad (1)$$

Here, n_0 is the electron density at $z = 0$, and n_1 is the ion density in the beam. The potential distribution $\varphi(z)$ is determined from the Poisson equation:

$$\frac{d^2\varphi}{dz^2} = 4\pi e\left(n_0 e^{\frac{e\varphi}{T_e}} - n_1 - n_2\right). \qquad (2)$$

Assuming

$$\chi = -\frac{e\varphi}{T_e}\,(\chi \geqslant 0),\quad s_z = \frac{z}{l_z}\quad \left(l_z = \frac{\sqrt{\frac{2T_e}{M}}}{\langle\sigma_{ii}v_i\rangle n_n}\right),$$

$$N = \frac{n_1}{n_0},\quad G(T_e) = \frac{\langle\sigma_{ii}v_e\rangle}{\langle\sigma_{ei}v_i\rangle},$$

we can rewrite (2) in the dimensionless form

$$-\frac{\langle\sigma_{ii}v_i\rangle^2 n_n^2 M}{8\pi e^2 n_0}\frac{d^2\chi}{ds_z^2} = e^{-\chi} - N - \int_0^{s_z}\frac{N + Ge^{-\chi'}}{\sqrt{\chi' - \chi}}\, ds_z'. \qquad (3)$$

We see from (3) that the neutrality is violated only in regions near the walls with dimensions of the order of the Debye length. Assuming for simplicity that the density of primary ions N is constant over the beam cross section, we find the following result from the neutrality condition (by means of an Abel transformation):

$$(N + Ge^{-\chi})\frac{ds_z}{d\chi} = \frac{2}{\pi}\frac{d}{d\chi}[F(\sqrt{\chi}) - N\sqrt{\chi}], \qquad (4)$$

where $F(x) = e^{-x^2}\int_0^x e^{t^2}dt$ is the well known tabulated function.[2] We now introduce the variable $u = \sqrt{\chi}$; following ref. 3, we determine the potential drop in the plasma, $u_r = (-e\Delta\varphi_r/T_e)^{1/2}$, from the condition

$$\frac{ds_z}{du} = \frac{2}{\pi}\frac{F'(u) - N}{N + Ge^{-u^2}} = 0. \qquad (5)$$

We see from (5) that when $1 > N > 0$ the corresponding values of u_r lie in the range $0 < u_r < 0.92$, i.e., the potential drop in the neutral region does not exceed $0.92\,T_e$. Interestingly, the numerator in (5) contains the ratio of the density of electrons to that of primary ions, while the denominator contains the density of secondary ions. Accordingly, regardless of the mechanism by which the ions are produced in this region the potential drop in the plasma is governed solely by the ratio of the density of "background" ions to the total ion density. The potential distribution is given by

$$s_z = \frac{2}{\pi}\int_1^u \frac{1 - N - 2xF(x)}{N + Ge^{-x^2}}\, dx. \qquad (6)$$

Neglecting the Debye length compared with h, we find from (6)

$$\frac{\langle\sigma_{ii}v_i\rangle n_n}{\sqrt{\frac{2T_e}{M}}}h = s_h = \frac{2}{\pi}\int_0^{u_r}\frac{1 - N - 2xF(x)}{N + Ge^{-x^2}}\, dx. \qquad (7)$$

It follows from (5) and (7) that if T_e, n_n, h, and the velocity of the primary ion beam are specified, the quantities u_r and N are determined unambiguously. To find the total potential drop from the axis to the wall we use the steady-state equality of the fluxes of electrons and secondary ions to the wall:

$$n_0\sqrt{\frac{2T_e}{m}}\exp\left\{\frac{e(\Delta\varphi_r + \Delta\varphi_0)}{T_e}\right\} = \langle\sigma_{ii}v_i\rangle n_n n_1 h + \langle\sigma_{ie}v_e\rangle n_n n_0\int_0^h \exp\left(\frac{e\varphi}{T_e}\right) dz$$

or, in dimensionless form,

$$u_c^2+u_r^2=-\ln\left\{\sqrt{\frac{m}{M}}\left(s_hN+G\int\limits_0^{s_h}e^{-u^2(s)}ds\right)\right\}. \qquad (8)$$

Using Eqs. (5), (7), and (8) we can determine u_r, u_c, and N as functions of the type of gas, the pressure, the geometric dimension h, and the electron temperature T_e. It is convenient to replace s_b by the T_e-independent quantity $s_w = \sqrt{T}s_h$, where $T = T_e/eV_i$. Figure 1 shows illustrative functional dependences of N on s_w calculated from (5) and (7) for argon for various values of T [1) 0.5; 2) 0.3; 3) 0.5; 4) 0.125; 5) 0.2]. In the calculations we assume the primary ions to have an energy of 1 keV. Figure 2 shows the corresponding potential drops u_r^2 (dashed curves) and $u_r^2 + u_c^2$ as functions of s_w [1) 0.5; 2) 0.3; 3) 0.05; 4) 0.125; 5) 0.2]. Since the potential drop in the plasma u_r^2 is lower than T_e, the potential drop $u_r^2 + u_c^2$ is governed primarily by u_c^2. We see from Fig. 1 that N → 1 for all T as s_w decreases, i.e., the density of the secondary plasma becomes small. With h ~ 1 cm and $n_n \leq 10^{13}$ cm^{-3} we have $s_w \leq 10^{-2}$; for $T_e < 0.3eV_i$, according to the curves, N ≥ 0.8. An estimate for argon for $T_e \simeq 0.2eV_i$ yields $G(T_e) \simeq 0.9$, i.e., the ionization by ions is comparable to that by electrons. As T_e decreases, G increases exponentially, and when $T_e < 0.2eV_i$ the ionization by ions becomes predominant. As s_w increases N decreases, i.e., the density of the secondary plasma increases. This means, in particular, that the ionization by electrons becomes predominant, even if the electron temperature is low [$G(T_e) \ll 1$], as, e.g., the geometric dimension h increases. These results suggest the following procedure for finding the boundary values of $\Delta\eta$ and n_1 for various values of h, mentioned above. Specifying certain values of Λ, i.e., of s_w, we use the corresponding curves (Figs. 1 and 2) to determine (for a particular value of T) the values of $u_c^2 + u_r^2$ and N, which can then easily be converted to $\Delta\eta = \theta_0(u_r^2 + u_c^2)$ and $n_1 = Nn_0$. In particular, if the conditions are such that most of the ionization is due to ions, $IN \gg \nu(\theta_0)$, we find the initial potential drop to be given by $\Delta\eta/\theta_0 \simeq \ln \Lambda Q\sqrt{\theta_0}/IN$. The unknown function δ(s) introduced in ref. 1 can be assigned a boundary value δ(0) of u_r^2. As $s \to s_c$ we have δ → 0, so it is natural to assume δ(s) < 1. At Λ ≤ 0.1-0.2 the detailed nature of the function δ(s) is unimportant.

QUASI-ONE-DIMENSIONAL TREATMENT

According to the one-dimensional theory[1] the properties of the sheath are essentially independent of the choice of initial conditions, including n_0. Solution of the quasi-one-dimensional system of equations for finite h and for various initial conditions shows (as in the one-dimensional case) that variations in j_0 and E_0 at fixed n_0 lead to a negligible scatter in the discharge characteristics about their average value. However, the solutions are sensitive to the choice of n_0 – the more so, the higher Λ. If the quantities $j_i(0)$, θ_A, θ_c, E_c, and η_c remain essentially independent of n_0 then $j_d = j(s_0)$ and n_c falls off relatively slowly (logarithmically) with increasing n_0. We are thus led to the question of choosing n_0. At pressures which are not too low (p ~ 10^{-3}-10^{-5} torr) we can evidently approximate n_0 by

$$n_0\geqslant n_i(0)=\beta\int\limits_0^{s_c}\frac{\nu n+In_1}{\left(1+\Lambda^2 s\frac{\theta}{E}\right)\sqrt{\eta}}ds \quad \left(\beta=\sqrt{\frac{M}{2m}\frac{\nu_i\nu_0}{\omega_e^2}}\sim n_n\right), \qquad (9)$$

where $n_i(0)$ is the ion density in the initial cross section.

Taking the two-dimensional effects into account we find, in addition to K and $\mathscr{E}$, the dimensionless parameters $\Lambda \sim \sqrt{\varphi_0}/hH$, $Q \sim H/n_n$. It should be noted that the experiments on the discharges are carried out in devices which cannot be treated as one-dimensional: Using the quantity Λ as a measure of the importance of two-dimensional effects, we find its value to be 0.05-2, 0.2-0.5, 0.25, and 0.2 for the experimental conditions of refs. 4-7, respectively. Figures 3-5 show how the distributions of the quantities over the sheath vary with increasing Λ (parameters of the curve). Figure 3 shows typical η(s) and θ(s) distributions, Fig. 4 shows n(s) and E(s), and Fig. 5 shows j(s) and $j_i(s)$ (the solid and dashed curves, respectively). The coordinate s is measured from the anode on the curves, and the electron-depleted region corresponds to the horizontal parts of the E(s) and j(s) distributions. For convenience in comparing with the results of the one-dimensional treatment we use the same scaling and parameters (K = 63, $\mathscr{E}$ = 0.05, I = 10^{-2}, Q = $6.7\cdot10^3$, β = 10^{-2}, α = 5, and Λ = 0.25/h, corresponding to φ_0 = 1 kV, H = 1 kOe, and p = $5\cdot10^{-5}$ torr for argon).

It follows from these curves that with Λ → 0 we find the results of the one-dimensional treatment. As Λ increases, we find differences, which are particularly

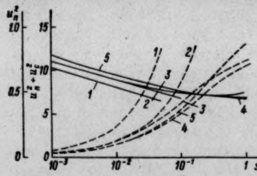

Fig. 2

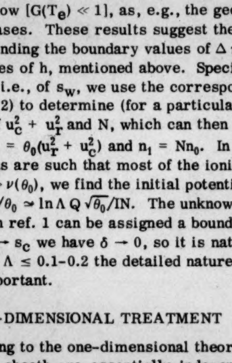

Fig. 1

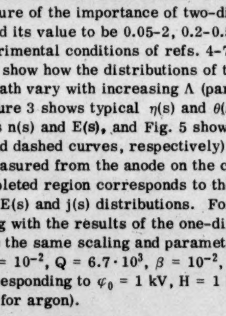

Fig. 3

marked in the distributions of the currents and the density of electrons. The loss of electrons along the magnetic field to the cathodes reduces the electron density and thus the number of ionization events caused by electrons and the electric field. Consequently, there is a certain decrease in the ion current at the exit of the system, but the loss of electrons has a particularly marked effect on the electric current which reaches the anode. As Λ is increased from 0 to 0.1 the ratio of this leakage current to the discharge current changes from 0 to 2. These values can be found from the curves in Fig. 5 and

$$\frac{\int_0^{x_0} j'_w dx}{A j_e(x_0)} = \frac{h}{A}\frac{j_i(0) - j_e(x_0)}{j_e(x_0)} > \frac{j_i - j_d}{j_d}.$$

Another interesting quantity is the ratio of the power evolved at the anode to that supplied to the discharge, which is equal to the average electron energy at the anode in units of $e\varphi_0$. As Λ increases this quantity decreases slightly. As Λ changes, the distributions become deformed in a relatively narrow region near the anode (Figs. 3-5). The length of the sheath and the nature of the distributions at the beginning of the sheath change negligibly. In the electron-depleted region, despite its comparatively small size, the electrons acquire roughly half the energy brought to the anode.

Let us examine the discharge characteristics as functions of the pressure. The density of neutrals governs the value of Q and, when condition (9) is used, the value of n_0. Analysis of the solutions shows that when the pressure is changed by two orders of magnitude the sheath characteristics j_l, j_d, E_c, n_c, and θ_A vary over 30%. Certain difficulties arise in interpreting the solutions obtained at very low pressures ($p < 10^{-5}$ torr). In this case the distributions of all the quantities display a tail, over which there is an increasing voltage drop ($\eta_b > 0.1$). Adjacent to this part of the sheath, which should be included in the transition region, is the sheath proper, in which the predominant changes occur in the physical properties. Using the substitution $\eta' = (\eta - \eta_b)/(1 - \eta_b)$, which takes account of the actual voltage drop over the sheath, we can compare the solutions for different pressures. There are also changes in the scale quantities l^*, j^*, and θ^*, which lead to correction factors of $(1 - \eta_b)^{-1/2}$ for j and s and of $(1 - \eta_b)^{-1}$ for θ. After this conversion we find that all these characteristics of the sheath and its actual thickness are approximately the same for the different pressures. Figure 6 shows some finer features of the sheath, which are governed by the nature of the distributions: the ion energy spectra $j_l(\eta')$ for various pressures and Λ = 0.1. The absence of ions at energies of 0.85-1.0 from the spectrum is due to the electron-depleted region. We see that the retardation characteristics agree over a broad range of pressures. If we plot the distributions over the sheath of the leakage current (corresponding to the electrons escaping along the magnetic field to the cathodes), we find that the curves do not agree as well as those in Fig. 6. The corresponding curves are asymmetric because of our simplified model of the electron-depleted region.

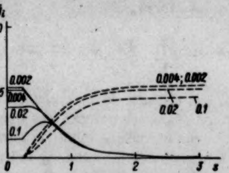

Fig. 5

DISCUSSION OF RESULTS AND COMPARISON WITH EXPERIMENT

Experimental study of low-pressure discharges with inhibited Hall current has led to the following conclusions. The discharge current increases with increasing voltage[6,8] and with increasing magnetic field[4] (this latter conclusion holds for an anode which is well-aligned along the magnetic field). The discharge current, the current corresponding to electrons being lost to the cathode, and the ion current are proportional to the pressure, while the Hall current is essentially independent of the pressure.[4-6] The effective thickness of the anode sheath increases with increasing discharge voltage and decreasing magnetic field and is independent of the pressure.[4] The distribution of the electron current to the cathode and the retardation curves for the ion current are independent of the pressure.[4,6] These results imply that the electron density and the potential distribution are also independent of the pressure. These discharge characteristics are also obtained theoretically; the solution leads to distributions corresponding to a sheath near the wall whose thickness is ~2-3 units of the quantity $l^* \sim \sqrt{\varphi_0}/H$ over broad ranges of the physical properties K, Q, Λ, and $\mathcal{E}$, independent of the initial conditions. The discharge current, the leakage current, and the ion current are expressed in units of $j^* \sim n_n H \sqrt{\varphi_0}$. The unit of measurement for the Hall current, $\omega\tau j^* \sim H^2 \sqrt{\varphi_0}$, is independent of the pressure. The density of the negative space charge is expressed in units of $n^* \sim H^2$. As noted above, the ion energy spectrum (Fig. 6) is only a weak function of the pressure. The values of the

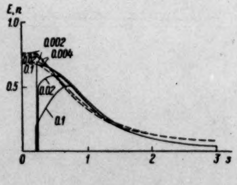

Fig. 4

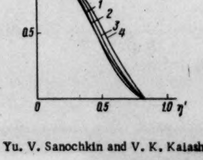

Fig. 6. 1) $p = 3 \cdot 10^{-4}$, 2) $5 \cdot 10^{-5}$; 3) $5 \cdot 10^{-6}$; 4) $5 \cdot 10^{-7}$ torr.

basic characteristics of the sheath, j_i, j_d, E_c, n_c, θ_A, and θ_c are approximately the same for various pressures. Accordingly, the basic functional dependences among the discharge properties are incorporated in the scales chosen for the physical quantities, l^*, j^*, and n^*, and the calculations reveal only the coefficients of the proportionalities between the corresponding quantities and their units of measurement for the various conditions.

Let us attempt a quantitative comparison of the calculated and experimental results for several situations. According to ref. 4, for $p = 3 \cdot 10^{-4}$ torr, $\varphi_0 = 1$ kV, and H = 1 kOe in an inverted magnetron having dimensions of h = 3.7 cm, A = 3.5 cm, and $r_A = 0.9$ cm the discharge current is about 7.5 mA for an adjusted anode, i.e., we would have $ej_d \simeq 0.19$ mA/cm². Under the specified conditions for argon, assuming $\nu_i/\nu_0 = 0.1$, we find $l^* = 0.24$ cm, $n^* = 10^{10}$ cm^{-3}, $\nu_i \simeq 1.5 \cdot 10^{-7} n_n$, $ej^* = 0.62$ mA/cm², $\Lambda \simeq 0.07$, K = 63, $Q = 1.24 \cdot 10^3$; $\beta = 5.5 \cdot 10^{-2}$. The values of j_d calculated for these parameter values lie in the range 0.22-0.40 for the reasonable range $\mathscr{E} = 0.035$ 0.055. The corresponding current density is $ej_d \simeq 0.14$-0.25 mA cm²; the calculated value agrees with experiment at $\mathscr{E} = 0.044$. The calculations also yield the following values of the other quantities: $\theta_A \simeq 0.46$-0.43, $\theta_c =$ 0.26-0.23, $n_c = 0.3$-0.5, $E_c = 0.75$-0.77, and $j_i \simeq 0.55$ ($ej_i \simeq 0.34$ mA/cm²). The ratio of the leakage current to the discharge current varies from 1.5 to 0.4; with $\mathscr{E} =$ 0.044, it is ~0.8.

A detailed study has been made[5] of the discharge conditions in argon for $p \simeq 2.7 \cdot 10^{-4}$ torr, $\varphi_0 = 4$ kV, and H = 1 kOe in an inverted magnetron having dimensions of A = 2.5 cm, h = 2.7 cm, and $r_A = 0.9$ cm. The measurements yielded the following values: a discharge current $I_d \simeq$ 11.5 mA ($ej_d \simeq 0.41$ mA/cm²), an ion current $I_i \simeq 18$ mA, and an electron leakage current $I_e \simeq 6.5$ mA (the corresponding ratios are $I_e/I_d \simeq 0.56$ and $I_e/I_i \simeq 0.37$). The energy evolved at the anode and cathode disks was measured calorimetrically, so that the value $\theta_A = 0.37$ could be determined. Knowing the ion energy spectrum[4] we can estimate the energy evolved by ions at the cathode and write the heat balance equation; from it we can estimate the parameter $\mathscr{E} \simeq 0.06$-0.08. For the specified conditions we have $l^* \simeq 0.5$ cm, $n^* \simeq 10^{10}$ cm^{-3}, $ej^* \simeq 1.1$ mA/cm², $\Lambda \simeq 0.19$, K = 252, $Q = 1.35 \cdot 10^3$, $\beta \simeq 5 \cdot 10^{-2}$, and $I \simeq 10^{-2}$. For the specified range of $\mathscr{E}$ the calculations yield $j_d =$ 0.16-0.38, $j_i = 0.55$-0.53, $\theta_A = 0.42$-0.38, $\theta_c = 0.23$-0.2, $n_c = 0.21$-0.49, and $E_c = 0.81$-0.82 (or, in dimensional form, $ej_d \simeq 0.18$-0.42 mA/cm²). The corresponding current ratios fall in the ranges $I_e/I_d \simeq 2.4$-0.4 and $I_e/I_i \simeq$ 0.70-0.29. At $\mathscr{E} = 0.075$ the calculated and experimental values agree: $ej_d \simeq 0.38$ mA/cm², $\theta_A \simeq 0.39$, $I_e/I_d \simeq 0.58$, and $I_e/I_i \simeq 0.37$. The correspondence between the experimental and calculated data is evidence that the diffusion theory can in fact be used to describe the discharge. The assumption that the electron transport to the anode is due primarily to binary collisions also seems to be justified.

It is interesting to note the strong functional dependences of the discharge current j_d and the density n_e in the sheath on $\mathscr{E}$. To obtain unambiguous results we must drop the assumption $\mathscr{E}_i =$ const and use reliable data on the "cost" of an ion.

At the same time we have learned that variations in $\mathscr{E}$ and the two-dimensional effects have little influence on such parameters as E_c, θ_A, θ_c, j_i and the effective sheath thickness, so that these parameters can be estimated on the basis of the one-dimensional theory. The discharge current and the electron density in the sheath, on the other hand, are strongly influenced by the two-dimensional effects. Our model for the escape of electrons along H is evidently extremely crude, as we see, e.g., from the circumstance that the calculations predict the leakage to be concentrated primarily in a region from 0.5 to 1.0 unit in size adjacent to the stripping region, while experimentally[4] the leakage current apparently reaches a maximum near the beginning of the sheath. Furthermore, the calculations predict a weak functional dependence of the distribution of this leakage current on the pressure. We can thus assert that the electrons in a low-pressure discharge with magnetized electrons do not have a purely Boltzmann distribution.

It is now established that the anode sheath is not in a steady state at these parameter values;[9,10] in particular, periodic pulses have been observed in the electron leakage current along with the constant component of this current. The frequency of these relaxation oscillations increases with increasing pressure.

In this work we have attempted to determine the steady-state characteristics; it seems reasonable to speak of a steady state as long as the fraction of the current associated with the pulses is small in comparison with the constant current, i.e., at a sufficiently low pressure.

In conclusion the authors thank V. S. Erofeev for useful discussions.

Formation of a plasma focus in a plasma erosion accelerator.
II. Energy characteristics of the dense plasma focus

(Submitted April 18, 1972; resubmitted October 20, 1973)
Zh. Tekh. Fiz., 44, 2519-2522 (December 1974)

The integrated characteristics of the plasma focus in erosion plasma accelerators have been determined: the enthalpy and specific heat flux of the focus, the energy and light efficiencies, the utilization factor of the working medium, and the overall energy balance in the system. It is shown that these characteristics can be varied over broad ranges to suit a specific problem.

Under certain conditions, stable quasistationary, self-constricting plasma flows form beyond the end of pulsed electromagnetic plasma accelerators of the erosion type.[1-3] The flow velocity is $\sim 10^7$ cm/sec, the temperature is ~ 5 eV, and the particle density is $5 \cdot 10^{18}$ cm^{-3}.

The plasma properties attained in the plasma focus and the circumstance that these properties can be adjusted comparatively easily over wide ranges raise the hope that this type of plasma flow will find many applications.[4] In this connection it is worthwhile to study the integrated characteristics of the plasma focus – the energy and light efficiencies, the utilization factor of the working medium, etc.

We have previously reported[2] a study of the properties of the plasma in the focus; there we were concerned with determining the energy characteristics of the plasma focus in erosion plasma accelerators.

The local enthalpy of the compressed flow is given as a function of the time by

$$i^*(r,\ t) = n(r,\ t)\left[kT(r,\ t) + \frac{mV^2(r,\ t)}{2}\right], \tag{1}$$

where n(r, t) is the particle density, T(r, t) is the plasma temperature, V(r, t) is the average-mass velocity in the zone of maximum compression, m is the particle mass, r is the coordinate, t is the discharge time, and k is the Boltzmann constant.

The total enthalpy of the flow at the focus is

$$I^* = \frac{2\pi \int_t dt \int_{S(t)} i^*(r,\ t)\, r dr}{\int_t S(t)\, dt}, \tag{2}$$

where S(t) is the cross-sectional area at the region of maximum compression. The specific heat flux q is defined as the product of the enthalpy of the flow and the average-mass velocity,

$$q(r,\ t) = i^*(r,\ t)\, V(r,\ t), \tag{3}$$

while the total specific heat flux $\bar{q}$ is

$$\bar{q} = \frac{2\pi \int_t dt \int_{S(t)} i^*(r,\ t)\, V(r,\ t)\, r dr}{\int_t S(t)\, dt}. \tag{4}$$

We define the energy efficiency of the plasma focus as the ratio of the plasma energy at the focus to that stored in the capacitor bank:

$$\eta_{\text{en}} = \frac{\int_t dt \int_{S(t)} q(r,\ t)\, r dr}{W_0}, \tag{5}$$

where W_0 is the energy stored in the bank. The utilization factor of the working medium is

$$\varepsilon_{\text{wm}} = \frac{m \int_t dt \int_{S(t)} n(r,\ t)\, V(r,\ t)\, r dr}{\dot{m}}, \tag{6}$$

where the numerator is the amount of medium which passes through the focus during the discharge pulse, and $\dot{m}$ is the expenditure of working medium per pulse.

The light efficiency is defined as the ratio of the energy emitted over the range 50-20,000 Å to that stored in the capacitor bank. Measurements of the relative mass outflow and of the particle density at the surface of the dielectric in the discharge gap[5] and at the focus show that the degree of compression of the flow can be determined under the assumption of a polytropic process. As is shown in ref. 3, this is the case when the focus is formed under certain conditions. Thus,

$$\nu_{\text{co}} = \frac{\rho_{\max}}{\rho}\left[(\gamma - 1)\frac{C_{A0}^2}{C_{T0}^2}\right]^{1/\gamma-1}, \tag{7}$$

where

$$C_{A0}^2 = \frac{H_0^2}{4\pi\rho_0} \text{ and } C_{T0} = \gamma\frac{p_0}{\rho_0}$$

are the Alfvén and sound velocities, respectively, and γ is the ratio of the specific heats. Finally, the electrical efficiency of the system, which is a measure of how efficiently the energy stored in the capacitor bank is transferred to the discharge, is defined by

$$\eta_{\text{el}} = \frac{\int_t dt \int_t I(t)\, U(t)\, dt}{W_0}. \tag{8}$$

The energy characteristics of the plasma in the focus defined in this manner are shown in Table 1 as functions of the initial voltage on the capacitor bank, U_0. The M2-K accelerator is described in ref. 2, and the working medium is Fluoroplast-4 (Teflon) or copper.

The enthalpy and the specific heat fluxes increase rapidly as the energy supplied to the discharge is increased, and their values differ only slightly in accelerators differing in the geometry of the accelerating electrodes. These values are much higher at U_0 = 2 kV than at U_0 = 1 kV because of the markedly smaller size of the plasma in the case U_0 = 2 kV. The maximum heat fluxes, like the maximum degrees of compression, are obtained in accelerators whose electrodes have a "compressional" geometry. The degree of compression increases with the energy supplied to the discharge, amounting to ~ 100 at U_0 = 5 kV.

TABLE 1. Energy Characteristics of the Plasma Focus

Plasma forming material	U_0, kV	i^*, erg/cm^3	q, erg/sec·cm^2	η_{en} %	ε_{wm}, rel. units	ν_{co}, rel. units	η_{li} %	η_{el} %
Teflon	1	$5.7 \cdot 10^6$	$1.3 \cdot 10^{13}$	22	0.42	—	7.4	62
	2	$9.0 \cdot 10^8$	$2.7 \cdot 10^{15}$	54	0.59	38	5.2	78
	3	$3.1 \cdot 10^9$	$1.2 \cdot 10^{16}$	67	0.73	62	13.9	79
Copper	1	$4.2 \cdot 10^6$	$1.1 \cdot 10^{13}$	19	0.33	—	8.0	58
	2	$7.3 \cdot 10^8$	$1.8 \cdot 10^{15}$	51	0.58	45	18.4	74
	3	$8.9 \cdot 10^8$	$4 \cdot 10^{15}$	48	0.51	71	24.5	70

Its minimum values are found in end-type accelerators, i.e., the "two-step" compression due to processes in the interelectrode gap and in the external currents is more effective than the free pinching in the external currents. By shaping the electrodes in the appropriate manner it is possible to obtain a high flow velocity and to increase the kinetic component of the enthalpy [Eq. (1)], which is the predominant component.

It should be noted that the energy efficiency is reduced by 8-22% when the plasma is formed from a metal, because of the much more intense emission from the focus, the increased loss in the accelerator itself, and the removal of working medium in the form of droplets.

This high utilization factor of the working medium in erosion plasma accelerators (in comparison with gas-discharge plasma accelerators[6]) is evidently a characteristic feature of this type of accelerator.

As noted in ref. 2, the decrease in the light efficiency as the energy supplied to the discharge is raised to 1-2 kJ (i.e., the energy threshold for the formation of a focus) is due to sharply intensified reabsorption in focus. The energy of this emission increases ~45% in operation with a metal plasma (copper or aluminum), the nature of the emission spectrum changes (there is a sharp intensification of the continuum), and the light efficiency at $U_0 \doteq 3$ kV is 24.5%. From the standpoint of the light efficiency the best accelerator is the end-type accelerator working with a metal plasma. By choosing the working medium and discharge parameters properly one can achieve focused light pulses of any desired intensity and duration with any desired energy spectrum.

The overall energy balance consists of the components corresponding to the processes occurring in the accelerator and at the focus. The loss at the electrodes[7] is ~10-15% of the energy stored in the capacitor bank, essentially independent of the energy supplied to the discharge. The other losses in the accelerator – due to ablation of the dielectric, ionization, etc. – make up ~ 10% of the total energy balance. Thus the transfer of energy from the capacitors to the plasma focus can be very efficient in erosion accelerators with high electrical efficiency (up to ~0.94).

The properties of the plasma flow at the focus can be manipulated in order to achieve a high efficiency in the particular application, e.g., the production of a high-energy plasma flow for some plasma-chemistry process,[4] the production of a flow with a high working-medium utilization factor and a highly monoenergetic nature for use in hypersonic aerodynamics, or the production of focused light pulses for optical pumping of laser media. The particular plasma properties are achieved by choosing the appropriate accelerator geometry, working medium, and energy and dynamic characteristics of the discharge loop.

Effect of rf ionization on Hall-current plasma accelerator

I. I. Demidenko, N. S. Lomino, A. I. Morozov, and V. G. Padalka

(Submitted December 12, 1973)
Zh. Tekh. Fiz., 44, 2523-2528 (December 1974)

The effect of auxiliary radio-frequency ionization of the gas near the anode on the properties of a Hall-current plasma accelerator are investigated. Displacement of the region in which the entering gas is ionized toward the anode by the rf fields leads to an increase in the ion energy in the plasma and to a reduction of the spatial divergence of the plasma jet.

Of the various injectors used in thermonuclear research the most common are ion sources and pulsed plasma accelerators. Potential plasma injectors operating continuously or quasicontinuously with ion currents of ~1-10 kA at an ion energy of 1-10 keV are promising sources of plasma for thermonuclear reactors. Since the medium remains neutral in the acceleration region the plasma accelerator is not subject to the space-charge limitations of an ordinary ion source.

An electric field can only exist in a cool, low-density plasma in the presence of a magnetic field and electron drift; the electric field is perpendicular to both H and $\mathbf{v}_e$ (ref. 1). The marked reduction in the transverse electron conductivity in a strong magnetic field makes it possible for a strong electric field to penetrate into the plasma; this penetration can be exploited in effective acceleration of the ions.

Hall-current accelerators can be divided into two groups on the basis of the transverse electronic conductivity: If this conductivity is due to binary Coulomb collisions, the corresponding Hall-current accelerators have a comparatively short accelerating gap, $\Lambda_E \sim \rho_e$. Accelerators of this type have a metal channel, containing the accelerating gap, and a system for ionizing the working medium. In accelerators of this type the beam of accelerated ions is highly monoenergetic, ion beams at energies up to 20-30 keV can be produced, and the beam divergence is small. However, the currents are relatively weak ($j_i \sim 10^{-1}$ A/cm^2), and strong magnetic and electric fields must be used.[2]

In Hall-current accelerators with an extended acceleration region the mechanisms responsible for the transverse electron conductivity are the more intense turbulent and wall mechanisms. These systems can produce extremely high ion current densities (1-3 A/cm^2) at an overall ion current ~1 kA, and the electric and magnetic fields are weak. However, the ion beams are decidedly not monoenergetic, and the angular divergence is large (up to ± 30°) (ref. 3). These properties are consequences of the relatively large size of the region in which the working medium is ionized; these effects make difficult the analysis of the possible use of such accelerators as injectors for thermonuclear devices.

One type of Hall-current accelerator with an extended acceleration zone is the two-lens accelerator. It has an axial accelerating channel with a "two-lens" radial magnetic field; the field is in opposite directions in the first and second lenses. The working gas entering the system is ionized in this channel, and the ions are accelerated by the electric field along the channel. The magnetic field serves two purposes: It "freezes" the electron component and focuses the ion beam.

The ion motion in the accelerating channel is analyzed in detail in ref. 4. The ions crossing the exit plane of the accelerators move along straight lines whose directions are governed by the relations among v_z, v_r, and v_φ, i.e., the longitudinal, radial, and azimuthal components of the ion velocity $\mathbf{v}_i$ at the exit plane. In general the shape of the ion beam leaving the accelerator can be described by a set of surfaces of revolution (single-sheet hyperboloids) which intersect the exit plane of the accelerator.

Since the plasma density in the accelerating channel is relatively low (~10^{11}-10^{12} cm^{-3}), the motion of an ion under the influence of the electric and magnetic fields can be assumed to be collisionless. If we neglect plasma noise and the azimuthal components of the magnetic and electric fields, we can estimate the ratio of the azimuthal component of the ion velocity to the magnitude of the total velocity at the exit plane on the basis of conservation of the azimuthal component of the generalized momentum:

$$P_\varphi = Mv_\varphi + \frac{e}{c}A_\varphi = \frac{e}{c}\frac{r^0}{r}A_\varphi^0, \qquad (1)$$

where A_φ, the only nonvanishing component of the magnetic vector potential, is related to the field components by

$$H_r = -\frac{\partial A_\varphi}{\partial z}; \quad H_z = \frac{\partial A_\varphi}{\partial r}, \qquad (2)$$

where A_φ^0 denotes the value of A_φ at the point at which an ion with radial coordinate r_0 is produced (we assume that the ion velocity is zero at this point). The total ion velocity can be estimated from energy conservation:

$$\frac{Mv^2}{2} + e\Phi = e\Phi_0, \qquad (3)$$

where Φ is the electric potential. Then we have

$$\frac{v_\varphi}{v} = \frac{v_\varphi}{v_z}\frac{1}{\sqrt{1+\left(\frac{v_r}{v_z}\right)^2+\left(\frac{v_\varphi}{v_z}\right)^2}} = \sqrt{\frac{e}{2M}}\,\frac{r^0A_\varphi^0 - rA_\varphi}{cr\sqrt{\Phi_0-\Phi}}. \qquad (4)$$

In the exit plane of a two-lens accelerator we have $A\varphi = \Phi = 0$ and

$$\frac{v_\varphi}{v} = \sqrt{\frac{e}{2M}}\,\frac{r^0A_\varphi^0}{cr\sqrt{\Phi_0}} = f(r^0,\ z^0), \qquad (5)$$

where r^0, z^0 are the coordinates of the point at which the ion is produced.

The ionization occurs over a long distance in the accelerating channel[5] (~10 cm), spanning essentially the entire length of the first lens. Measurements of the ion current lines in the accelerator channel have confirmed this conclusion. In certain cases the ionization region even extends into the second lens.[6] These effects tend to smear the energy spectrum of the accelerated ions at low energies and produce a pronounced divergence of the beam leaving the accelerator.

If we assume the ideal case of collisionless ion motion in an accelerator with two sections of equal radial magnetic flux, then the ions produced near the anode ($A_\varphi^0 = 0$) acquire an azimuthal velocity v_φ as they move through the first lens (the length of the lens is $L < \rho_i$, where ρ_i is the characteristic ion Larmor radius); when the ions intersect the magnetic flux of the second lens they lose this velocity. As a result, the flux of ions produced near the anode should have a low divergence and the maximum possible energy at the accelerator exit. In the other limiting case in which the ion is produced in the region between lenses ($A_\varphi^0 = A_{\varphi\max}^0$) the particle is accelerated to an intermediate energy and is deflected significantly after passing the maximum magnetic flux. Accordingly, the optimum acceleration of ions in a two-lens Hall-current accelerator would require the displacement of the ionization to the region near the anode; this displacement can be achieved by using correcting magnetic fields or by preliminary ionization of the working gas entering the accelerator.

Figure 1 shows the two-lens Hall-current accelerator studied here which uses rf ionization of the working gas. The inner, alundum wall of the accelerator is 8 cm in diameter, and the outer glass wall is 13.5 cm in diameter. The accelerator is 30 cm long. It is part of a vacuum chamber with a volume of 1 m^3; the cathode is made up of the exit flange of the accelerator and the walls of the evacuated volume. The power supply is a 350 μF capacitor bank, which is discharged through a line which produces a rectangular voltage pulse. For typical operating conditions the voltage on the accelerator is 1 kV (with a current ~1 kA and a pulse length of 750 μsec. The working gas (hydrogen) is admitted into the accelerator in quantities ~1 $cm^3 \cdot$ atm by means of an electrodynamic valve through an aperture in the anode. The initial pressure in the volume, before the gas is admitted, is $5 \cdot 10^{-6}$ torr. The radial magnetic field in the lenses is ~250 Oe, and the lenses are 10 cm apart (Fig. 2). The lens-shaped magnetic field provides magnetic and electrostatic focusing of the ion beam.[1,4]

The gas entering the system is ionized by a three-turn rf coil around the outer wall of the accelerator, between the anode and the first magnetic lens. The pulsed rf oscillator is a half-wave circuit using a GI-14B metal-ceramic triode; it operates at a frequency ~180 MHz with a pulse length ~600 μsec). Power is fed from the oscillator to the load by a conductive coupling; the power taken from the oscillator is ~100 kW. The unipolar voltage pulse at the oscillator is produced by the capacitor bank through the pulse-shaping line and a step-up transformer. Effective absorption of rf energy by the plasma is achieved by using the electron cyclotron resonance. Under the coil the longitudinal magnetic field H_z is 50 Oe at the mean radius of r = 5.4 cm, and the oscillator frequency is $\omega \simeq \omega_{He}$.

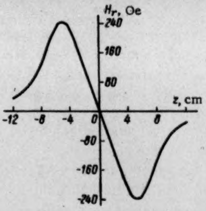

Fig. 2. Radial magnetic field H_r along the accelerator at r = 5.4 cm.

The voltage is fed to the accelerator 750 μsec after the electrodynamic gas valve is operated; the shape of the voltage pulse at the source is approximately rectangular (Fig. 3c), and the pulse height is ~1 kV. We do not study the spatial distribution of the hydrogen pressure in the system at the beginning of the discharge or the rate at which the hydrogen is supplied. The shape of the current pulse is different from the shape of the voltage pulse but similar to the time dependence of the plasma emission from the accelerator (Fig. 3b). The peak current is ~1 kA.

The energy spectra of the plasma ions and the angular divergence of the jet have been studied with and without the auxiliary rf ionization of the working gas. The rf oscillator is turned on 650 μsec after the inlet valve is operated (Fig. 3a shows the envelope of the rf pulse). The measurements show that this time delay is optimum in terms of the change in the plasma energy spectrum at the second maximum of the discharge current and the plasma emission (500 μsec after the beginning of the discharge in the source).

The plasma energy spectra are measured by a retarding-potential method with a wide-aperture multigrid

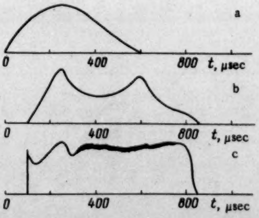

Fig. 3. Oscillograms of a) the envelope of the rf pulse; b) the plasma emission; c) the voltage across the accelerator.

probe,[3,7] which consists of four high-transmission, plane-parallel molybdenum grids in front of a (solid) ion collector. The first grid, connected to the housing of the probe, is at a floating potential, so that there is no current flow from the discharge through the probe housing. The second grid is at a negative potential ~100 V, to separate the plasma entering the probe into its ion and electron components. The third grid is used for the energy analysis of the ions, with a retarding potential (from 0 to 1 kV). The fourth (suppressor) grid shields the collector from the fields of the other grids and suppresses secondary electron emission from the collector; it is held at a negative potential of −100 V. The ion current drawn by the collector is displayed on an S1-29 oscilloscope. The probe is held 60 cm from the exit plane of the accelerator and can be moved in the radial direction ($\Delta r = \pm 45$ cm).

Figure 4 shows the ion current drawn by the collector as a function of the retarding potential with and without the auxiliary rf ionization of the hydrogen in the anode region of the accelerator. These measurements are carried out with the probe at the axis at a time $t = 500$ μsec after the beginning of the discharge (the second maximum in the ion flux). Turning on the rf ionizer does not affect the current drawn at a zero retarding potential (with respect to the housing of the probe), but the functional dependence of the ion current on the retarding potential is shifted toward higher retarding voltages. This behavior implies a shift in the energy spectrum of the accelerated ions toward higher energies because of the auxiliary rf ionization.

The average ion energy can be estimated from

$$\bar{\varepsilon}_{\parallel}=\frac{\int_0^{\infty}\varepsilon_{\parallel}g(\varepsilon_{\parallel})\,d\varepsilon_{\parallel}}{\int_0^{\infty}g(\varepsilon_{\parallel})\,d\varepsilon_{\parallel}}, \qquad (6)$$

where

$$g(\varepsilon_{\parallel})=\left.\frac{dJ_i}{d\varepsilon_{\parallel}}\right|_{\varepsilon_{\parallel}=eV_{\parallel}}.$$

The numerator of this fraction is proportional to the area bounded by the given curve and the coordinate axes, while the denominator is proportional to the ion current at $V_{\parallel} = 0$. Calculations show that in the absence of the rf ionization of the gas near the anode the average ion energy is $\bar{\varepsilon}_{\parallel} = 400$ eV; the ionizer increases this energy to 550 eV.

The ion energy spectra can be found by a graphical differentiation of the curves in Fig. 4, although the error of this procedure can be large. Figure 5 shows the results of a differentiation of the functional dependence of the ion current on the retarding potential with and without the rf ionization. In the absence of the auxiliary rf ionization the energy sepctrum has two peaks, at 150 and 600 eV, apparently due to ionization of the gas in both lenses, confirming the extension of the ionization region into the accelerating channel. The auxiliary rf ionization increases the height of the higher-energy peak and shifts it up to 700 eV. At the same time, the lower-energy peak falls to half its height and shifts to 250 eV. This behavior implies that the auxiliary rf ionization of the gas near the anode tends to increase the relative number of particles which traverse the entire potential difference and tends to reduce the relative number of accelerated particles which are produced near the exit plane of the accelerator in the vicinity of the second magnetic lens. Accordingly, the shift of the hydrogen-ionization region toward the anode increases the average energy of the ions in the plasma jet produced by the accelerator.

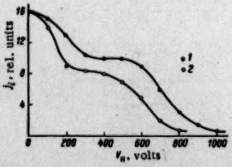

Fig. 4. Ion current drawn by the collector of the multigrid probe as a function of the retarding potential. 1) With; 2) without rf ionization of the hydrogen in the anode region of the accelerator.

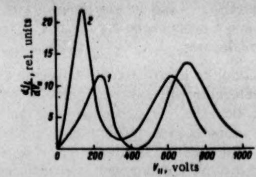

Fig. 5. Energy spectra of the plasma ions with (1) and without (2) rf ionization of the hydrogen in the anode region of the accelerator.

An increase in the average ion energy in the plasma jet should be accompanied by a contraction of the angular distribution of the ion velocities beyond the exit plane. In the ideal case in which an ion is produced in a region with $A_{\varphi}^{0} = 0$ and $\Phi_0 = \Phi_{0\max}$, the azimuthal velocity would be $v_{\varphi} = 0$, and we would have $v = v_{\max}$. We measure the spatial divergence of the plasma jet with the multigrid probe with a zero retarding potential in a plane parallel to the exit plane of the accelerator and 60 cm away from it. These measurements are carried out at the same time ($t = 500$ μsec) as the measurements of the ion energy spectra. The results are shown in Fig. 6. The angular divergence of the accelerated plasma in the case of no rf ionization is ± 35°; the rf ionizer contracts the ion spatial distribution to ± 25° and increase the signal level at the axis.

Accordingly, the properties of the plasma jet produced by a Hall-current accelerator with an extended acceleration region can be significantly improved by a more

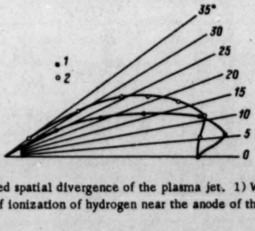

Fig. 6. Measured spatial divergence of the plasma jet. 1) With; 2) without the auxiliary rf ionization of hydrogen near the anode of the accelerator.

rationally planned ionization of the working gas. By displacing the region in which the gas entering the accelerator is ionized toward the anode, through the use of auxiliary rf fields, one can increase the energy of the plasma ions and reduce the angular divergence of the plasma jet.

Analytic model for the arc regime and the thermionic converter

V. D. Bondarenko and A. I. Loshkarev

(Submitted November 5, 1973)
Zh. Tekh. Fiz., 44, 2529-2536 (December 1974)

Questions involved in the determination of absolute work functions for the cathode and anode from the experimental voltage–current characteristics for an arc are discussed. This diagnostic procedure is based on a matching of the quenching region on the theoretical characteristic, where a virtual cathode forms, with the corresponding region on the experimental characteristic. Simple analytic expressions for the theoretical dimensions of this region are derived. The changes in the electron temperature over the gap are taken into account in the approximation according to which all the ions generated in the volume are scattered to the cathode. Analysis of many experimental voltage–current characteristics by this method reveals a good agreement between the theoretical electrode work functions obtained and the results of independent measurements.

The diagnostics of the internal properties of thermionic converters (the cathode work function Φ_K, the anode work function Φ_A, etc.) on the basis of the voltage–current characteristics is an extremely important question, e.g., from the standpoint of interpreting lifetime tests. Essentially no work has been reported on the development of procedures for determining the emission properties of electrodes in the arc regime at high cesium vapor pressures, in which case there is no clearly defined break on the arc branch of the voltage–current characteristic at the transition from the region in which the potential in the cathode drop is distributed monotonically to the region with a virtual cathode. Even when there is a clearly defined break the current J at the break cannot be identified with the emission current J_{em}. As is shown below, the coefficient $t = J_{em}/J$ at this point takes on significantly different values for various gaps d and for various cesium pressures p_{Cs}. The method of ref. 1 determining emission properties of cathodes requires that the interelectrode gap be changed, but this is not always possible. For diagnostic purposes there are definite advantages in the use of analytic models, which can be used to trace the explicit functional dependence of the voltage–current characteristics on all the adjustment parameters, so that a closed system of algebraic equations can be found and used to determine several of the internal properties. The successful use of analytic models for diagnostics depends on a good matching of the theoretical and experimental voltage–current characteristics. In the familiar arc-regime model,[2,3] the effects of Coulomb scattering and volume recombination are neglected, but these processes can contribute significantly to the developed arc. These effects are incorporated in the analytic model of ref. 4. In both these models the assumption that the electron temperature T_e is constant over the gap leads to a symmetric density distribution over the gap, so that the same number of ions, S/2, where S is the total number of ions generated in the gap, is scattered to each electrode.

Actually, the maximum of the generation function is closer to the cathode than to the anode because the electron temperature is higher at the cathode, and most of the ions are scattered to the cathode.

It has been shown[4] that the voltage–balance equation

$$\Delta V = \frac{T_e}{e} \ln \frac{J}{J_{em}^{ef} - J} + J\,(R_{Cou} + R_n) \tag{1}$$

and the energy-balance equation for electrons,

$$e\Delta V J = J_{em}^{ef}(2T_e - 2T_K) + eSE_i^{ef} \tag{2}$$

retain the same form when there is a variation in the electron temperature, provided that the average electron temperature is used in these equations.

In these equations we have adopted the following notation: ΔV is the potential drop between the potential minimum at the cathode and the potential of the anode surface, $J_{em}^{ef} = J_{em}\exp(-e\Delta\varphi_{vir}/T_K)$ is the effective emission current in the presence of a virtual cathode having the effective work function, $\Phi_K^{ef} = \Phi_K + \Delta\varphi_{vir}$, $\Delta\varphi_{vir}$ is the additional potential jump, which retards the emitted electrons, $R_{Cou} = (4\sqrt{2\pi}/3)(m_e^{1/2}e^2T_e^{3/2})\Lambda d$ is the part of the plasma resistance due to Coulomb scattering and independent of the density profile in the gap, Λ is the average value of the Coulomb logarithm, $R_{Cou} = (8\sqrt{2}/3\sqrt{\pi}) \cdot (m_e^{1/2}/e^2)\sigma_{ea}T_e^{1/2}n_a \int_{x_K}^{x_A} dx/n$ is the part of the resistance due to scattering by neutrals, σ_{ea} is the cross section for scattering of electrons by neutrals, and $E_i^{ef} \approx 6$ eV is the effective energy expended on the formation of an electron–ion pair.[4]

The minimum average electron temperature in the arc can be determined from

$$\delta^2 \equiv 1.44 \cdot 10^{-12} \exp\left(-\frac{3.21}{T_e}\right) n_a v_{eT} \frac{d_E^2}{D_a} = \pi^2, \tag{3}$$

where n_a is the average density of atoms in the gap, v_{eT} is the mean electron thermal velocity, d_E is the extrapolated size of the interelectrode gap, and D_a is the average ambipolar diffusion coefficient.

It follows from the equation for R_n that this quantity is governed primarily by the density near the electrode. Since

$$S = \frac{1}{2} n_K v_{iTK} + \frac{1}{2} n_A v_{iTA},$$

where n_K (n_A) is the plasma density near the cathode (anode), and v_{iTK} (v_{iTA}) is the electron thermal velocity near the cathode (anode), we can write R_n approximately as

$$R_n = \frac{K_{RS}(S)}{eS}, \tag{4}$$

where $K_{RS}(S)$ is a slowly varying function of S, governed by the nature of the density profile in the gap.

The details of the density profile are important only near the electrodes, where n reaches its minimum values. Using a sinusoidal density profile after the model of ref. 3 to calculate K_{RS} we find

$$K^0_{RS} = 4\sqrt{2}\sqrt{\frac{m_e}{m_i}}\frac{\sigma_{ea}}{\sigma_{ia}}\sqrt{\frac{T_e}{T_i}}\left(\frac{T_i}{e}+\frac{T_e}{e}\right)\cos\pi\frac{\Delta d_E}{d_E}\ln\frac{1}{\operatorname{tg}\frac{\pi}{2}\frac{\Delta d_E}{d_E}}, \quad (5)$$

where $\Delta d_E = (1/2)(d_E - d)$ is the extrapolated increment. Calculations of K_{RS} for a density distribution described by an elliptic sine, as in the model of ref. 4, and calculations in the piecewise-linear approximation for the density profile, in which case the densities and their derivatives are equal at the edges of the gap (so that S is constant in all three cases), give approximately equal results. The scatter is comparable to the scatter in values of the ratio σ_{ea}/σ_{ia}.

Calculations show that, with the maximum of the generation function right at the cathode surface, we have, for a broad range of $\Delta d_E/d_E$,

$$K_{RS} \approx (2-3)K^0_{RS}. \quad (6)$$

System (1), (2), (4) can be used to construct a J^{ef}_{em} = const grid in the V−J plane for each value of δ.

A perturbation study of the stability of this grid shows that as δ is changed from its minimum value of π (corresponding to a weakly developed arc with negligible recombination) to $\delta = 15$ (a highly developed arc with an ionization equilibrium in a large part of the gap), and for K_{RS} or E_i^{ef} different from its actual value by a factor of 2, the maximum deformation of the J_{em} = const grid near the turning point is no more than $0.4\,T_K$ for the specified current. The error in the current on the gently sloping branches of this grid is extremely small (a few percent).

Accordingly, the J_{em} = const grid is stable with respect to the detailed structure of the model, specified by the quantities δ, K_{RS}, and E_i^{ef}; and the maximum deformation of this grid due to errors must not exceed 0.1 V. For the analysis below we therefore adopt the values $\delta = \pi$, $K_{RS} = 2k^0_{RS}$, $E_i^{ef} = 6$ eV, $\sigma_{ia} = 10^{-13}$ cm², $\sigma_{ea} = 2.5 \cdot 10^{-14}$ cm², $T_{i,a} = (1/2)(T_K + T_A)$, and $\Lambda = 5$.

In the arc-quenching region, where a virtual cathode is formed, the potential drop near the cathode, $\Delta\varphi_K$, measured from the potential minimum in the cathode sheath, is related to the parameters $t = J^{ef}_{em}/J$ and $\theta_K = T_{eK}/T_K$ by[5]

$$(t-1)\exp\left(\frac{e\Delta\varphi_K}{T_{eK}}\right) = \frac{\pi}{\sqrt{2}\,b_{iE}}\frac{\sigma_{ia}}{\sigma_{ea}}\left[\frac{1+\theta_K^{1/2}}{\theta_K^{1/2}}(t-1)+1\right]^2, \quad (7)$$

where $b_{iE} \approx 2$ is the ratio of the flux of ions scattered to the cathode to the random ion flux at the cathode.

Using the boundary condition on the electron current at the cathode,

$$J = J^{ef}_{em} - \frac{1}{4}n_K v_{eTK}\exp\left(-\frac{e\Delta\varphi_K}{T_{eK}}\right),$$

and the assumption that all the ions generated in the gap are scattered to the cathode, we conclude that

$$\frac{eS}{J} = \frac{\pi}{\sqrt{2}}\frac{\sigma_{ia}}{\sigma_{ea}}\frac{1}{\theta_K^{1/2}}\sqrt{\frac{m_e}{m_i}}\left[\frac{1+\theta_K^{1/2}}{\theta_K^{1/2}}(t-1)+1\right]^2. \quad (8)$$

Through a joint solution of Eqs. (1), (2), and (8) we find the following parametric functional dependences of the current voltage in the part of the voltage−current characteristics corresponding to quenching of the arc and the formation of a virtual cathode:

$$J_{vir}(t) = \frac{1}{R_{Cou}}\left\{\frac{2T_K}{e}t(\theta-1)+\frac{T_K}{e}\theta\ln(t-1) + \frac{E_i^{ef}}{e}A\left[\frac{1+\theta_K^{1/2}}{\theta_K^{1/2}}(t-1)+1\right]^2 - \frac{K_{RS}}{A}\left[\frac{1+\theta_K^{1/2}}{\theta_K^{1/2}}(t-1)+1\right]^{-2}\right\}, \quad (9)$$

$$V_{vir}(t) = \Phi_K^{ef} - \Phi_A - \frac{2T_K}{e}(\theta-1)t - \frac{E_i^{ef}}{e}A\left[\frac{1+\theta_K^{1/2}}{\theta_K^{1/2}}(t-1)+1\right]^2, \quad (10)$$

where

$$\theta = \frac{T_e}{T_K}, \quad A = \frac{\pi}{\sqrt{2}}\frac{\sigma_{ia}}{\sigma_{ea}}\frac{1}{\theta_K^{1/2}}\left(\frac{m_e}{m_i}\right)^{1/2},$$

and Φ_K^{ef} can be evaluated by means of the Richardson equation, from

$$J^{ef}_{em}(t) = tJ(t).$$

Equation (8) describes a weak functional dependence on the quantity Θ_K. Calculations carried out under the assumption $\theta_K = \theta$ and $\theta_K = 2\theta$ show that the quenching curve, i.e., the function $J_{Cou} = J_{Cou}(V_{Cou})$, remains essentially constant, while the values of the parameter t at the corresponding points of this curve differ by less than 20%. Thus, assuming $\theta_K > \theta$, we set $\theta_K = 2\theta$ in the calculations below.

The maximum value of Φ_K^{ef} can be estimated in the following manner: The plasma synthesized at the hot cathode has an equilibrium chemical potential $\mu_K(T_K, p_{Cs})$. For typical conditions ($T_K = 2000$°K, p_{Cs} = 1-10 torr) we have $\mu_K \approx 2.95$, and the optimum value is $\Phi_K \approx 2.7$-2.8 eV (ref. 4). Accordingly, under approximately optimum conditions the arc discharge in a thermionic converter is usually ignited from an undercompensated regime. The ion flux from the plasma toward the cathode resulting from volume ionization, which is much higher than the equilibrium random fluxes, reduces or totally eliminates the virtual cathode, and the equilibrium chemical potential μ_K can be used as an upper estimate of Φ_K^{ef}.

Then the characteristic regions of the voltage−current characteristics can be constructed in the following manner (Fig. 1). In region 1 we can assume that the characteristic coincides with the $J^{ef}_{em} = J_{em}$ line, determined from the cathode work function for the specified values of p_{Cs} and T_K at zero field. This assumption is valid for cathodes for which the work function is homogeneous over the surface. Taking account of the normal Schottky effect and the change in the coverage of the cathode surface with

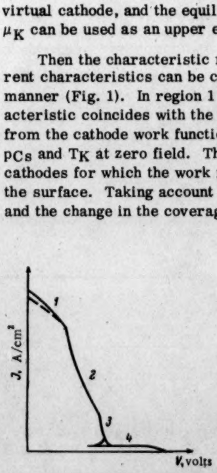

Fig. 1. General nature of the voltage−current characteristics of the thermionic converter.

a change in the degree of ionization of the plasma in the gap[6] leads us to the conclusion that J_{em}^{ef} will increase and the characteristics in region 1 will deviate from the J_{em}^{ef} = const line. Since these effects cancel out to a certain extent, this region can be constructed approximately from Eqs. (1) and (2) with fixed J_{em}^{ef}.

Equations (9) and (10) describe region 2. Since there is an upper limit on the virtual cathode, these equations apparently hold for currents $J > J_{\mu}$, where J_{μ} is the random electron current in the equilibrium plasma at temperature T_K. As the current is reduced further, two limiting cases can be reached. First, a diffusion region of the plasma, in which there is negligible volume ionization, can appear and expand.[7] Beyond this region is a layer in which there is a rapid potential jump, $\Delta\varphi$, within a Debye length. We note that, as follows from ref. 5, the total and oppositely directed electron flux Γ_e and ion flux Γ_i in this region are related by

$$\frac{\Gamma_e}{|\Gamma_i|}\sqrt{\frac{m_e}{m_i}} \approx \frac{1}{\theta^{1/2}}\frac{\sigma_{ia}}{\sigma_{ea}}\frac{\sqrt{2}\,\pi}{b_i^2}\exp\left(-\frac{2e\Delta\varphi}{T_{eK}}\right) \ll 1\ ;$$

i.e., the Langmuir equation for the double sheath, used in ref. 7, does not hold here.

The other possible limiting case can arise if the discharge is shunted. Nor do we rule out the possibility of a hybrid quenching mechanism, involving the contraction of the discharge and the simultaneous expansion of the diffusion region. It is difficult to treat such a two-dimensional system theoretically, since slight deviations of the electrodes from the isothermal, equipotential models can have strong effects. These effects are manifest in region 3 of the voltage–current characteristics.

Region 4 corresponds to a diffusion branch and negligible volume generation.

To compare these theoretical conclusions with experiment we use the most systematic experimental data available, that of refs. 8-13. Since the cathodes in these experiments are fabricated from gaseous tungsten, with a predominant orientation of the (110) faces, or are cut from tungsten single crystals, the patch effects (neglected in the theory) are minimized.

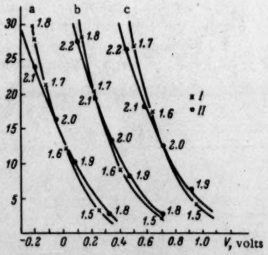

Fig. 2. Theoretical regions of arc quenching and the formation of a virtual cathode; variation of the parameter t along the quenching curve. a) T_K = 1600, b) 1800; c) 2000°K. T_A = 970°K, Φ_A = 1.8 eV. I) p_{Cs} = 0.70; II) 7 torr.

The theoretical regions of the characteristics constructed from Eqs. (9) and (10) are shown in Fig. 2. We see that even with a significant change in the pressure these regions are quite stable, due to the constancy of the anode work function assumed for the calculations (Φ_A = 1.8 eV). Furthermore, the parameter t is a strong function of the pressure at a specified current. The experimental characteristics of refs. 8-10 are influenced strongly by the cesium pressure; we can associate the changes in the characteristics with the significant changes which occur in the anode work function with increasing pressure. To determine Φ_A from the arc characteristics we bring the theoretical quenching regions (Fig. 2) into coincidence with the experimental regions (region 2 in Fig. 1). We observe good agreement between the theoretical and experimental regions over a broad current range, especially at high values of p_{Cs}. The values of Φ_A obtained in this manner are shown in Fig. 3 and Table 1. The good agreement between the values of Φ_A and the results of independent measurements by other methods[12-14] implies that the output voltages predicted by the theory are correct.

It should be noted that this model for the arc regime neglects inverse emission from the anode, and the anode potential drop is assumed to retard the electrons coming from the plasma.

At low cesium vapor pressures, and with a sufficiently hot anode, for which inverse emission becomes comparable to the current through the converter, there is an additional voltage loss

$$\Delta V_{inv} \approx \frac{T_e}{e}\ln\frac{J + J_{em,A}}{J}$$

where $J_{em,A}$ is the emission current from the anode. In this case the experimental treatment of the characteristics by the procedure described above should lead to a value of Φ_A larger than the actual value at low cesium pressures; we in fact observe this behavior in Fig. 3 (an estimate of ΔV_{inv} yields a value on the order of 0.05 V).

The tendency for an increase in Φ_A at high cesium pressures can be attributed to a reduction of the potential jump near the anode and even a change in the sign of this

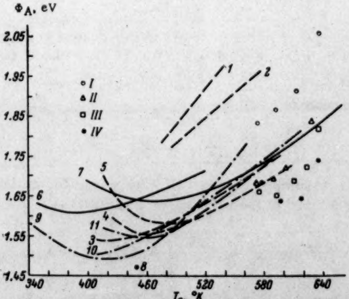

Fig. 3. Anode work function as a function of the cesium pressure and temperature, as determined by various methods.

jump, since there is a decrease in the ion current to the anode and a simultaneous increase in the current through the converter.

We note that, as shown in Fig. 3, it is incorrect to describe the experimental data on Φ near the minimum by a universal function of T_K/T_{Cs}. The minimum work function displays a strong temperature dependence, explaining the large scatter in the values of Φ_{min} plotted in Rasor coordinates.

The cathode work function is determined in the following manner: The beginning of the formation of the virtual cathode is identified with that point on the voltage–current characteristic at which the characteristic begins to deviate from the theoretical quenching regions as the current increases. The value of the parameter t at this point is chosen from the theoretical curve (Fig. 2). In this manner we treated about 200 characteristics spanning the following parameter ranges: $T_K = 1600$–2000°K, $p_{Cs} = 0.7$–10 torr, $d = 0.036$–1.0 mm, and $T_A = 673$–1073°K. As the gap is reduced in size we observe some decrease in the calculated value of J_{em}, which corresponds to an increase in Φ_K by no more than 0.03 eV. More pronounced differences are observed when Φ_A is plotted in Rasor coordinates and the cathode temperature is raised (Fig. 4). The designations are explained in Table 2. These differences can hardly be attributed solely to errors of the model used, since the parameter t would have to be increased to 3 or 4 in order to suppress the differentiation at a temperature of 2000°K. Nevertheless, the agreement between the emission properties of the cathode obtained by the various methods is quite good: All the data for a given cathode fall within a band 0.1 eV wide. In comparing the data in Fig. 4 it is necessary to take into account the fact that the emission determined from the measurements in the overneutralized regime (Fig. 4b) corresponds to the emission of spots of minimum work function in the cesium vapor in the presence of an extracting field at the surface. The proposed procedure (Fig. 4a) makes it possible to determine the emission when there is essentially no field at the cathode, when the virtual cathode begins to form above spots of maximum work function in the cesium vapor. We note that the emission is inhomogeneous even on single-crystal cathodes, as detailed studies have shown.

The functional dependence of the values of Φ_K on the cathode temperature and the gap size can be attributed partially to the variations in the density of cesium atoms over the gap. The formation of the equilibrium surface coverage of the electrode is governed primarily by atoms

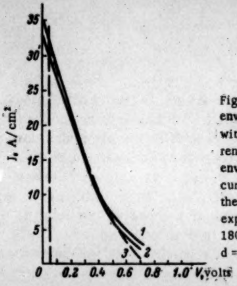

Fig. 5. Comparison of the theoretical envelope and the quenching curve with the experimental voltage–current characteristic. 1) Theoretical envelope of the characteristic; 2) curve corresponding to quenching and the formation of a virtual cathode; 3) experimental characteristic. T_K = 1800°K, T_A = 970°K, T_{Cs} = 636°K, d = 0.25 mm, Φ_A^{calc} = 1.8 eV.

in a sheath near the electrode having a thickness on the order of the atomic mean free path λ_a. If $d \approx \lambda_a$, the density of these atoms is governed by the electrode temperature for a fixed pressure in the cesium reservoir. In the case $d \gg \lambda_a$ the density is governed by half the sum of the cathode and anode temperatures. Accordingly, for small gaps and for identical cesium pressures, the cathode coverage will be higher and the anode coverage will be lower than for large gaps. Another factor leading to this dependence is the decrease in coverage due to the increase in the degree of ionization of the plasma near the cathode with increasing T_K. Nor do we rule out an effect of the temperature coefficient of the work function (in the Rasor coordinates). This dependence is also observed when the cathode work function is determined from the dynamic voltage–current characteristics.[15]

The curves corresponding to quenching and the formation of a virtual cathode at high currents lie near the envelopes bounding the characteristics.[4] According to our model the envelope can be calculated from

$$\frac{JR_{Cou}}{T_K} = 2t(\theta - 1) + \theta \ln (t - 1)$$

$$+ \frac{(E_i^{ef} K_{ks}^{0})^{1/2}}{T_K} \frac{[1 + 2t(\theta - 1)](t - 1) - [1 + t(\theta - 1)]}{\{[1 + 2t(\theta - 1)](t - 1)[1 + t(\theta - 1)]\}^{1/2}}, \tag{11}$$

which is easily found from (1) and (2) by setting $\partial(\Delta V) \cdot (\partial J_{em})^{-1} = 0$. Figure 5 compares the experimental voltage–current characteristics from refs. 8 and 9 with the envelope and the curve corresponding to quenching and the formation of a virtual cathode.

In conclusion the authors thank N. V. Kudryavtseva for assistance in the calculations.

Dielectric breakdown of detonation products

V. L. Korol'kov, M. A. Mel'nikov, and A. P. Tsyplenko
Scientific-Research Institute of High Voltages, Tomsk

(Submitted October 15, 1973; resubmitted April 1, 1974)
Zh. Tekh. Fiz., 44, 2537-2538 (December 1974)

An experimental study has been made of the dielectric breakdown of the products of the detonation of PETN and RDX behind the detonation front. The measured breakdown voltages are of the same order as those for solid dielectrics.

Study of the dielectric breakdown of detonation products is inspired by the use of high explosives in electrical separation devices, in which the detonation products are located between the parts of the ruptured conductor and are subjected to a strong electric field. The dielectric strength of these detonation products thus strongly influences the separation process.

The high-voltage pulses are produced by a 100 kV pulse generator with a capacitance of 400 pF and a pulse front which rises at 0.8 mV/μsec [sic]. The test gap (with a "point–point" geometry) has an interelectrode separation of 0.5±0.03 mm. The jacket of the explosive charge is designed to prevent breakdown outside the test gap. The charge is 7 mm in diameter and has a density of 1.0 g/cm^3.

Figure 1 shows the electrical circuit for the apparatus. As the detonation front propagates through the charge it acutates an ionization gauge; the pulse generator and the oscilloscope are triggered. The distance between the test gap and the ionization gauge is varied so that the voltage pulse is fed to the test gap at various times after the shock front of the detonation wave passes the plane of the test gap. This range of times is 0-4 μsec, being limited by structural features of the separation devices used.

A pulsed x-ray photograph (exposure time 10^{-7} sec) is taken of the detonating charge in order to detect the position of the gap electrodes. The resulting photographs show that the electrodes remain coaxial for 4 μsec after the shock front passes the plane of the test gap, and the distance between the electrodes does not increase by more than 30%. This increase in interelectrode distance is determined for various times and taken into account in the analysis of the results. The conductivity of the detonation products is measured by an electrical-contact method like that of ref. 1.

Behind the detonation front the detonation products constitute a dense ionized gas with a high electrical conductivity which evidently is of major importance in determining the nature of the discharge. Measurements of the conductivity of the detonation products show that this conductivity reaches $10^{-1}\ \Omega^{-1}\cdot\text{cm}^{-1}$ behind the shock front; it then falls rapidly, reaching 10^{-4}-$10^{-5}\ \Omega^{-1}\cdot\text{cm}^{-1}$ after 2 to 3 μsec (the time reference is the time at which the shock front passes the test gap).

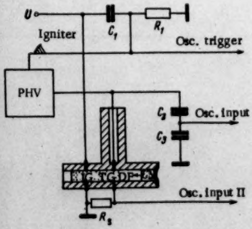

Fig. 1. Experimental apparatus.

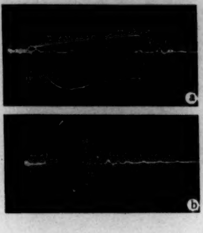

Fig. 2. Oscillograms of the discharge in the test gap. The pulse is triggered at: a) 0.7; b) 2.3 μsec. The time markers are 0.1 μsec apart.

Oscillograms of the gap voltage and current show that the breakdown involves a significant deformation of the voltage pulse over the interval 0-1.6 μsec: The height and front steepness of the pulse are lower than in the no-load case. Large prebreakdown currents are observed (Fig. 2a). This behavior results from the high conductivity of the test gap (10^{-1}-$10^{-3}\ \Omega^{-1}\cdot\text{cm}^{-1}$) and the limited power of the pulse generator.

The oscillograms of the gap breakdown are reminiscent of the breakdown of conducting liquids, for which the formation of the discharge channel occurs after some delay. This similarity probably results from the circumstance that the detonation products are essentially a liquid[1] in this interval (pressure ~ 10^4 kbar, temperature ~ $3\cdot10^{30}$ °K, density 0.8-0.5 g/cm^3).

The reduced temperature and pressure in the test gap which result from the use of an inert additive (10% talc) in the explosive charge lead to a reduced conductivity and to the loss of the conducting-liquid properties of the test gap; over the specified interval the breakdown occurs at the front of the nondeformed voltage wave.

The conductivity of the test gap becomes low (~ 10^{-4} $\Omega^{-1}\cdot\text{cm}^{-1}$) by 1.7-1.8 μsec, and the breakdown occurs at the

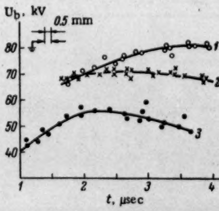

Fig. 3. Functional dependence of the dielectric strength of the test gap on time. 1) PETN; 2) RDX; 3) 90% PETN + 10% talc.

front of the pulse with a steepness governed solely by the generator parameters (Fig. 2b). We measure the dielectric strength of the gap in the interval 1.7-4 μsec; the functional dependence of this dielectric strength on time is shown in Fig. 3. We see that the breakdown voltage of the test gap is of the same order of magnitude as those for solid dielectrics. Complex, uncontrollable processes occur in the gap, and there are simultaneous changes in the pressure, the temperature, the electrical conductivity, and the density. It is difficult to separate the effects of these changes on the basis of the information available. The increase in the breakdown voltage at the beginning of the interval 1.7-4 μsec is due to a reduction of the electrical conductivity; then the pressure decrease becomes predominant, and the breakdown voltage decreases.

Anomalous high emission of a nonevaporating thermionic cathode in an arc

B. Ya. Moizhes and V. A. Nemchinskii

(Submitted December 28, 1973)
Zh. Tekh. Fiz., 44, 2539-2547 (December 1974)

Various factors that can increase the emission of a thermionic cathode in an arc are examined. The effect on the thermionic emission of fluctuations in the electric field at the cathode due to the discrete nature of the ion charge is calculated. Under conditions typical of high-pressure arcs ($j < 10^5$ A/cm², $E < 10^7$ V/cm), the number of additional electrons emitted by the cathode due to fluctuations in the electric field is much less than one per ion. Under these conditions the average electric field of all the ions increases the electron emission by more than one electron per ion. A rigorous resolution of the field of an individual ion from the average field avoids the divergences which usually arise in such calculations. The range of applicability of the classical description of thermionic emission is discussed, and the need for quantum-mechanical corrections for local decreases in the potential barrier at the surface is analyzed. It is shown that faces of working cathodes with relatively low work function evaporate less because of the intense emission cooling, so that the surface can acquire a faceted structure dominated by faces with the minimum work function. Then the effective work function of the cathode should decrease to this minimum value. Another possible reason for an increase in emission is the formation of a microscopic roughness on the cathode surface. This roughness arises because of the intense electronic cooling of protuberances.

INTRODUCTION

One of the most important questions in the physics of the arc discharge is the mechanism for the cathode emission. It is now generally agreed that in an arc with a tungsten cathode at a pressure of 0.1-1 atm the emission mechanism is thermionic, supplemented by the Schottky effect. Experimentally, however, thermionic cathodes sometimes display an anomalously high emission, which seems at odds with the concept of thermionic emission.[1] It has been suggested[2,3] that this anomalous emission could be due to the influence of fields of individual ions.

The emission current density is a strong function of E, the electric field at the cathode surface. In an arc this field is produced by the space charge due to the ions in the cathode sheath. The average field j_e is usually determined from the Mackoen equation, and the ion charge is assumed to be continuous. The field $\bar{E}$ is related to the average ion density n_i by $\bar{E} = 4\pi n_i d$, where d is the thickness of the space-charge sheath. Since the ion charges are actually discrete, however, the field E can be much higher than the average value $\bar{E}$ as an ion approaches the surface. Since the function $j_e(E)$ is very nonlinear in the region of the strong Schottky effect, the average emission density can be higher than that corresponding to a homogeneous charge distribution. We are thus concerned with calculating the influence of those fluctuations in the electric field at the cathode surface which result from the discrete nature of the ion charge.

Ecker and Muller[4] and Ecker[5] have carried out calculations for this effect in the case of field emission, finding a significant increase in the emission only at very strong fields (on the order of $5 \cdot 10^7$ V/cm).

Bauer[2] analyzed the influence of the individual-ion fields on thermionic emission, concluding that the effect could also be important at fields $\sim 10^6$ V/cm, typical of an arc. In these calculations, however, the field associated with an individual ion is in a sense added to the general space-charge field, so that the field of each ion is taken into account twice: in the average field and in the calculation of the individual field. Another shortcoming of these calculations[2] is that they incorporate only the field at the cathode and do not deal with the entire potential well produced by an ion at the cathode; in particular, the fact that the emission can be limited by a potential peak behind the ion, rather than at the cathode, is neglected. As a result, divergences appear in the calculations at small and large distances from the cathode; these divergences are eliminated by an arbitrary cutoff of the potential.

In the present work we calculate the influence of the individual ion fields on thermionic emission in a manner that avoids these shortcomings. We also discuss other effects which can intensify thermionic emission in an arc, e.g., the formation of a faceted structure at the cathode surface dominated by faces with the minimum work function, because of the instability of a smooth cathode surface.

INDIVIDUAL ION FIELDS

Singling out a particular ion in the cathode sheath, we want to find how many more electrons are emitted by the cathode because the field near this ion differs from the average field. We construct a coordinate system (Fig. 1) in which the ion moves along the z axis, and the cathode surface is the z = 0 plane.

The normal component of the field at the cathode surface at point (r, 0) produced by this ion and its image is

$$\Delta E = \frac{2ez_0}{(r^2 + z_0^2)^{3/2}}, \tag{1}$$

where z_0 is the coordinate of the ion and e is its charge. The resultant normal field component consists of the average field $\bar{E}$ produced by all the ions, and the field due to the ion in question, ΔE, minus the contribution of this ion to the average field, $\overline{\Delta E}$:

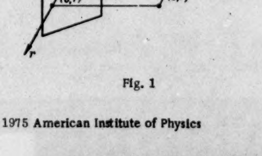

Fig. 1

$$E=\bar{E}+\Delta E-\overline{\Delta E}. \qquad (2)$$

The additional emission current due to the deviation of the local field from the average field is$^{1)}$

$$\Delta I_e=2\pi\int rdr\,[j_e(E)-j_e(\bar{E})]. \qquad (3)$$

To find the additional number of thermionic electrons emitted by the cathode (per ion), we integrate (3) over the time of the ion motion, and divide by the electron charge. Denoting the result by γ_T, we have

$$\gamma_T=\frac{1}{e}\int dt\Delta I_e=\frac{2\pi}{e}\int\frac{dz_0}{v}\int rdr\,[j_e(E)-j_e(\bar{E})], \qquad (4)$$

where v is the ion velocity. The total emission current can be expressed in terms of γ_T:

$$j_e=j_e(\bar{E})+\gamma_T j_i+\gamma j_i, \qquad (5)$$

where j_i is the ion current density and γ is the ordinary ion–electron emission yield, which is related to the transfer of the ion-neutralization energy to a single electron (the Auger effect), rather than to the emission of thermionic electrons.

We assume that the charge of the given ion is distributed over some surface of area S; then, $\overline{\Delta E} = 4\pi e/S$. We can show that the additional current in (4) due to $\overline{\Delta E}$ is independent of S: We can always choose S so large that $\overline{\Delta E} \ll \bar{E}$, so that

$$\Delta j=\frac{dj}{d\bar{E}}\overline{\Delta E}\ \text{and}\ \Delta I_e=2\pi\int rdr\frac{dj_e}{d\bar{E}}\overline{\Delta E}=S\frac{dj_e}{d\bar{E}}\frac{4\pi e}{S}=4\pi e\frac{dj_e}{d\bar{E}}.$$

The fact that this result is independent of S justifies our approach. We now write

$$\gamma_T=\frac{2\pi}{e}\int\frac{dz_0}{v}\left\{\int_0^\infty rdr\,[j_e(\bar{E}+\Delta E)-j_e(\bar{E})]-2e\frac{dj_e}{d\bar{E}}\right\}. \qquad (6)$$

Since we have not yet specified the nature of the function $j_e(E)$, we conclude that (6) holds for both field and thermionic emission as well as for the case in which the emission is governed by the entire profile of the potential barrier in the cathode sheath. In the case of thermionic emission we have

$$j_e(E)=j_e(0)\exp\frac{\sqrt{e^3E}}{T_k}, \qquad (7)$$

where T_k is the cathode temperature. The two integrals in (6) can be combined into a single integral; also, using (1), we can write

$$\gamma_T=\frac{2\pi}{e}\int_{z_L}^{z_U}\frac{dz_0}{v}\int_0^\infty rdr\left\{\exp\left(\frac{\sqrt{e^3(\bar{E}+\Delta E)}-\sqrt{e^3\bar{E}}}{T_k}\right)\right.$$
$$\left.-1-\frac{\Delta E}{T_k}\sqrt{\frac{e^3}{\bar{E}}}\right\}j_e(\bar{E}). \qquad (8)$$

We again emphasize the need to consider $\overline{\Delta E}$, which leads to the last term in the integrand in (8): Without it, the integral diverges at large distances (this divergence forced an arbitrary cutoff of the integral in refs. 2, 3 at $0.1n_i^{-1/3}$). Equation (8) does not diverge at large distances, and the integration can be extended to infinity ($z_b = \infty$).

However, the integral in (8) does diverge at small z_0, because of the unlimited decrease in the effective work function calculated from the Schottky equation as the ion approaches the cathode. The integral in (8) is usually cut off at the ion-neutralization distance at small z_0. Since the integrand in (8) increases rapidly at small z_0, a small error in z_L can significantly change γ_T. However, a more detailed analysis of the potential near the emitting surface shows that this cutoff is not necessary. As the ion approaches the surface a second potential-energy peak forms behind it, limiting the emission.[3]

In the presence of the ion the effective potential of the emitted electron consists of the potential produced by the average field, the potential of the interaction between the electron and its image, and the potential of the interaction between the ion and its image.$^{2)}$ The potential at (r, z) is (Fig. 1)

$$U(r,z)=-\frac{e}{4z}-\bar{E}z-\frac{e}{\sqrt{(z-z_0)^2+r^2}}+\frac{e}{\sqrt{(z+z_0)^2+r^2}}. \qquad (9)$$

The maximum potential determines the reduction of the work function; in the absence of the ion this maximum is $-\sqrt{e^3\bar{E}}$ (the Schottky correction). In the presence of the

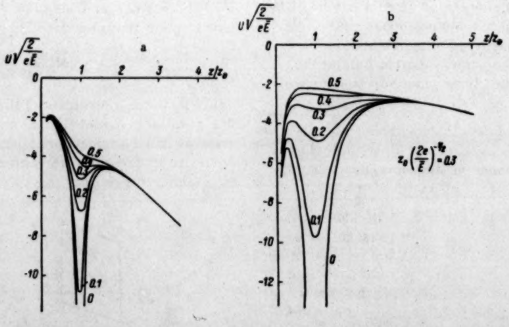

Fig. 2. Electron potential energy for the cases in which the ion is far from (a) and close to (b) the surface. a) $z_0(2e/\bar{E})^{-1/2} = 1$; b) 0.3. The curves are labeled with the values of $r - (2e/\bar{E})^{-1/2}$.

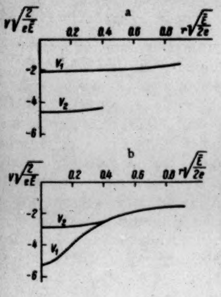

Fig. 3. Height of the front potential barrier V_1 and height of the rear barrier of V_2 as functions of the radius for the cases in which the ion is far from (a) and close to (b) the surface. a) $z_0(2e/\bar{E})^{1/2} = 1$; b) 0.3.

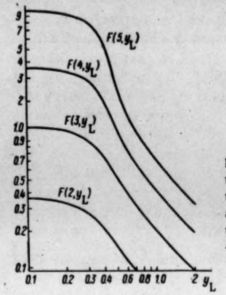

Fig. 4. Additional emission per ion as the ion moves from infinity to a distance y_L from the surface for various average electric fields [$F(\alpha, y_L)$ is taken from (11); $\alpha = \sqrt{e^3\bar{E}}/T_k$ = 2, 3, 4, 5].

ion the profile of the function U becomes more complicated. Figure 2 shows intersections of the U(r, z) surface with r = const planes; Fig. 2a corresponds to a large separation of the ion from the cathode, while Fig. 2b corresponds to a small separation. Figure 3 shows the height of the potential peak as a function of r. We see that there are two crests on the potential surface: in front of the ion and behind it. The corresponding maximum potentials at these crests are described by the $V_1(r)$ and $V_2(r)$ curves.

Accordingly, the effective cathode emission is governed not only by the field at the electrode but also by the entire profile of the potential energy of the emitted electron. In this connection we should write thermionic-emission equation (7) as

$$j_e = j_e(0)\exp\frac{\Delta\varphi(r)}{T_k}, \tag{7a}$$

where $\Delta\varphi = \max(V_1(r), V_2(r))$. Equation (8) should also be modified slightly:

$$\gamma_T = \frac{2\pi}{e}\int\limits_{z_L}^{z_U}\frac{dz_0}{v}\int\limits_0^\infty r\,dr\left\{\exp\left(\frac{\Delta\varphi - \sqrt{e^3E}}{T_k}\right) - 1 - \frac{\Delta E}{T_k}\sqrt{\frac{e^3}{E}}\right\} j_e(E). \tag{8a}$$

When the ion is far from the surface (Fig. 3a) the front potential barrier determines the emission. Since the ion is comparatively far from the cathode in this case, the field of the ion varies little between the cathode surface and the crest in the potential surface, so we can write $\Delta\varphi \simeq \sqrt{e^3(\bar{E} + \Delta E)}$. This approximation is valid as long as the front barrier is higher than the second. When the ion is close to the cathode the rear barrier is higher than the front barrier over part of the surface (Fig. 3b). In this case the problem of the emission of an electron from the cathode is complicated, and a classical approach must, generally speaking, deal with the various trajectories between the front and rear barriers. In our calculations we assume that an electron which has overcome the barrier is emitted if its energy is greater than the absolute minimum of barrier V_2. We see from Fig. 3 that the function $V_2(r)$ is weak, so that the overestimate resulting from this approximation is not serious.

Introducing the dimensionless quantities

$$y = \frac{z}{\sqrt{\frac{2e}{E}}},\quad \alpha = \frac{\sqrt{e^3E}}{T_k}, \tag{10}$$

we can express $\gamma_T(z_L)$ in terms of the dimensionless function $F(\alpha, y_L)$:

$$\gamma_T(y_L) = \frac{2\pi j_e(\bar{E})}{ev}\left(\frac{2e}{\bar{E}}\right)^{3/2} F(\alpha, y_L). \tag{11}$$

Figure 4 shows the calculated functions $F(\alpha, y_L)$ for various values of α; the values of $F(\alpha, 0)$ are shown in Table 1. We can use these data to determine the effect of the individual ion fields on the emission. For example, for argon ions and a tungsten cathode (work function of 4.5 eV), heated to T_k = 3500°K in a field of $E = 2.5 \cdot 10^6$ V/cm, and with a cathode drop of 10 V, we find $\alpha = 2$ and $j_s(\bar{E}) = 3.2 \cdot 10^3$ A/cm². Here the distance is measured in units of $\sqrt{2e/\bar{E}}$ = 34 Å. The neutralization distance for argon ions at tungsten is ~ 5 Å (ref. 7), so that we find an effective value $\gamma_T = \gamma_T(0.15)$. From Fig. 4 we see that we can accurately assume $\gamma_T(0.15) = \gamma_T(0)$, so that it is the lifting of the rear barrier, rather than the neutralization, which governs the decrease in the local emission of the cathode as the ion approaches it. We see from Table 1 that the value of γ_T for a singly charged ion is $3.6 \cdot 10^{-3}$, while that for a doubly charged ion is $\gamma_T = 1.6 \cdot 10^{-2}$. At a strong field of $E = 10^7$ V/cm we find $\gamma_1 = 2.9 \cdot 10^{-2}$ and $\gamma_2 = 0.27$, respectively.

These calculations show that the increase in γ due to the individual ion fields is usually slight; at the same time the value of γ under the influence of the average field $\bar{E}$ (the collective value γ_{coll} corresponding to the ion charge),

$$\gamma_{\text{coll}} = \frac{j_e}{j_i}[1 - \exp(-\alpha)],$$

is usually larger than unity, since $j_e/j_i > 1$ and $\alpha > 1$. The large value of γ_{coll} is evidently due to long-range Coulomb forces and the circumstance that the thickness of the space-charge sheath is much larger than the average distance between ions.

In these calculations we have distinguished the field of one ion from the background field due to a smearing of the charges of the other ions. We now have an a posteriori justification for this approach: The individual ion field should be distinguished at distances on the order of $(2e/\bar{E})^{1/2}$, and the probability of finding another ion this close to the ion in question is on the order of $n_i(2e/E)^{3/2}$, usually much less than unity.

To conclude this section we turn to the range of applicability of the classical approach to thermionic emission for the case in which there are local depressions of the potential barrier for electrons. In determining the emission from the cathode as the ion approaches the surface we assume that the electron can have any velocity parallel to the surface (v_x and v_y); in particular, this velocity can be zero. Turning to Figs. 2 and 3 now, we see that in the case of emission into the potential-energy saddle the electron will be localized in the xy plane. According to the uncertainty principle this localization means an uncertainty in the electron momentum. An electron moving into the plasma must thus have an additional energy; if this minumum additional energy is larger than or on the order of T_k, the electron emission must be much weaker than that predicted in the classical treatment.

To evaluate this minimum additional energy, we note that an electron whose energy exceeds the potential minimum is free to move in the z direction but is confined in a two-dimensional potential well in the x and y directions. If the size of this well (in the z direction) is much longer than the de Broglie wavelength of the electron, as it clearly is in our case, we conclude that a system of discrete energy levels associated with the x and y motion of the electron is formed in the well:

$$\mathcal{E}=\hbar\omega_0(n_x+n_y+1)+\frac{\hbar k_z^2}{2m};\quad n_x,\ n_y=0,\ 1,\ 2\ldots.$$

We see that the minimum electron energy related to the motion in the xy plane must be larger than $\hbar\omega_0$, where $\omega_0=\sqrt{(1/m)(\partial^2U/\partial r^2)}|_{r=0}$. For example, with $y_0=0.48$ (the separation of the ion from the surface at which the front and rear barriers are comparable in height) and $E=3\cdot10^6$ V/cm we find $\hbar\omega_0\simeq0.1$ eV. However, even at higher energies there must be a quantum-mechanical coefficient for reflection of the electron from the potential barrier.

Accordingly, in calculating the electron emission through local depressions of the potential barrier (corresponding to an ion at the surface, an adsorbed ion, a microscopic sharp point, etc.) we must incorporate quantum-mechanical corrections, whose calculation is an independent problem.

STABILITY OF VARIOUS FACES OF A CRYSTALLINE EMITTER

Since the anomalously high emission of a thermionic cathode cannot be explained on the basis of the individual ion fields, it is worthwhile to consider other mechanisms, which could intensify the cathode emission under the actual experimental conditions. Among these mechanisms we can cite the crystallographic orientation of the surface and the existence of a microscopic roughness, which leads to a concentration of the electric field near sharp protuberances.

The work function can vary considerably as a function of the crystallographic orientation of the surface, e.g., while the average work function of tungsten is 4.5 eV, there are faces whose work functions range from 4.2 to 5.1 eV (ref. 8). At high temperatures the migration of atoms over the surface leads to the growth of the faces having the minimum surface energy (cleavage planes), but during the operation of a cathode the faces having relatively low work functions will be cooled relatively intensely because of the thermionic emission, so that the evaporation from these faces will be reduced. The result should be a tendency for faces of minimum work function to grow, even if their surface energies are relatively high, and the effective emissivity of the cathode should increase.

To evaluate the local change in the cathode temperature corresponding to a change in the local work function we assume that the work function varies sinusoidally along the surface:

$$\varphi(x)=\bar{\varphi}+a_\varphi\cos kx\quad(a_\varphi\ll\bar{\varphi}).\tag{12}$$

Here the x axis is parallel to the cathode, and the z axis is normal to it. The cathode temperature satisfies the Laplace equation with the boundary condition

$$\varkappa\frac{\partial T_k}{\partial z}\Big|_{z=0}=q,\tag{13}$$

where $\varkappa$ is the thermal conductivity of the cathode, and q is the heat flux to its surface. We assume that q consists of the heat carried by ions to the cathode and the heat flux associated with the emission cooling:[9]

$$q=j_i(E_i+V_k+2T_p-\varphi)-j_e(\varphi+2T_k),\tag{14}$$

where E_i is the ionization potential of the plasma atoms, V_k is the cathode drop, and T_p is the plasma temperature. A change in the electron current along the surface leads to a variation in the emission cooling and thus to a change in the cathode temperature. The solution of the Laplace equation for the cathode temperature is

$$T_k(x,\ z)=\bar{T}+\frac{\overline{dT}}{dz}z+a_T\cos kxe^{kz},\tag{15}$$

where $\bar{T}$ is the average surface temperature and $\overline{dT}/dz$ is the average gradient due to the unperturbed heat flux $\bar{q}$. We write the distribution of the electron current as

$$j_e=\bar{j}_e+a_j\cos kx.\tag{16}$$

From the Richardson equation we have

$$a_j=\frac{\bar{j}_e}{\bar{T}}a_\varphi+\frac{\bar{j}_e\bar{\varphi}}{\bar{T}^2}a_T.\tag{17}$$

If the dimensions of the spots are smaller than the ionization length in the plasma, the ion current remains constant over the cathode surface; then from (13) and (14) we find

$$a_T=a_\varphi\frac{\frac{\bar{\varphi}\bar{j}_e}{\bar{T}}}{k\varkappa+\frac{\bar{\varphi}^2\bar{j}_e}{\bar{T}^2}}.\tag{18}$$

We see that those faces whose work functions are relatively high are in fact heated most. Let us estimate the effect of inhomogeneities of micron size, with $k=10^4\,\mathrm{cm}^{-1}$.

TABLE 1

α	$F_1(\alpha,0)$	$F_2(\alpha,0)$
1	$4.48\cdot10^{-2}$	0.14
2	0.36	1.58
3	1.29	7.61
4	3.65	32.9
5	9.97	166.9

Note: The number of additionally emitted electrons per singly charged ions, γ_1, and per doubly charged ion, $(2\pi/ev)j_e(\bar{E})(2e/\bar{E})^{3/2}F_{1,2}(\alpha,0)$; $\alpha=\sqrt{e^3\bar{E}}/T_k$.

With $\varkappa = 1$ W/cm · deg, $\alpha\varphi = 0.2$ eV, and $\bar{j}_e = 2 \cdot 10^4$ A/cm^2 we find $\alpha_T \cong 6$°K. Since the evaporation rate is a strong exponential function of the temperature, a difference of this magnitude in temperatures can lead to a rapid restructuring of the surface. Faces having the minimum work functions turn out to be stable. Accordingly, in evaluating the work function of an emitting cathode it is more accurate to use the minimum work function among the various faces rather than the average work function, i.e., for pure tungsten we should use $\alpha_\varphi = 4.2$–4.3 eV, which would lead to an emission intensification by a factor of 2 or 3 at a cathode working temperature of 3500°K.

A similar effect should occur on film cathodes, e.g., of tungsten containing Th or La additives. The faces for which the heat of adsorption is relatively high should be relatively stable. It should be kept in mind here that the work function of a film cathode can vary much more significantly than that for a pure emitter. The useful anisotropy effect vanishes in the formation of the liquid film, so that the work function should evidently increase upon melting.

STABILITY OF A FLAT EMITTING SURFACE

Another factor which could increase the effective emissivity of a cathode is a surface roughness, which would lead to a local intensification of the electric field. However, for such a roughness to actually exist, it would have to be stable. This stability could be achieved if the protuberances were relatively cool and evaporated less than depressions; otherwise the roughness on a working cathode would be reduced, and the cathode would become polished.

We can classify possible surface roughnesses into three groups from the standpoint of the thermal and electrical processes which occur on the cathode. For a roughness of the finest scale (for which the characteristic dimension is shorter than the thickness of the space-charge sheath, L_{sc}), the lines of force of the electric field can concentrate at sharp protuberances, and this concentration can result in an anomalous large Schottky effect. For a coarser roughness this concentration of lines of force does not occur; as long as the characteristic dimension of this roughness is shorter than the distance over which ions are generated (L_i; see ref. 9), the heat flux associated with the ions can be assumed to be homogeneous. Finally, for roughness of the coarsest nature ($k \ll L_i^{-1}$) the ion flux would no longer be homogeneous, and different parts of the surface would emit independently. Let us examine the first and second types of roughness, for which the ion flux is homogeneous and for which variations in the emission cooling lead to temperature variations.

The stability of a surface roughness can be affected by many factors other than the thermal processes associated with the evaporation and migration of atoms. For example, a flat surface is subjected to two balanced forces: the force exerted by the electric field on the charged cathode surface and the ion pressure. If the surface is curved (if there is a roughness) this equilibrium will be disrupted, and there may be a tendency for the roughness to become more pronounced. A competing process is the smoothing of the surface under the influence of surface-tension forces.

During evaporation, even if the surface is heated uniformly, the resultant evaporation rates at protuberances and depressions will be different, because an atom evaporated in a depression can revert to the condensed state there, while the probability of this reversion for an atom evaporated from a sharp protuberance is lower. Even if the evaporation occurs in a plasma-forming gas, rather than in vacuum, the diffusion of atoms evaporated from protuberances will still be easier than that of atoms evaporated from depressions. This effect (the geometric factor) tends to make a flat surface stable.

To illustrate these arguments we consider the stability of a surface roughness characterized by $L_{sc}^{-1} > k > L_i^{-1}$; in this case we can assume that the potential in the plasma satisfies the Laplace equation, so that

$$V(x,\ z) = Ez + \alpha_s \cos kx e^{-kz} \simeq Ez + \alpha_s (1 - kz) \cos kx. \quad (19)$$

At the cathode surface we have V = 0, so that the equation of the surface is

$$z(x) = -\frac{\alpha_s \cos kx}{E} = \alpha_z \cos kx. \quad (20)$$

The temperature distribution is given as before by Eq. (15). Because of the change in the surface temperature, there will be changes in the electron current [Eq. (17) with $\alpha_\varphi = 0$] and the heat flux to the cathode [Eq. (14)]. After some straightforward calculations we find

$$\alpha_T = \alpha_z \left\{ \frac{\overline{dT}}{dz} - \frac{\varphi J_e}{\varkappa + \frac{\varphi^2 J_e}{T^2}} \left[\frac{\varphi}{T^2} \frac{\overline{dT}}{dz} + \frac{k\sqrt{e^3 E}}{2T} \right] \right\}. \quad (21)$$

If the cathode conducts heat poorly, we have dT/dz → 0; in this limiting case we obtain

$$\alpha_T = -\alpha_z \frac{\varphi J_e}{\varkappa + \frac{J_e \varphi^2}{T^2}} \frac{k\sqrt{e^3 E}}{2T_k}. \quad (22)$$

We see that in the case of a coarse roughness the protuberances on the cathode can be cooler than the depressions. To evaluate α_T for $j_e = 10^4$ A/cm^2, $\varkappa = 1$ W/cm · deg, $T_k = 3500$°K, $\varphi = 4.5$ eV, and $\Delta\varphi_s = \sqrt{e^3 E} = 0.35$ eV, we adopt $1/k = \alpha_z = 5 \cdot 10^{-4}$ cm, finding $\alpha_T \simeq 10$°K.

It is difficult to evaluate the effects of various types of roughness on the thermionic emission of a cathode, especially since the shape of the roughness must be found from a self-consistent solution taking into account the heat fluxes, electrical currents, and evaporation of the cathode. Our purpose here has been to demonstrate that there are factors which lead to the development of, and prevent the smoothing of, a cathode surface.

---

1) In some cases the current cannot be written in terms of the field at the surface; instead, the entire curve for the potential energy of the emitted electron should be taken into account (see the text below).

2) Emeleus has shown recently[6] that the surface charge can be replaced by its mirror image down to small distances from a metal surface.

High-pressure hot-cathode arc without forced cooling

V. A. Nemchinskii

(Submitted December 28, 1973)
Zh. Tekh. Fiz., 44, 2548-2550 (December 1974)

The operation of a nonevaporating thermionic cathode in a high-pressure arc is analyzed for the case in which the cathode is cooled by radiation alone. Calculations are carried out for a tungsten cathode for two pressures of the gas (argon): 20 and 760 torr. The cathode potential drop under these conditions is relatively low (8-10 V). The range of possible current densities is governed by the gas pressure: At low pressures the range of possible current densities is comparatively narrow and the cathode is comparatively cool.

A large part of the electrical power of a high-current arc can be evolved near the cathode; much of this energy is transferred to the anode, which is thus heated intensely. Overwhelming and failure of the cathode are prevented by cooling, with either flowing water or gas. In several applications, however, effective external cooling is impossible, or it is desirable to minimize its use. In an effort to determine possible operating conditions for which forced cooling would not be necessary, we have calculated the parameters of this type of operation in a high-pressure arc in a neutral gas. Specific calculations have been carried out for an arc in argon at pressures of 20 torr and 1 atm with a tungsten cathode.

The equations used to describe the operation of the cathode are essentially the same as those used to calculate the parameters of the cathode spot in a high-current arc in refs. 1 and 2. The calculations are based on the energy-balance equation for the cathode. We assume that the cathode is heated by ion bombardment and by the inverse flux of hot plasma electrons reaching the cathode, and we assume that the cathode is cooled as a result of the particle emission and the natural electromagnetic radiation. Then the total heat flux to the cathode is

$$q=j_i(E_i+V_k+2T_p-\varphi)+j_e^{(\mathrm{inv})}(2T_p+\varphi) -j_e^{(\mathrm{em})}(\varphi+2T_k)-\varepsilon\sigma T_k^4\;, \tag{1}$$

where j_i and $j_e^{(\mathrm{inv})}$ are the ion flux and the flux of inverse electrons to the cathode, $j_e^{(\mathrm{em})}$ is the cathode emission current density, E_i is the ionization potential of the neutral gas, V_k is the cathode potential drop, φ is the cathode work function, T_k and T_p are the temperatures of the cathode and of the plasma near the cathode, respectively; σ is the Stefan–Boltzmann constant, and ε is the cathode emissivity (we assume $\varepsilon = 0.5$ for the calculations). Without forced cooling $q = 0$.

It is sometimes assumed that the emission of a thermionic cathode can be anomalously high because of fluctuations of the electric field at the cathode surface (due to the "effect of the individual ion fields"),[3,4] but calculations[5] have shown that this effect is negligible for ordinary operating conditions ($j_e \leqslant 10^5$ A/cm², $E \leqslant 10^7$ V/cm). We can thus assume that the emission is described by the Richardson equation with a correction for the Schottky effect (the field intensity at the cathode is taken from the Mackoen equation):

$$j_e^{(\mathrm{em})}=AT_k^2\exp\left(-\frac{\varphi}{T_k}\right), \tag{2}$$

$$\varphi=\varphi_0-\gamma V_k^{1/4}j_i^{1/4}, \tag{3}$$

where φ_0 is the cathode work function for the case of zero field at the cathode, and γ is the constant in the Mackoen equation.

The ion current is governed by the energy balance in the plasma near the cathode, which involves the energy carried to the plasma by the emitted electrons, that carried away from the plasma by ions and the inverse electron flux to the cathode, and that carried by electrons into the interior of the plasma:

$$j_e^{(\mathrm{em})}(V_k+2T_k)=j_i(E_i+2T_p)+j_e^{(\mathrm{inv})}(V_k+2T_p)+3.2jT_p. \tag{4}$$

The density of the total current to the cathode is

$$j=j_e^{(\mathrm{em})}-j_e^{(\mathrm{inv})}+j_i. \tag{5}$$

The temperature of the plasma near the cathode, T_p, is determined from the condition that the plasma must be heated to a temperature high enough to provide the necessary density of the ion current to the cathode:

$$j_i=\alpha qn(T_p)v_i. \tag{6}$$

Here, q is the ion charge, $n(T_p)$ is the (Saha) equilibrium charged-particle density corresponding to temperature T_p, and α is a numerical factor governed by the mechanism generating ions in the cathode sheath. Since T_p appears exponentially in $n(T_p)$, the temperature can be determined accurately from (6) without refining the value of α. Finally, the density of the inverse electron flux to the cathode is

$$j_e^{(\mathrm{inv})}\simeq\frac{1}{4}qn(T_p)v_e\exp\left(-\frac{V_k}{T_p}\right). \tag{7}$$

Using these seven equations we can determine the seven unknowns ($j_e^{(\mathrm{em})}$, j_i, $j_e^{(\mathrm{inv})}$, T_k, T_p, V_k, φ) as functions of the cathode current density j. We proceed in the follow-

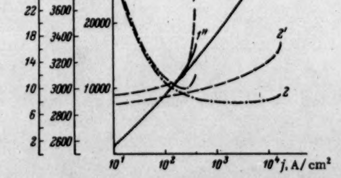

Fig. 1. The cathode fall V_k, the plasma temperature, and the cathode temperature of the tungsten cathode T_k, as functions of the current for various argon pressures. p (mm Hg): 1, 1', 1") 20; 2', 2") 760, for V_k, T_p, T_k respectively.

ing manner: After specifying an ion current j_i we determine T_p from (6). Then we select some value of V_k; we find $j_e^{(inv)}$ from (7) and j and $j_e^{(em)}$ from (4) and (5). Equation (3) then yields φ, and Eq. (2) yields T_k. Finally, we use Eq. (1) to determine how well the selected value of V_k corresponds to the selected value of j_i. By choosing V_k we ensure that Eq. (1) is also satisfied. We find the functional dependences of all quantities of interest on j_i or, equivalently, j.

Figure 1 shows the calculated results for two argon pressures (20 torr and 1 atm). We can draw certain conclusions from this figure.

1. Operation of the cathode without forced cooling requires a small cathode drop (8-10 V).

2. The voltage–current characteristic has rising and falling branches. Because of the strong exponential function $j_e^{(em)}(T_k)$, the cathode temperature varies relatively slowly along the characteristic. If the electron current density is low, the ion current density is corresponding low [Eq. (4)]. Accordingly, the ions must be accelerated by a high cathode barrier to heat the cathode to the necessary temperature. As the electron current density increases, so does j_i, and there is a corresponding drop in V_k. The plasma temperature increases to maintain the necessary ion current; the increase in the ion current with the plasma temperature continues until the plasma is completely ionized. With a further increase in the current the necessary increase in the heat flux is provided by an increase in V_k, until doubly charged ions appear in the plasma.

2. The possible cathode current densities are governed by the neutral gas pressure, because the plasma can provide only a limited ion current to the cathode. The magnitude of this current is governed by the gas pressure; at high pressures, the value of j_i can be high at a comparatively low plasma temperature, so that this operating regime spans a broad current range. At low pressures, on the other hand, the range of possible values of j is narrower.

Hot probe measurements in a rarefied streaming plasma

E. M. Netsvetailov, L. V. Nosachev, and V. V. Skvortsov

(Submitted December 18, 1973)
Zh. Tekh. Fiz., 44, 2551-2558 (December 1974)

An experimental and theoretical investigation has been made of the error in the readings of a hot probe, as a function of the parameters of the surrounding medium and the emitter operating conditions. The case in which the probe current is electron space-charge-limited, the energy of directed motion of the ions is appreciably larger than the plasma potential, and the electron distribution in the plasma is Maxwellian is treated. The problem has been solved numerically in the one-dimensional case. From an analysis of the results an approximate equation is found for the potential barrier near the probe emitter surface. The results show that the thermionic electron component of the volt–ampere characteristic must have two asymptotes on a semilogarithmic scale. The point of intersection of the asymptotes gives the plasma potential with high accuracy. A method is described for constructing the potential field in a flow using a hot probe; it is based on a combination of the asymptote intersection method and the widely-used method for determining the potential of a plasma from the point of intersection of the characteristics of hot and cold probes. The combination method gives good accuracy with comparatively small effort.

A hot probe is widely used to determine the potential of a plasma at rest (refs. 1-3). There is information on the use of such probes in a rarefied streaming plasma (e.g., (refs. 4, 5). However, in the latter case the literature as yet has no results of a systematic investigation of the probe operation; no one has determined the dependence of probe error on the emitter temperature, its emission properties, and the parameters of the surrounding plasma.

The special feature of the hot probe is that it operates in a regime in which the current is limited by the electron space charge, i.e., there is a potential dip near the emitter surface.

This paper presents the results of a theoretical and experimental investigation of special features of the operation of a hot probe in the above application.

The hot probe is a spiral 1.0 mm in diameter, containing 10 turns of tungsten wire 0.089 mm in diameter, and is used with the circuit (Fig. 1) described in ref. 3. In this arrangement the probe cooling curve, observed on an oscilloscope, can be used to determine the point of divergence of the characteristics of the hot and cold probes. The probe is switched repetitively at a frequency of 20 Hz, by means of a relay, from the hot regime to the measurement regime, the spiral being heated by means of a dc current of 0.6–1.0 A. When the probe is switched to the measurement regime it has a certain potential, whose value is determined by means of a circuit consisting of a battery B and potentiometer R_p. Since there is no heating current in the measurement regime, the difference in potentials at the ends of the spiral is determined only by the voltage drop due to the emission current and the current of electrons and ions arriving from the plasma. In our experiments this quantity is of the order of 10^{-3} V, i.e., considerably less than the accuracy of measurement of the plasma potential.

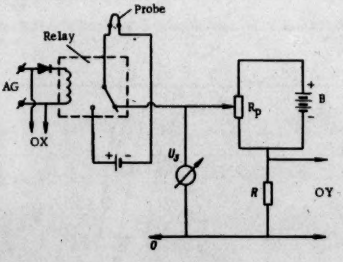

Fig. 1

The signal from the resistor R, proportional to the probe current, goes to the OY input of the oscilloscope. The horizontal sweep of the oscilloscope beam is generated by the audio generator AG, which feeds the relay winding.

If the probe potential is less than the plasma potential, the probe receives ions and the fastest electrons from the surrounding plasma, while the thermionic electrons leave the probe. In one cycle of measurement the thermionic emission current drops off as the probe cools. An oscillogram of this signal has the form 1 shown in Fig. 2. As the emitter potential approaches the plasma potential the electron current from the probe to the plasma decreases, and the signal on the oscilloscope screen takes the form 2 of Fig. 2.

For probe potentials appreciably greater than the plasma potential thermionic electrons cannot reach the probe, and the probe surface only receives electrons and ions from the plasma; the current does not change during the measurement cycle, so that the signal takes the form of the straight line 3, parallel to the horizontal axis. Thus, by varying the probe potential from values certainly less than the plasma potential and increasing, one can determine the time when the signal on the oscilloscope screen becomes rectangular. The probe potential corresponding to this time is taken initially to be the plasma potential.

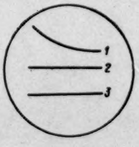

Fig. 2

Experiments are conducted in so-called synthesized plasma streams, which are created by neutralizing a stream of ions from an ion source with electrons emitted by a heated tungsten wire: The charged particle density is 10^{13} to 10^{14} m^{-3}, the ion energy is 100 eV, and the electron temperature is 1 eV. The working gas for the ion source is argon.

It is noted in the experiments that the hot probe gives increased values of the plasma potential in comparison with results obtained by means of a multielectrode probe (ref. 6), which is taken as a standard. As the emitter temperature increases the error in determining the potential increases. To find the cause of this phenomenon, the volt–ampere characteristics of the hot probe are measured for various heating currents I_h of the spiral (Fig. 3). As can be seen from the results, the shape of the characteristics does not depend on the emitter temperature, for large positive potentials on the hot probe relative to the plasma potential. However, as the spiral potential decreases, the curves begin to diverge in a fanwise manner. The greater the heating current, the earlier the curve deviates from the characteristic of the cold probe. This behavior of the characteristic can be explained by the effect of the initial velocities with which the electrons leave the probe: The higher the emitter temperature, the larger the initial velocity of these thermal electrons, and the higher the potential at which divergence of the characteristics of the hot and cold probes occurs.

The decrease in the slope of the volt–ampere characteristics when the probe potential is lower than that of the plasma is apparently due to the fact that at the emitter–plasma interface there is a potential dip associated with the current being limited by the electron space charge. Experiments and estimates of the present authors show that this effect cannot be explained by simple Richardson current limitation of the emitter.

The following fact is also noted: When the thermionic component of the volt–ampere characteristic of the heated probe is drawn on a semilogarithmic scale the curve has two asymptotes for large positive probe potentials and for large negative values (Fig. 4). The point of intersection of the asymptotes is a better approximation to the plasma potential as determined by the multielectrode probe than the potential determined from the point of divergences of the characteristics of the hot and cold probes.

To explain the experimental results a theoretical analysis is made of the distribution of potentials at the emitter surface. The problem is solved in the one-dimensional case. The potential distribution near the emitter surface has the form shown in Fig. 5. The X axis is directed along the normal to the emitter surface. For x = 0 the spatial potential U is equal to the surface potential U_x, and the potential has a minimum dV/dx = 0 in region 2. Region 3 corresponds to the region of neutralization $d^2V/dx^2 = 0$; the plasma potential V_n in this region has a finite value, but changes rather slowly, and one can take $(dV/dx)_3 = 0$ in the calculations.

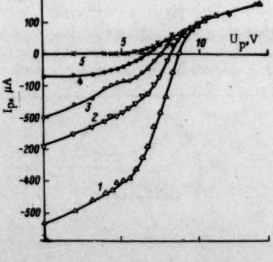

Fig. 3. I_h(A): 1) 1.0; 2) 0.9; 3) 0.8; 4) 0.7; 5) 0.

We assume, as is the case in the experimental conditions, that the energy of the ions in the stream is appreciably greater than the probe potential and that the ion density is constant, while the electron distribution function in the plasma is Maxwellian. The total current density of thermionic electrons is determined only by the temperature and the emission properties of the surface material.

The starting equation is the Poisson equation

$$\frac{d^2V}{dx^2} = 4\pi(\rho_+ - \rho_-), \tag{1}$$

where ρ_+ is the ion charge density and ρ_- is the electron charge density.

A similar problem has been solved in ref. 7 in an application concerning neutralization of an ion beam. But the authors do not take account of the electron current from the plasma to the emitter, and make the assumption, quite unacceptable for our case, that dV/dx = 0 on the emitter surface. For these reasons the results obtained in ref. 7 cannot be used to explain the effects arising when a hot probe is operated in a plasma stream.

We turn now to the solution of the problem. The density of thermionic electrons ρ_k in regions 2 and 3 can be found in the same way as for the space charge in a plane diode:

$$\rho_k = \frac{m}{kT_k}\int\limits_{\sqrt{eV/m}}^{\infty} j_k \exp\left(-\frac{mv^2}{2kT_k}\right) dv, \tag{2}$$

where T_k is the emitter temperature, v is the electron velocity, m is the electron mass, e is the electron charge,

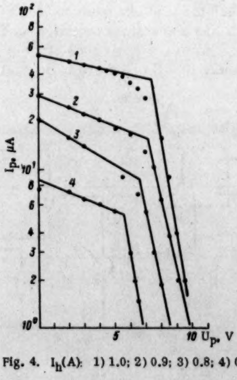

Fig. 4. I_h(A): 1) 1.0; 2) 0.9; 3) 0.8; 4) 0.7.

k is the Boltzmann constant, and j_k is the total emission current density as given by the Richardson law.

We express the ambient velocity v in terms of its initial value v_0:

$$\frac{mv^2}{2}=\frac{mv_0^2}{2}-(V_m+V_k)+V. \tag{3}$$

Substituting the value of v_0 obtained from Eq. (3) into Eq. (2), we can integrate over energy instead of velocity. Then, since

$$\frac{2}{\pi}\int_0^\infty \exp(-x^2)\,dx=1,$$

$$\frac{2}{\pi}\int_0^y \exp(-x^2)\,dx=P(y),$$

where P(y) is the probability integral, and $\eta = eV/kT_k$, $\mu = e(V_m-V_H)/kT_k$, we obtain a final expression for the density of electrons emitted by the probe:

$$\rho_k=\sqrt{\frac{\pi m}{2kT_k}}\,j_k\exp(\eta-\mu)(1-P\sqrt{\eta}). \tag{4}$$

The density of electrons coming from the plasma, ρ_a, in regions 2 and 3 can be written in the form

$$\rho_a=\frac{\pi m}{2kT_a}j_a\exp\left[(\eta-\nu)\frac{T_k}{T_a}\right]\left(1-P\sqrt{\eta\frac{T_k}{T_a}}\right), \tag{5}$$

where $\nu = eV_m/kT_k$; T_a is the electron temperature in the plasma, $j_a = evN$ is the density of the random electron current from the plasma to the probe, and N is the density of charged particles in the plasma.

We introduce the dimensionless variable $\xi = C(x-x_m)$, where x_m is the distance from the emitter to the section in which the potential reaches its minimum, and C is a scale constant, for example the Debye radius in the plasma.

In the variables η and ξ Eq. (1) takes the form

$$\frac{d^2\eta}{d\xi^2}=4\pi\frac{kT_k}{eC^2}\left[eN-j_k\frac{\pi m}{2kT_k}\exp\left[-\frac{e(V_m-V_k)}{kT_k}\right](1-P\sqrt{\eta})\right.$$
$$\left.-j_a\sqrt{\frac{\pi m}{2kT_a}}\exp\left(\eta\frac{T_k}{T_a}\right)\left(1-P\sqrt{\eta\frac{T_k}{T_a}}\right)\right], \tag{6}$$

and has the boundary conditions

$$\left.\begin{array}{l}\text{for } \xi=\xi_m,\ \eta=0,\ \frac{d\eta}{d\xi}=0,\\ \text{for } \xi=\xi_3,\ \eta=\mu,\ \frac{d\eta}{d\xi}=0,\ \frac{d^2\eta}{d\xi^2}=0.\end{array}\right\} \tag{7}$$

We integrate Eq. (6):

$$\frac{1}{2}\left(\frac{d\eta}{d\xi}\right)^2=2\pi\frac{kT_k}{eC^2}\left\{eN\eta-j_k\sqrt{\frac{\pi m}{2kT_k}}\exp\left[-\frac{e(V_m-V_k)}{kT_k}\right]\right.$$
$$\times\left(\exp\eta-\exp\eta P\sqrt{\eta}+\frac{2}{\sqrt{\pi}}\sqrt{\eta}-j_a\sqrt{\frac{\pi m}{2kT_a}}\frac{T_a}{T_k}\exp\left(-\nu\frac{T_k}{T_a}\right)\right.$$
$$\left.\times\exp\left(-\nu\frac{T_k}{T_a}\right)\left[\exp\left(\eta\frac{T_k}{T}\right)+\exp\left(\eta\frac{T_k}{T_a}\right)P\sqrt{\eta\frac{T_k}{T_a}}-\frac{2}{\sqrt{\pi}}\sqrt{\eta\frac{T_k}{T_a}}\right]\right\}-C_1. \tag{8}$$

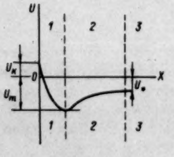

Fig. 5

Using the boundary conditions of Eq. (7) and introducing the notation

$$\beta=\frac{eU_k}{kT_k},\ T=\frac{T_a}{T_k},\ j=\frac{j_a}{j_k},\ \alpha=\frac{eN}{j_k\sqrt{\frac{\pi m}{2kT_k}}}=\frac{j}{\sqrt{T}},$$

we reduce Eqs. (6) and (8) to the form

$$\alpha-\exp(-\beta-\nu)\exp\mu(1-P\sqrt{\mu})$$
$$-2\alpha\exp\left(-\frac{\nu}{T}\right)\exp\left(\frac{\mu}{T}\right)\left(1+P\sqrt{\frac{\mu}{T}}\right)=0, \tag{9}$$

$$\alpha\mu-\exp(-\beta-\nu)\left(\exp\mu-\exp\mu P\sqrt{\mu}+\frac{2}{\sqrt{\pi}}\sqrt{\mu}-1\right)$$
$$-2\alpha T\exp\left(-\frac{\nu}{T}\right)\left(\exp\frac{\mu}{T}+\exp\frac{\mu}{T}P\sqrt{\frac{\mu}{T}}-\frac{2}{\sqrt{\pi}}\sqrt{\frac{\mu}{T}}-1\right)=0. \tag{10}$$

The results of numerical solution of the system of equations (9) and (10) are shown graphically in Fig. 6. By analyzing this system of equations and the result of numerical solution we can obtain an approximate equation

$$\Phi_{\min}=\nu+\beta=-1.2+2.3\lg\frac{1}{j}+1.4\lg T$$
$$+0.033T+4.71\cdot10^{-3}\beta+0.33\cdot10^{-3}\beta T$$
$$+\exp(0.11T+0.07\beta), \tag{11}$$

where $\Phi_{\min}$ is the dimensionless value of the potential dip.

In the range $-20 > \beta > -200$ the difference in values calculated using Eq. (11) for the data for numerical solution of the system of equations is less than a few tenths of a percent. For $\beta > -20$ the error increases and for values $\beta > 0$ the error can be 10% or more.

It can be seen from Eq. (11) and the curves of Fig. 6 that when $\beta < -50$ the potential dip varies in a linear manner with decreasing β. For large positive values of β the value of ν tends to zero, and the potential opposing electrons leaving the emitter surface tends to β. The electron current from the probe to the plasma is

$$I=I_0\exp(-\nu-\beta),$$

where I_0 is the total current from the emitter.

Then the thermoelectric component of the volt–ampere characteristic of the hot probe, drawn on a semilogarithmic scale, must have two asymptotes. One asymptote is due to the linear dependence of the depth of the potential barrier on the emitter potential, and the second is due to the fact that at large positive potentials $\nu \to 0$ and the current from the emitter becomes a function of β only.

Using these results we find the error in determining

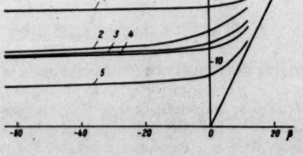

Fig. 6. j, T: 1) 10^{-8}, 3; 2) 10^{-5}, 10; 3) 10^{-5}, 5; 4) 10^{-5}, 3; 5) 10^{-3}, 3.

the plasma potential at the point of intersection of the asymptotes. We write the equation of the asymptotes in the coordinates $[\Phi_{\min}, \beta]$. For negative values of β we have

$$\Phi_{\min} = -1.2 + 2.3 \lg \frac{1}{j} + 1.4 \lg T$$
$$+ 0.033T + 4.71 \cdot 10^{-3}\beta + 0.33 \cdot 10^{-3}\beta T,$$

and for positive values of β,

$$\Phi_{\min} = \beta.$$

The point of intersection of the asymptotes is found by the simultaneous solution of the equations*

$$\beta = -1.2 + 2.3 \lg \frac{1}{j} + 1.4 \lg T + 0.033T$$
$$+ 4.71 \cdot 10^{-3}\beta + 0.33 \cdot 10^{-3}\beta T.$$

The last two terms on the right side of this expression can be neglected in comparison with β, and then the error in the probe readings is determined from the equation

$$\beta = -1.2 + 2.3 \lg \frac{1}{j} + 1.4 \lg T. \qquad (12)$$

From the results shown in Fig. 6 it can be seen that $\beta > 0$ in Eq. (12). We can find the ratio for which the current from the emitter will not be limited by the electron space charge. The latter case cannot be examined in the present form of the theory.

We now find the error in determining the plasma potential from the point of divergence of the characteristics of the hot and cold probe. For emitter potential values close to the point of divergence of the characteristics, the depth of the potential well at the emitter surface is zero. In this case the current density of electrons from the probe to the plasma is

$$j_{ek} = j_k \exp(-\beta). \qquad (13)$$

At the point of divergence of the characteristics we obtain

$$\frac{j_{ek}}{j_{ea} - j_i} \ll 1,$$

where j_{ek} is the current density of electrons from the probe to the plasma, j_{ea} is the current density of electrons from the plasma to the probe, and j_i is the current density of ions from the plasma to the probe.

For our estimates we assume that

$$\frac{j_{ek}}{j_{ea}} = 0.1. \qquad (14)$$

The quantity j_i can be neglected, since for probe potentials equal to and larger than the plasma potential $j_i \ll j_{ea}$. Substituting Eq. (13) into Eq. (14) and taking into account that $j = j_{ea}/j_k$, we find that

$$\beta = \ln 10 + \ln \frac{1}{j} = 2.3 + 2.3 \lg \frac{1}{j}.$$

Comparing the expression obtained for the error with Eq. (12), we see that the error in determining the plasma potential from the intersection point of the asymptotes gives greater accuracy than the method of determining the plasma potential from the point of divergence of the characteristics of the hot and cold probes.

The results obtained here are in qualitative agreement with experimental data. However, it follows from the theoretical analysis that the slope of the right asymptote of the volt–ampere characteristic of the hot probe must be numerically equal to 0.43e/kT, while its value is less by a factor of 2 or 3 as given by the experimental relations. To explain this discrepancy in the results we turn to Fig. 6. It is not difficult to see that the dependence of $\nu + \beta$ on β approaches the asymptote and in practice, in processing the experimental results beyond the right asymptote, a certain value of an approximate straight line is assumed for which the tangent of the slope is smaller than for the asymptote. In this case the point of intersection of the left asymptote and the straight-line approximation is closer to the true value of the plasma potential than the point of intersection of the asymptotes.

A quantitative comparison between the theoretical and experimental results has not been made because the emitter temperature is not constant along the length of the spiral, and it would be difficult to correct the measurement.

A defect of the above method is that it is laborious, since it entails a determination of the characteristics of the hot and cold probes, which is particularly complicated when one constructs the potential field for the space occupied by the plasma. Therefore we estimate the dependence of the error in determining the plasma potential from the point of divergence of the characteristics on the the properties of the emitter surface and the parameters of the surrounding plasma. It is clear that when the plasma potential is determined using a hot probe, a relation analogous to Eq. (14),

$$\frac{I_{ek}}{I_{ea}} = \frac{S_{\mathrm{em}} j_k}{S_{\mathrm{tot}} j_{ea}} = \frac{S_{\mathrm{em}}}{S_{\mathrm{tot}}} \frac{j_k \exp\left(-\frac{eU}{kT_k}\right)}{j_{ea}} \leqslant 0.1, \qquad (15)$$

must hold, where I_{ek} is the total ion current passing from the probe to the plasma, I_{ea} is the total current from the plasma to the probe, S_{em} is the area of the emitter surface, S_{tot} is the area of the effective probe surface; and V is the probe potential relative to the plasma, i.e., the value of the error of measurement. We find the value of j_{ea} from the equation

$$j_{ea} = \frac{1}{4} en \sqrt{\frac{8kT_a}{\pi em}}.$$

We transform Eq. (15) and find the error

$$U = \frac{kT_k}{e} \ln\left(10 \frac{j_k}{j_{ea}} \frac{S_{\mathrm{em}}}{S_{\mathrm{tot}}}\right). \qquad (16)$$

But we are interested in the variation of V when the probe is moved from point 1 with plasma parameters n_1 and T_{a1} to the point 2, where $n = n_2$ and $T = T_{a2}$:

$$\Delta U = \frac{kT_k}{e} \ln \frac{n_1 \sqrt{T_{a1}}}{n_2 \sqrt{T_{a2}}}. \qquad (17)$$

If the distribution function for electrons in the plasma is Maxwellian, then $T_{a1} = T_{a2}$. It follows from Eq. (17) that as the parameters of the surrounding plasma vary, the error varies over a narrow range; thus, in constructing the potential field for the flow we can use the heated probe, in the circuit shown in Fig. 1, and then introduce a correction for the whole potential field due to individual sections of the flow. This correction is found by comparing results obtained at one point in space from the point of intersection of the asymptotes and from the point of divergence of the characteristics.

Wave excitation at half the gyrofrequency in counterstreaming electron beams

A. P. Timoshenko, D. V. Iremashvili, and Yu. K. Udovichenko

(Submitted January 21, 1974; resubmitted March 12, 1974)
Zh. Tekh. Fiz., 44, 2559-2562 (December 1974)

An experimental study has been made of the influence of the transverse and thermal electron velocities in counterstreaming beams on the excitation of oscillations at half the gyrofrequency and its harmonics. The injection current is 1.5 A, the energy of the beam electrons is 15 keV, and the magnetic field is 200-600 Oe. An increase in the transverse electron velocity leads to stronger oscillations, but this process is limited by collisionless damping due to the large spread in electron velocities.

A system of counterstreaming electron beams in a fixed, homogeneous, longitudinal magnetic field can support waves at half the gyrofrequency and its harmonics:[1,2] $n\omega_H/2(n = 1, 2, 3, \ldots)$. Waves exist at the harmonic frequencies only if there are waves at the fundamental frequency ($n = 1$).

Under certain conditions, such waves cannot be excited in counterstreaming beams because of collisionless damping.[3,4] These conditions can be derived from

$$\frac{\lambda_1}{\lambda_D}=\frac{\frac{\omega_b}{\frac{\omega_H}{2}}}{}\frac{v_z}{v_T}, \qquad (1)$$

where $\lambda_1 \doteq 4\pi v_z/\omega_H$ is the wavelength of the standing wave at the fundamental frequency, $\lambda_D = 2\pi v_T/\omega_b$ is the Debye length in the beam, ω_b is the electron plasma frequency in the beam, v_z is the longitudinal electron velocity in the beam, and v_T is the thermal velocity, which we identify with the spread of electron velocities in the beam. When the wavelength of the driven wave, λ_1, becomes comparable to the Debye length λ_D, the damping predominates over growth, so there is no instability. Experimentally this situation has been observed[4] at $\lambda_1/\lambda_D < 5$. We see from Eq. (1) that a lower limit on the excitation of waves in counterstreaming beams is set by the beam density ($\omega_{bcr} \sim \omega_H$), while an upper limit is set by the magnetic field ($\omega_{Hcr} \sim \omega_b$), for a fixed value of the parameter v_T/v_z for the injected beams. These limits have been studied experimentally for a system with a homogeneous magnetic field in the absence of a transverse velocity of the beam electrons[4] ($v_\perp = 0$).

It follows from the theory of ref. 5 that the growth rate increases if the electrons in the beam have a transverse velocity ($v_\perp \neq 0$). As a rule, such beams also have large values of v_T, which must significantly restrict the excitation of waves because of collisionless damping. For beams with a nonvanishing transverse electron velocity ($v_\perp \neq 0$), Eq. (1) remains valid for the longitudinal component v_z.

The excitation of waves at half the gyrofrequency in counterstreaming high-current beams has also been observed[6] in a system with an inhomogeneous magnetic field and $v_\perp \neq 0$, but no definite conclusions were drawn about the influence of $v_\perp$ on the wave excitation.

We report here a study of the conditions for the excitation of waves at half the gyrofrequency when electrons having a large velocity spread v_T and a large transverse velocity component $v_\perp$ are injected into the system. We find how the parameters v_T/v_z and $v_\perp/v_z$ affect the damping and growth of the high-frequency waves. We find the beam parameters for which it is possible to obtain a significant increase in the wave intensity because of $v_\perp$.

The experimental apparatus is described in ref. 6. Most of these experiments are carried out with an unshielded electron gun, which is located, along with a working chamber up to 40 cm long, in a fixed, homogeneous, longitudinal magnetic field H = 200–600 Oe. The injected beam current is 1.5 A, the electron energy is 15 keV, and the current pulse is 10–40 μsec long. The beam diameter at the entrance to the working chamber is 1 cm. The residual pressure in the system is $5 \cdot 10^{-6}$ torr. The counterstreaming beams are obtained upon the reflection into the chamber of an electron beam from an electrode held at the negative potential of the gun cathode. In measurements of the injected current the reflection electrode is used as a collector. The longitudinal distribution of the beam electrons is measured with a multigrid analyzer; the analyzer is moved across an aperture 0.03 cm in diameter in the collector, which can be moved to various beam radii. The currents in the collector circuit and in the circuit of the gun cathode are measured by a Rogowski loop. The high-frequency waves are detected by coaxial probes and then displayed on an oscilloscope.

Electron beams with $v_\perp \neq 0$ can be produced by injecting the beams through an increasing magnetic field. As a rule, hot beams result.[7] In our experiments, in a system with a homogeneous magnetic field, such beams are produced by injection through a transverse magnetic field of 100 Oe over a distance ~ 4 cm at the entrance to the chamber. The transverse magnetic field is produced by two magnetic coils arranged symmetrically with respect to the axis of the solenoid.

The excitation of high-frequency waves in counterstreaming beams is studied in ref. 6 under conditions such that the transverse electron velocity in the beam is comparable to the longitudinal component ($v_\perp \sim v_z$). A large transverse component $v_\perp$, as determined from the pulsations, is obtained by injecting the beam into the interaction chamber through a growing axisymmetric magnetic field. In such a beam we would expect pronounced changes in the parameters $v_\perp/v_z$ and v_T/v_z along a diameter. In fact, as the experiments show, the beam has complex characteristics over a cross section. As an example, Fig. 1 shows the beam energy spectra along the radius of the working chamber, r, at the maximum of the pulsations. We see from this figure that the velocity v_z falls off with increasing r, as does the current density, while v_T/v_z increases (curves 1-4). Because of energy conservation, there is an increase in the transverse velocity of the beam electrons: $v_\perp^2 = v_0^2 - v_z^2 (v_0 = \sqrt{2eU/m}$, e and m are the electron charge

and mass, and U is the accelerating voltage). According to Eq. (1), when $\lambda_1/\lambda_0 \geq 5$, those beam electrons for which $v_T \leqslant 0.14\ v_z$ can contribute to the wave growth. Curve 2 corresponds to beam electrons with $v_\perp = 0.3\ v_z$ and $v_T = 0.08\ v_z$, for which there should be growth in the interaction of counterstreaming electron beams of this type.[5] The beam electrons (curve 3) have $v_T = 0.22\ v_z$, and they should not contribute to the wave intensity, despite the large value $v_\perp \simeq 0.6\ v_z$. The peripheral part of the beam (curve 4), on the other hand, exhibits a large transverse velocity ($v_\perp \simeq v_z$) but a low current density and a large value of v_T($v_T = 0.43\ v_z$), so that these electrons cannot drive instabilities.

When we take collisionless damping into account, we see that the velocity $v_\perp$ can affect the wave excitation in this system only near the central part of the beam. The important factor is that the variation in $v_\perp$ over the beam cross section be accompanied by a variation in v_z. As a result, the condition for optimum excitation (the condition that the length of the working chamber be equivalent to an integral number of half-waves of the fundamental mode) does not hold for all "layers" of electrons over the beam cross section. It is a complicated matter to analyze the effect of $v_\perp$ on the wave intensity in such a system, so we carry out an experiment in which the electrons acquire a transverse velocity $v_\perp$ while v_T is held constant over the beam cross section.

In the system with the homogeneous longitudinal magnetic field the beam is essentially monoenergetic over the cross sections. When a transverse magnetic field is imposed, the beam as a whole acquires a transverse velocity $v_\perp$, and the distribution over the cross section changes slightly. Figure 2 shows longitudinal electron energy spectra of the beam injected into the system for a fixed velocity component v_z, corresponding to a longitudinal energy of E_z = 8 keV and to an increase in the initial electron energy E_0 with increasing $v_\perp$ (curves 2-4). Curve 1 shows the monoenergetic (cold) beam. Curve 2 shows a beam with $v_T = 0.11\ v_z$ and $v_\perp = 0.25\ v_z$. Here, the amplitude at the fundamental frequency has approximately doubled. The increase in the wave intensity with increasing $v_\perp$ agrees with the theory of ref. 5. Curves 3 and 4 show hot beams with v_T/v_z equal to 0.2, 0.4 and with v_T/v_z equal to 0.35, 0.6, respectively. As v_T increases the beam diameter increases. For curve 2 the beam diameter is nearly the same. For curve 3 the increase is about 20-25%, while for curve 4 it reaches 50%. Despite the significant increase in $v_\perp$ for the beams with the distribution functions described by curves 3 and 4, we observe a pronounced damping of the high-frequency waves; this can be attributed to the collisionless damping resulting from the increase in ($\lambda_1/\lambda_D < 5$). The damping of the waves for curves 3 and 4 is 15 and 30 dB. Figure 3 shows the change in the amplitude of the high-frequency waves under the experimental conditions corresponding to Fig. 2. The damping at harmonics of half the gyrofrequency becomes apparent at values of v_T lower than that at which the damping at the fundamental frequency becomes apparent.

We note that in practice it is difficult to produce beams with a high transverse electron velocity ($v_\perp \sim v_z$) with $v_T/v_z \leq 0.1$. An increase in the transverse magnetic field to 100 Oe leads, because of the fringing fields and the inhomogeneity of the distribution with respect to the coil diameter, to an appreciable increase in the beam diameter (or a reduction in the beam density) and to a significant increase in the parameter v_T/v_z.

Figure 4 shows the critical value of the parameter v_T/v_z as a function of the beam plasma frequency (line 1) at which the waves begin to be damped. We see from this figure that the experimental functional dependence differs significantly from the theoretical functional dependence (line 2) for the case $\lambda_1/\lambda_D = 5$. The quantitative discrepancy can be attributed to the circumstance that the distribution of the oscillating beam electrons is stretched out significantly during the growth of the high-frequency waves.[8]

The results shown in Figs. 2-4 are obtained in the case v_z = const, corresponding to optimum excitation of high-frequency waves in the system.

On the basis of an analysis of these results we can assert that electron beams can be used in a system of counterstreaming beams to excite waves at frequencies $n\omega_H/2$ with a velocity spread $v_T > 0.1\ v_z$ with an increase in the beam density for a fixed magnetic field. We can thus also use beams having large values of $v_\perp$ to produce more intense high-frequency waves. On the other hand, as the current decreases it is necessary to have beams which are monoenergetic. This latter requirement is apparently responsible for the fact that waves at frequencies $n\omega_H/2$ are not observed[9] in a system of counterstreaming beams involving low-current beams in the case in which the electron beam is in an inhomogeneous magnetic field.

Accordingly, we have shown experimentally that an increase in the transverse electron velocity of the beam injected into a system of counterstreaming beams, $v_\perp$, leads to a growth of the waves at half the gyrofrequency and at its harmonics. However, an increase in $v_\perp$ is accompanied by an increase in v_T. At a certain value of v_T the wave amplitude becomes limited by collisionless damping.

(Submitted December 19, 1973; resubmitted April 26, 1974)
Zh. Tekh. Fiz., 44, 2563-2567 (December 1974)

The mass spectrum of charged and neutral particles ejected from the surface of single-crystal films of gallium arsenide by Ar^+ ions is studied. The charged particles include ions of the elements of the gallium arsenide lattice and complex ions like Ga_mAs_n. In addition, ions of molecules of surface compounds of lattice elements with residual gas molecules are found. The composition of the ejected neutrals is significantly different from that of the secondary ions.

The construction of almost all present-day semiconductor devices requires the synthesis of compounds of the $A^{III}B^{V}$ groups in the form of homo- or heteroepitaxial layers with various dopings.[1]

Up to the present time the methods used to investigate the processes of formation and growth of epitaxial layers and their doping do not give information on the initial stages of these processes. The method of secondary ion–ion emission (SIIE)[2,3] can be used to study the initial stages of the formation of thin films[4-6] and the distribution of impurities over the thickness of a thin layer of material.[3-7]

It is advantageous to use the SIIE method to study the important semiconductor compound gallium arsenide (GaAs). We present the results of a study of the mass spectrum of secondary ions formed in the surface bombardment of single crystals of gallium arsenide by argon ions. This information is necessary for more detailed information.

This work is performed on a mass spectrometer built from a modified MI-1305 mass spectrometer. The construction and characteristics of this instrument are described in refs. 8 and 9. A GaAs target is bombarded with a beam of 2 keV Ar^+ ions at a current density of 0.6 $\mu A/cm^2$. The pressure of the residual gas in the target chamber is 10^{-6} torr. The targets are single crystals or single-crystal epitaxial layers of GaAs 30–100 μ thick grown on oriented GaAs substrated by the method described in ref. 10 and doped with tin or tellurium to a level of $\sim 10^{18}$ cm^{-3}.

The mass spectra of secondary ions obtained from thick single crystals and from epitaxial films are identical both in structure and in the relative intensities of the mass lines, within the limits of experimental error. Most of the mass lines correspond either to secondary ions of target particles or various complexes of these, or to secondary ions of compounds of target particles or complexes of them with particles of the residual gases. In addition the mass spectra contain the usual secondary ions produced from molecules of the residual gases adsorbed on the target surface, and secondary ions from the bulk contamination of the target material (Na^+, Al^+, Si^+, K^+).

Table 1 shows the secondary ions ejected by Ar^+ ions from the (100) face of an epitaxial film of GaAs at 700°K. The intensities of the beams of secondary ions are summed over all isotopes. The relative intensities of the beams of ions of gallium isotopes and ions of various of its com-

pounds correspond to the values calculated from tabulated data on the abundance of gallium isotopes by better than ±5%, which is within the limits of experimental error.

Table 1 shows that the intensities of the mass lines corresponding to various secondary ions vary over wide limits. The intensity of the line corresponding to the arsenic ion As^+, in contrast with the results reported in ref. 11, is more than two orders of magnitude smaller than the intensities of the lines for Ga ions.

It is worth noting that the mass spectra show lines corresponding to ions of complex compounds of gallium and arsenic atoms like $Ga_mAs_n^+$. While cluster forms of arsenic particles As_n^+ are also observed in thermal evaporation,[12] particles of the form Ga_mAs_n have so far been assumed to be unstable.[13] The lifetimes of Ga_m^+ and $Ga_mAs_n^+$ particles estimated from their energies and ranges from the target to the secondary ion detector are at least $2 \cdot 10^{-5}$ sec.

In addition to the mass spectrum of secondary ions our investigation includes a study of the mass spectrum of neutral particles ejected from the surface of GaAs by primary Ar^+ ions and then ionized by a beam of electrons. The structure of the mass spectrum of neutrals obtained in this way is shown in Table 2. The table shows that the neutrals ejected from the surface of gallium arsenide are mainly atomic and cluster forms of neutral arsenic particles: As, As_2, As_3, and As_4. No gallium atoms or molecules are found in the mass spectrum of neutrals.

A comparison of Tables 1 and 2 shows that the composition of atomized neutrals differs radically from the composition of the ejected ions, and is closer to the composition of particles evaporated by heating gallium arsenide. Possible reasons for this difference are given in ref. 14.

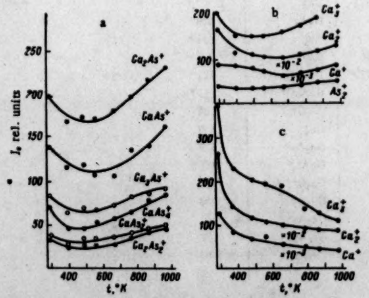

Fig. 1. J (T) for beams of secondary ions Ga_m^+, $Ga_mAs_n^+$, As_2^+. a, b) (100) face; c) (111) face.

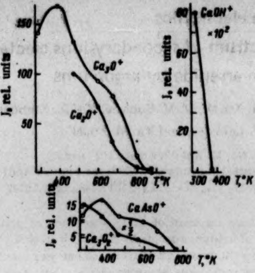

Fig. 2. J (T) for beams of secondary ions of oxides and hydroxides, (100) face.

The intensities of the beams of secondary ions J listed in Table 1 are found as functions of the target temperature T. Below, these relations are denoted by J(T).

Figure 1 shows the intensities of beams of ions of the first group, which includes ions of target elements and their various complexes, and varies slowly with temperature in the 300–1000°K range. Only for the ions Ga^+, Ga_2^+, and Ga_3^+ ejected from the (111) face of a single crystal of GaAs is there a significant decrease in intensity with rising target temperature. At the same time Figs. 2 and 3 show a rapid variation of intensity with target temperature for secondary ions of various compounds of target particles and their complexes with particles of the residual gases (ions of the second group). The decrease in intensity for ions of gallium hydroxides ($GaOH^+$, Ga_2OH^+) with an increase in target temperature is much more rapid than for ions of gallium oxide or an ion of the complex compound $GaAsO^+$.

The difference in the character of the J(T) curves for secondary ions of the first and second groups enables us to state with considerable confidence that ions of the first group are ejected mainly from the GaAs crystal lattice, while precursors of ions of the second group are molecules of chemical compounds of lattice particles with particles adsorbed on its surface.

A comparison of Figs. 2 and 3 shows that the J(T) curves for the (111) and (100) faces of a GaAs single crys-

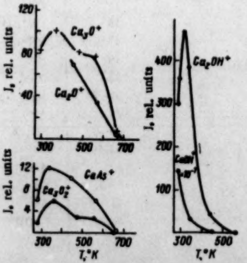

Fig. 3. J (T) for beams of secondary ions of oxides and hydroxides, (111) face.

tal behave somewhat differently. This may be a consequence of the difference in adsorbing power and chemical activity of these faces.

The currents of secondary ions of the first and second groups are also found as functions of the primary ion current J_0.

Over the whole range of primary beam currents studied the relation $J = f(J_0)$ is found to be linear for ions of the first group, which indicates a bulk origin of these ions. At the same time the curve of $J = f(J_0)$ for ions of the second group shows saturation, which is characteristic of ions ejected from surface compounds.[15]

It is interesting to note that there is a definite correlation between the mass spectrum of particles ejected by a beam of Ar^+ ions from the surface of a GaAs single crystal and its crystal lattice.

It is known that the GaAs crystal lattice consists of body-centered tetrahedrons of Ga_4As and $GaAs_4$. At the same time if no account is taken of ions of sorbed particles and bulk impurities in gallium arsenide the mass spectrum of ejected particles contains mainly ions of fragments of unit cells of the Ga_4As lattice and ions of compounds of these fragments with sorbed particles (Tables 1 and 2). By examining the mass spectra of particles ejected from semiconductor compounds having different types of crystal lattices we hope to obtain information on the mechanism of the breaking of bonds in a unit cell of a crystal lattice by the transfer of momentum to some particle of this lattice from a cascade of atomic collisions arising from the penetration of a primary ion into the depth of the lattice.

An important practical conclusion of these results is that in an ordinary vacuum (~ 10^{-6} torr) at a temperature of the order of 900°K it is possible to clean a GaAs crystal surface of molecules of surface chemical compounds of lattice atoms with particles adsorbed on its surface.

The authors thank their co-workers of the V. M. Kozlov Laboratory of Ionic Processes for their help.

Coherent Compton effect in crystals

V. A. Bushuev and R. N. Kuz'min
Department of Physics, M. V. Lomonosov Moscow State University
(Submitted December 10, 1973; resubmitted April 8, 1974)
Zh. Tekh. Fiz., 44, 2568-2571 (December 1974)

The effect of the dynamic interaction of scattered waves on the frequency and angular distribution of the scattered radiation is discussed using the Compton effect in ideal crystals as an example. It is shown that the presence of a perfect crystal lattice leads to the appearance of lines of the spatially coherent Compton effect superimposed on the ordinary incoherent Compton scattering background. The shapes and intensities of these lines are found by taking account of the absorption of the incident and scattered radiation.

The effect of a crystal lattice on the effectiveness of inelastic scattering of x rays appears in the change of shape and width of the Compton[1-3] and plasmon[4] scattering lines in comparison with scattering in a free-electron gas, in the appearance of the nonlinear Bragg condition of synchronism in parametric scattering,[5] and in the possibility of a mixture of x rays with the short-wavelength components of a field of optical frequency.[6]

In the present paper we point out another aspect of inelastic scattering related to the presence of a perfect crystal structure. Since the frequency of the scattered radiation (signal) depends on the scattering angle, it is easy to explain the directions in which the usual Bragg–Wolf conditions will be satisfied for the signal waves in the medium. Because of the dynamic exchange between the spatially coupled modes $q(\omega)$ and $q + H$, where H are the appropriate reciprocal lattice vectors, there must be a redistribution of energy in these modes, and radiation of frequency ω can be observed in new directions previously forbidden by the laws of conservation of energy and momentum. Now part of the momentum H will be taken up by the lattice itself. Thus this is interference of inelastically scattered waves as a consequence of spatial (lattice) coherence.

For simplicity we limit ourselves to a consideration of dynamic effects in Compton scattering. Suppose a monochromatic wave (pump) $e_1E_1\exp(ik_1r - i\omega t) + \text{c.c.}$ is incident on a crystal slab of thickness l, where the angle φ between k_1 and the plane perpendicular to H is different from the Bragg angle. The scattered radiation is observed in the far zone in the direction $\varkappa$ ($\varkappa = \omega/c$).

By generalizing the method developed in ref. 7 the differential scattering cross section in the two-wave approximation with respect to the signal can be obtained in the form

$$\sigma(\omega, \vartheta_0) = \sum_{m=1}^{2}\sum_{\mu=1}^{2} v_{m\mu}\,[D_{m\mu}^{(0)}(\mathbf{e}_{m0}\mathbf{e}_1)^2\sigma^{(0)}(\omega, \vartheta_0) + D_{m\mu}^{(H)}(\mathbf{e}_{mh}\mathbf{e}_1)^2\sigma^{(0)}(\omega, \vartheta_h)]\left[\sum_{m=1}^{2}(\mathbf{e}_{m0}\mathbf{e}_1)^2\right]^{-1}. \tag{1}$$

Here, $\sigma^{(0)}(\omega, \vartheta)$ is the Compton scattering cross section neglecting dynamic exchange and the absorption of the signal and pump; ϑ_0 and ϑ_h are the angles between k_1 and $\varkappa$ and between k_1 and $\varkappa + H$ respectively. For simplicity only those terms which make the main contribution to the scattered intensity are retained in (1). The coefficients $D_{m\mu}$ describe the effectiveness of the dynamic interaction.

$$D_{m\mu}^{(0)} = \frac{|p_m \pm \sqrt{p_m^2+1}|^2}{4(p_m^2+1)}, \quad D_{m\mu}^{(H)} = \frac{\gamma_0}{4\gamma_h(p_m^2+1)}, \tag{2}$$

$$\left.\begin{aligned} p_m = -\frac{\Delta\omega \sin^2\delta}{2\pi\omega|\alpha_m|}\sqrt{\frac{\gamma_0}{\gamma_H}}, \quad \sin\delta = \frac{H}{2\varkappa}, \\ \gamma_0 = \sin\rho\sin(\chi+\delta), \quad \gamma_h = \sin\rho\sin(\chi-\delta), \end{aligned}\right\} \tag{3}$$

where the parameter p_m characterizes the deviation of the signal frequency $\omega = \omega_B + \Delta\omega$ from the Bragg frequency ω_B found[1)] from $H = 2(\omega_B/c)\sin u$, where $(\pi/2 + u)$ is the angle between the vectors $\varkappa$ and H which define the so-called plane of linear scattering or the dynamic plane. Equations (2) and (3) are obtained under the assumption that $\gamma_h > 0$ (Laue case). Here, ρ is the acute angle between the dynamic plane and the crystal surface, χ is the angle between the normal to H, lying in the dynamic plane, and its line of intersection with the crystal surface. The upper and lower signs in (2) refer respectively to the centers of propagation $\mu = 1$ and 2. The unit vectors of the signal waves e_{m0} and e_{mh} are perpendicular to the dynamic plane for $m = 1$, and parallel to it for $m = 2$. The dynamic coupling coefficient is $\alpha_m \equiv \alpha^{(H)}(\omega q)(e_{m0}\hat{\pi}_q e_{mh})$, where $\alpha^{(H)}$ is the part of the linear polarizability which is nondiagonal in H, and is proportional to the structure factor corresponding to H, $\hat{\pi}_q$ is the operator which projects onto the plane perpendicular to q, and the medium is assumed isotropic.

The dimensionless quantity $v_{m\mu}$ characterizes the effect of absorption of the pump and signal on the effective scattering volume

$$v_{m\mu} = \frac{e^{-y_{m\mu}} - e^{-y_1}}{y_1 - y_{m\mu}}, \quad v_{m\mu}(|p| \gg 1) = \frac{e^{-y} - e^{-y_1}}{y_1 - y} \equiv v. \tag{4}$$

Here $y_1 = \beta l/\cos(k_1 \cdot n)$, $y = \beta l/\cos(\varkappa \cdot n)$, β is the linear absorption coefficient at the pump frequency, n is the normal to the crystal surface, and $y_{m\mu}(p) = \sigma_{m\mu}l$, where $\sigma_{m\mu}(p_m)$ is the absorption coefficient in the Laue case, given in ref. 9 for example. The absorption coefficient $\sigma_{m\mu}$ has resonances and can be very different for centers 1 and 2 (the Bormann effect). In a transparent medium ($\beta l \ll 1$) $v_{m\mu} = 1$, but it should be remembered that the thickness l has a lower bound ($l \gg 10^{-3}$ cm) which is determined by the limits of applicability of the dynamic theory.

The quantities u and ϑ_- must now be expressed in terms of ϑ_0. If the direction of $\varkappa$ is characterized by the polar angle ψ with respect to the equatorial plane perpendicular to the $(k_1 \cdot H)$ plane, and the azimuthal angle Φ measured from the direction of k_1 in the equatorial plane, it is easy to show that $\cos\vartheta_0 = \cos\psi\cos\Phi$,

$$\sin u = \sin\psi\cos\varphi - \cos\psi\sin\varphi\cos\Phi,$$
$$\cos\vartheta_h = \sin\psi\sin 2\varphi + \cos\psi\cos 2\varphi\cos\Phi.$$

For $|p_m| \gg 1$ the effects of the dynamic interaction can be neglected, and according to (1) and (2) we obtain the usual single-wave approximation result: $\sigma(\omega,\vartheta_0) = v\sigma^{(0)}(\omega,\vartheta_0)$.

The shape of the Compton line becomes distorted as $|p_m|$ decreases. Depending on the values of the parameters φ, γ_0/γ_h and $\Delta\omega_e$ – the effective width of the $\sigma^{(0)}$ cross section – a dip or a spike is superimposed on the ordinary shape of the Compton line at the frequency $\omega_0(\vartheta_0)$. This increment has a Lorentz shape with a width $\Delta\omega_L = (2\pi\omega|\alpha_m|/\sin^2\delta)\sqrt{\gamma_h/\gamma_0}$ which is two or three orders of magnitude narrower then the $\sigma^{(0)}$ line. In the x-ray region $|\alpha_m| \sim 10^{-4}$-10^{-6}. At the present time such narrow increments apparently cannot be observed in the spectral distribution, although their amplitudes are of the order of $\frac{1}{2}\sigma^{(0)}(\omega_B, \vartheta_0)$.

It follows from (1)-(3) that a coherent inelastic scattering line should be observed in the integrated distribution of $\sigma(\vartheta_0)$ against an almost uniformly incoherent Compton background. This phenomenon is the spatially-coherent Compton effect. According to (1) the condition for maximum dynamic exchange

$$\omega_B(\psi, \Phi) = \omega_{cs} = \omega_1\left(1 - 2\frac{\hbar\omega_1}{mc^2}\sin^2\frac{\vartheta_0}{2}\right) \tag{5}$$

determines the spatial position of the coherent Compton lines. For $\hbar\omega_1/mc^2 \ll 1$ Eq. (5) is the equation of a slightly deformed cone with its axis along **H**.

The coherent Compton effect line has an angular fine structure since there is an excess or deficiency of radiation in the $\varkappa$ direction. Its angular spectrum for $\varphi \neq 0$ consists of two narrow closely spaced lines, one of which is brighter than the background and the other dimmer. For $\psi > \varphi$ the dimmer line should lie closer to the direction of $\mathbf{k}_1$. The angular shape of each individual line repeats the frequency shape with a width of the order of $\Delta\omega_e/\omega_1$. For $v_{m\mu} = 1$ the contrast, i.e., the absolute value of the intensity over background at the center of the line, is estimated as a fraction to a few percent for light materials such as Be, C, or LiF. For crude estimates the contrast can be taken equal to $(\pi/2)(\Delta\omega_L/\Delta\omega_e)$. It should be noted, however, that if absorption is taken into account the contrast can become many times larger. Since $v_{m\mu}(p_m = 0) > v$, in the region of anomalous transmission, in an overall decrease in scattered intensity the background is depressed more strongly. Thus for $y \approx y_1 = 5$, $y(p_m = 0) \approx 0.05y$, from (4) $v_m(0) = 0.15$, and the ratio of effective volumes is ~20.

For small angles $\vartheta_{0,h}$ the main contribution to inelastic scattering is made by Raman scattering from collective fluctuations of electron density – plasmons. If $|\sin\varphi| - \sin\delta < 2\sin\vartheta_c$, where ϑ_c is the critical angle determining Landau damping for plasmons,[4] coherent (lattice) Raman scattering can occur from plasmons. Expressions for the cross sections for Compton and plasmon scattering $\sigma^{(0)}$ in a degenerate electron gas in a metal are given in ref. 7, for example.

The Bragg case ($\gamma_h < 0$) does not appear to be of great interest; because of the primary extinction the effective volume for scattering into a coherent Compton line is decreased by several orders of magnitude and only a thin boundary layer contributes.

The observation of the coherent Compton effect described in the present paper requires perfect single crystals, preferably large enough to suppress incoherent Compton scattering. A number of papers have reported the observation of slightly curved lines with a fine structure in the angular spectrum of the scattering of a slightly divergent beam of monochromatic radiation in diamond single crystals[10,11] and in LiF crystals previously bombarded with neutrons or deformed by compression.[12] On the basis of geometrical considerations these interference lines are explained by the presence of Compton scattering. Since the crystals used have a very pronounced mosaic structure the intensity of the Compton interference lines should be described within the framework of kinematics and not by the dynamic theory of the scattering of x rays, while their geometric position,[2] as for ideal crystals, is determined by the neutral condition (5).

Elastic scattering in mosaic crystals is generally more effective than in ideal crystals,[8] and apparently for just this reason the coherent Compton lines were not observed in scattering in perfect diamond crystals,[11] and became observable in LiF only after directional deterioration of the crystal structure. Therefore it is of interest to perform a special experiment to observe the coherent Compton effect in perfect crystals of such materials as germanium or silicon which exhibit a strong anomalous transmission.

For example, suppose a silicon single crystal is oriented in such a way that the reciprocal lattice vector H(220) is parallel to the axis of a cylindrical chamber and the crystal faces, and the Mo Kα pump is incident perpendicular to H($\gamma_0 = \gamma_h$, $\varphi = 0$). In this case an x-ray photograph should show a pair of dim lines symmetrically located with respect to the straight line $\psi = 0$ at a distance $\psi \geq \psi_0 = 10°40'$, where $\Delta\psi\,(\Phi_0 = 170°) = 43'$. If the scattering angle is such that $k_2 = 2k_1\sin\vartheta_0/2 = 2k_F$ ($k_F = 1.8$ A^{-1} is the Fermi wave vector in the free-electron model with a density equal to the density of the valence electrons in silicon[3]) $\Delta\omega_e = 56$ eV, $\Delta\omega_L = 3.1$ eV, and according to (1) and (4) for k_2 a crystal of length $l = 2$ mm ($\beta = 15.4$ cm^{-1}, $\beta_{anom} = 0.04\beta$) the contrast at the center of Compton scattered lines at points on an x-ray photograph with coordinates $\psi = \pm 10°41'$ and $\Phi = \pm 20°50'$ should amount to 50% for an angular half-width of the lines $\Delta\psi_{1/2} = (\Delta\omega_e/\omega_1)\tan\psi = 2.3'$.

The authors are indebted to D. N. Klyshko for helpful discussion and to E. V. Kolontsova and I. V. Telegina for information regarding their experiments.

---

[1] We recall that in the usual dynamic theory, where the frequency of the waves is specified, the deviation parameter is the difference between the scattering angle and the Bragg direction.[8] In experiments on inelastic scattering the viewing angle is generally fixed. Therefore we are developing a variant of the dynamic theory with a frequency difference.

[2] If the angle $\varphi = 0$, then for a change $\Delta\psi$ in the polar angle ψ as Φ increases from 0 to Φ_0 it follows from (3) that $\Delta\psi = (\hbar\omega_1/mc^2)\sin\psi_0(1-\cos\Phi_0)$, where ψ_0 is the scattering angle at $\Phi = 0$. The fact that $\Delta\psi$ is positive indicates that the interference lines should be bent upward slightly from the line $\psi = \psi_0$. In the scattering of Mo Kα in LiF [reflection (220), $\psi_0 = 10°$] for $\Phi_0 = 170°$ we have $\Delta\psi = 40.5°$, which is in good agreement with the experimental result.[12]

3) Calculations[13] show that for sufficiently large transfer of momentum k_2 and energy $(\omega_1 - \omega_{C3})$ the difference in effective widths $\Delta\omega_e$ in semiconductors and metals with the same electron density can be neglected.

Transformation of light beams by dynamic correctors using three-dimensional displacement phase holograms

V. G. Sidorovich and D. I. Stasel'ko

(Submitted June 11, 1974)
Zh. Tekh. Fiz., 44, 2572-2579 (December 1974)

The transformation of a beam consisting of several plane waves into a single plane wave is studied in an analysis of the nonlinear wave equation in the approximation of slowly varying amplitudes. The conditions under which essentially complete transformation is achieved are determined. The possibility of achieving these conditions in practice is examined.

Studies of the transformation of light beams by three-dimensional dynamic holograms are of considerable interest in connection with the use of such holograms to control the spatial and temporal characteristics of coherent radiation sources, one aspect of which is to correct the shape of nonstationary wave fronts. Experimental study of the simplest transformation case, in which two monochromatic plane waves at identical frequencies propagate in a three-dimensional dynamic phase hologram, has shown that a significant fraction of the energy of one wave can be transferred to the other wave when the hologram is displaced with respect to the sinusoidal interference pattern which forms it.[1] Theory for this situation has shown that a three-dimensional dynamic, displacement phase hologram can provide essentially complete energy transfer from one of the incoming waves to the other, regardless of the ratio of the corresponding wave intensities at the boundary.[2] In particular, this property makes it possible to stabilize the propagation direction of intense light beams. The transformation of light beams whose wave fronts have an arbitrary shape and which differ in frequency is of more practical interest. The recording and reconstruction of dynamic holograms by beams differing in frequency are analyzed in ref. 3 for arbitrary properties of the recording media; it is shown that the traveling dielectric-constant waves produced in such dynamic holograms are capable of transforming a plane reference wave into a wave of arbitrary shape. However, that analysis[3] is based on the assumption that the object and reference waves propagating in the hologram have constant amplitudes, so that the efficiency of this transformation could not be determined. Furthermore, no account is taken of the transformation of an object wave of arbitrary shape into a plane wave – a process which is important in connection with the problem of correcting wave fronts. In the present work we analyze the possible use of dynamic holograms recorded by beams of different frequency in cubic nonlinear media with inertial nonlinearity mechanisms to correct wave fronts. We find that the three-dimensional dynamic phase holograms recorded in such media are capable of transforming a beam consisting of several plane waves into a plane wave at a different frequency with essentially no energy loss. We derive the conditions under which this transformation is possible.

1. We choose a cubic nonlinear medium with inertial nonlinearity mechanisms as the material for recording the dynamic holograms on the basis of the following considerations: As beams at different frequencies propagate in such a medium, the phase lattices are displaced with respect to the sinusoidal interference patterns that shape them. This displacement is necessary for a high radiation-transformation efficiency.[4-7] There are many such nonlinear media, since significant changes in the dielectric constant due to such phenomena as electrostriction, heating, and the orientation of anisotropic molecules in optical-frequency fields occur under the influence of intense light beams in essentially any slightly absorbing medium. Also taking account of the possibility of recording dynamic holograms in large volumes (especially when liquid and gaseous nonlinear media are used) and the possibility of achieving short times for the establishment of the phase lattices (as short as 10^{-10}-10^{-13} sec), we see that these media have the necessary characteristics for practical use in dynamic holography. Among the processes leading to changes in the dielectric constant of cubic nonlinear media under the influence of light are vibrational processes (e.g., acoustic vibrations of the medium caused by electrostriction or vibrations of atoms in molecules excited by light). A distinctive feature of these processes is the resonant nature of the changes which they cause in the dielectric constant: When the difference between the frequencies of the interfering beams, Ω, is equal to the resonant frequency Ω_R, the amplitude of the phase lattice produced by the traveling interference patterns becomes a factor of $\Omega R/\Delta\Omega$ higher than the amplitude of the phase lattice formed by the beams of identical frequency (here $\Delta\Omega$ is the width of the resonance line of the oscillations), and the traveling lattice lags behind the interference pattern which forms it by one fourth of a period.[5,6] It becomes clear in the discussion below that the circumstance that the modulation of a traveling lattice becomes higher than that of a fixed lattice is extremely important for correction of wave fronts.

2. To analyze the correction of wave fronts by displacement dynamic phase holograms recorded in inertial cubic nonlinear media we state the problem as follows: We assume that the correcting beam – a plane wave of amplitude $c_1(0)$ – and the beam to be corrected [which consists of several plane waves propagating at small angles with respect to each other, e.g., two waves of amplitudes $c_2(0)$ and $c_3(0)$] are incident on the boundary of a transparent cubic nonlinear medium. The waves of the beam being corrected have the same frequency ω, while the frequency of the plane correcting wave is $\omega-\Omega (\Omega > 0)$. When the difference between the beam frequencies is of this sign, energy is transferred from the waves of the beam being corrected to the plane wave for the cases of most of the mechanisms which lead to a cubic nonlinearity of a medium.[8] We also restrict the discussion to the case $\Omega \ll \omega$, so that we can neglect dispersion of the medium. Figure 1 shows the geometry of the problem. The X and Y axes are

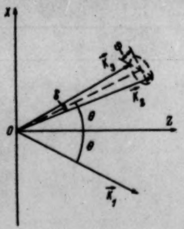

Fig. 1. Vector diagram of waves propagating in a dynamic hologram.

parallel to the surface of the medium, while the Z axis is normal to this surface. We assume that the wave vector of the correcting wave $\mathbf{k}_1$ and the bisector of the angle between the wave vectors $\mathbf{k}_2$ and $\mathbf{k}_3$ corresponding to the waves in the beam being corrected lie in the XoZ plane, making angles of $\pm\theta$ with the z axis. Here, φ is the angle between the XoZ plane and the plane containing $\mathbf{k}_2$ and $\mathbf{k}_3$, and δ is the angle between $\mathbf{k}_2$ and $\mathbf{k}_3$ ($\delta \ll 1$). Assuming that all the waves are polarized in the YoZ plane, we describe the light propagation in the medium by a nonlinear equation for that component E of the electric field **E** which is perpendicular to the plane of incidence:$^{1)}$

$$\nabla^2 E - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}(\varepsilon(E)E) = 0, \qquad (1)$$

where c is the speed of light in vacuum, and $\varepsilon(E) = \varepsilon_0 + \Delta\varepsilon(E)$ is the dielectric constant of the medium,$^{2)}$ and

$$|\Delta\varepsilon(E)| \ll \varepsilon_0. \qquad (2)$$

3. The transformation of light beams by a dynamic hologram in this case can be described in the following manner: The interference of the second and third waves at identical frequencies in the nonlinear medium produces a fixed phase lattice P_{23}, which coincides in position with the interference pattern of these waves. The interference of the first wave with the second and of the first wave with the third leads to the formation of traveling lattices P_{12} and P_{13}, displaced with respect to the corresponding interference patterns by some fraction of a period. Scattering of the incident waves by the lattices formed in the medium leads to a change in the complex amplitudes of these waves and to the appearance of new waves.

We first consider the case in which the amplitudes of the waves arising in the hologram are negligibly small in comparison with the amplitudes of the waves propagating in the directions of the initial waves and having their frequencies; in this case we achieve the maximum efficiency for the transformation of the beam being corrected into an undistorted plane wave. We thus write solution (1) as

$$E(x, y, z, t) = \sum_{j=1}^{3} c_j(z)\, e^{i(\mathbf{k}_j\mathbf{r} - \omega_j t)}, \qquad (3)$$

where $c_j(z)$ are the amplitudes of the plane waves propagating in the hologram, $\mathbf{k}_j = (k_{jx}, k_{jy}, k_{jz})$; $\mathbf{r} = (x, y, z)$; $\omega_1 = \omega - \Omega$; and $\omega_{2,3} = \omega$. Using (3) and the displacements mentioned above between the traveling interference patterns and the corresponding lattices, we write the nonlinear increment to the dielectric constant of the medium, $\Delta\varepsilon(E)$, as

$$\Delta\varepsilon(E) = \alpha J_\Sigma + [(\beta'' - i\beta')\, c_1 c_2^* e^{i[(\mathbf{k}_1 - \mathbf{k}_2)\mathbf{r} + \Omega t]}$$
$$+ (\beta'' - i\beta')\, c_1 c_3^* e^{i[(\mathbf{k}_1 - \mathbf{k}_3)\mathbf{r} + \Omega t]} + \alpha c_2 c_3^* e^{i(\mathbf{k}_2 - \mathbf{k}_3)\mathbf{r}} + \text{c.c.}], \qquad (4)$$

where

$$J_\Sigma = |c_1(z)|^2 + |c_2(z)|^2 + |c_3(z)|^2 = |c_1(0)|^2 + |c_2(0)|^2 + |c_3(0)^2|$$

is the resultant intensity of the waves propagating in the hologram, α is the nonlinearity coefficient corresponding to the fixed lattice, and β'' and β' are the nonlinearity coefficients corresponding to the undisplaced component of the traveling lattices and the component which is displaced by one fourth of a period.$^{3)}$ Equations for the nonlinearity coefficients α, β', and β'' are given in ref. 5.

Substituting (3) and (4) into (1) and neglecting terms containing second derivatives of $c_j(z)$, we find a system of nonlinear differential equations for $c_j(z)$:

$$\left.\begin{aligned}
\frac{dc_1}{dz} &= iD_1\alpha J_\Sigma c_1 + D_1(\beta' + i\beta'')\, c_1(|c_2|^2 + |c_3|^2),\\
\frac{dc_2}{dz} &= iD_2\alpha J_\Sigma c_2 + D_2 c_2[i(\alpha + \beta'')|c_3|^2 - \beta'|c_1|^2],\\
\frac{dc_3}{dz} &= iD_3\alpha J_\Sigma c_3 + D_3 c_3[i(\alpha + \beta'')|c_2|^2 - \beta'|c_1|^2],
\end{aligned}\right\} \qquad (6)$$

where $D_i = k_{0i}^2/2k_{iz}$, and k_{0i} is the wave number of wave i. Turning to the intensities of the plane waves propagating in the dynamic hologram, $J_1(z)$, $J_2(z)$, and $J_3(z)$, we write equations for these intensities in integral form:

$$\left.\begin{aligned}
\frac{J_1(z)}{J_1(0)} &= e^{2D\beta'\int_0^z [J_2(z') + J_3(z')]\,dz'},\\
\frac{J_{2,3}(z)}{J_{2,3}(0)} &= e^{-2D\beta'\int_0^z J_1(z')\,dz'}
\end{aligned}\right\} \qquad (7)$$

(here we have used the approximation $D_1 \simeq D_2 \simeq D_3 \simeq D$, which holds for $\delta \ll 1$ and $\Omega \ll \omega$). Using the integral in (5) to solve system (7), we find

$$\left.\begin{aligned}
J_1(z) &= \frac{J_\Sigma J_1(0)}{J_1(0) + S(0)\, e^{-2D\beta' J_\Sigma z}},\\
J_{2,3}(z) &= \frac{J_\Sigma J_{2,3}(0)}{S(0) + J_1(0)\, e^{2D\beta' J_\Sigma z}},
\end{aligned}\right\} \qquad (8)$$

where $S(0) = J_2(0) + J_3(0)$.

It follows from (8) that at large values of z we have $J_1(z) \simeq J_\Sigma$, i.e., if the additional waves which are produced in the hologram are neglected, we can transform the beam being corrected into an undistorted plane wave with essentially no energy loss.

4. We turn now to the range of applicability of this analysis, and find the conditions under which the amplitudes of the additional waves are small. On the basis of their formation mechanisms we can classify the additional waves into four groups: (1) waves which arise in the scattering of each of the plane waves of the beam being corrected by the traveling lattice which is formed without the participation of the given plane wave (the scattering of the second wave by lattice P_{13} and of the third wave by lattice P_{12}); (2) the waves of the same direction and frequency which appear in the scattering of the first wave by lattice P_{23}; (3) the higher orders of diffraction of the original waves by the lattices P_{12} and P_{13}; and (4) the higher orders of diffraction of the second and third waves by lattice P_{23}.

The propagation directions of the waves of the first and second types make angles with respect to the correcting wave which are approximately equal to the angles between the plane waves in the beam being corrected. Accordingly, if the amplitudes of these waves are comparable to the amplitude of the correcting wave, $c_1(z)$, the divergence of the radiation transformed by the dynamic hologram can be at least as large as the divergence of the beam being corrected.

To derive the condition under which the amplitudes of the additional waves of the first two types are small in comparison with amplitude $c_1(z)$, we write the solution of (1), writing one of these waves in the form

$$E(x,\ y,\ z,\ t)=\sum_{j=1}^{3} c_j(z)\,e^{i(\mathbf{k}_j\mathbf{r}-\omega_j t)}+E', \qquad (9)$$

where $E' = c'(z)e^{i(\mathbf{k}'\mathbf{r}-\omega' t)}$ is the projection of the electric field of the wave in question onto the Y axis, $c'(z)$ is a quantity which is equal in modulus to the amplitude of the additional wave in question, $\mathbf{k}' = \mathbf{k}_1 - \mathbf{k}_2' + \mathbf{k}_3$ is the wave vector of the polarization wave which excites it, and $\omega' = \omega - \Omega$. Assuming $|E|' \ll |c_i|$ and using Eq. (4) for $\Delta\varepsilon(E)$, after substituting (4) and (9) into (1) we find an equation for $c'(z)$:

$$\frac{dc'}{dz}-i\frac{A}{2k'_z}c'=i\alpha J_\Sigma\frac{k_{01}^2}{2k'_z}c'+i(\alpha+\beta'')\frac{k_{01}^2}{2k'_z}c_1c_2^*c_3+\beta'\frac{k_{01}^2}{2k'_z}c_1c_2^*c_3, \qquad (10)$$

where $A = k_{01}^2 - (k_x'^2 + k_y'^2 + k_z'^2)$; k'_x, k'_y, k'_z are the projections of $\mathbf{k}'$ on the coordinate axes; and $A/2k'_z$ is the modulus of the vector difference between the phase velocities of the given additional wave and the polarization wave which excites it. Substituting the equations found for $c_i(z)$ by converting (6) to "total-differential" form into the right-hand side of Eq. (10), and neglecting the quantity $(D_1 - D_2 + D_3 - D')\alpha J_\Sigma$ $(D' = k_{01}^2/2k'_z)$ in comparison with $A/2k'_z$, we rewrite (10) as

$$\frac{d}{dz}\left[c'e^{-i\left(\frac{A}{2k'_z}+\alpha J_\Sigma\frac{k_{01}^2}{2k'_z}\right)z}\right]=[\beta'+i(\alpha+\beta'')]\,DC_1(0)\,c_2(0)\,c_3(0)$$

$$\times e^{D\beta'\int_0^z[|c_2(z')|^2+|c_3(z')|^2-2|c_1(z')|^2]dz'}\,e^{-i\frac{A}{2k'_z}z}. \qquad (11)$$

The ratio of the moduli of the amplitudes of the additional wave in question and of the first wave,

$$\left|\frac{c'(z)}{c_1(z)}\right|=\left|\frac{[\beta'+i(\alpha+\beta'')Dc_1(0)c_2(0)c_3(0)\int_0^z e^{D\beta'\int_0^{z'}[|c_2(z'')|^2+|c_3(z'')|^2-2|c_1(z'')|^2]dz''}\,e^{-i\frac{A}{2k'_z}z'}\,dz'}{c_1(0)\,e^{D\beta'\int_0^z[|c_2(z'')|^2+|c_3(z'')|^2]dz''}}\right|, \qquad (12)$$

obtained with the help of (6) and (11), becomes small if the second exponential term in the integral over z' oscillates rapidly in comparison with the first term. Under this condition this integral can be calculated by the method of stationary phase:

$$\left|\frac{c'(z)}{c_1(z)}\right|\simeq\left|\frac{[\beta'+i(\alpha+\beta'')Dc_2(0)\,c_3(0)\left(e^{D\beta'\int_0^z[|c_2(z')|^2+|c_3(z')|^2-2|c_1(z')|^2]dz'}\,e^{-i\frac{A}{2k'_z}z}-1\right)}{\frac{A}{2k'_z}e^{D\beta'\int_0^z[|c_2(z')|^2+|c_3(z')|^2]dz'}}\right|<2\left|\frac{[\beta'+i(\alpha+\beta'')Dc_2(0)\,c_3(0)}{\frac{A}{2k'_z}}\right|<\frac{\sqrt{(\Delta\varepsilon_{\alpha+\beta''})^2+(\Delta\varepsilon_{\beta'})^2}\,k_{01}^2}{A}, \qquad (13)$$

where $\Delta\varepsilon_{\alpha+\beta''} = (\alpha + \beta'')J_\Sigma$ and $\Delta\varepsilon_{\beta'} = \beta' J_\Sigma$. Using (13), we can write the condition under which the additional waves of the first two types are suppressed, $|c'(z)/c_1(z)| \ll 1$, in the form[4])

$$\frac{\sqrt{(\Delta\varepsilon_{\alpha+\beta''})^2+(\Delta\varepsilon_{\beta'})^2}}{4\sin\delta\sin 2\theta\cos\varphi+2\sin^2\delta}\ll 1. \qquad (14)$$

It follows from (14) that the condition for the suppression of these additional waves is governed strongly by the orientation of the plane containing $\mathbf{k}_2$ or $\mathbf{k}_3$ with respect to the XoZ plane. This dependence is illustrated by Fig. 2, which shows the values of the angle δ which satisfy the equation $[((\Delta\varepsilon_{\alpha+\beta''})^2+(\Delta\varepsilon_{\beta'})^2/(4\sin\delta\,\sin 2\theta\cos\varphi+2\sin^2\delta))]^{1/2} = 0.1$ for various values of the angle φ between these planes (when this equation holds, the intensity of the additional wave in question does not exceed 1% of that of the correcting wave). We see that the lower limit on the values of the angle δ, at which the additional waves of the first two types have small amplitudes, is vastly more stringent in the case $\varphi = 90°$ than in the case $\varphi = 0$.

The waves of the third type propagate at large angles with respect to the correcting wave, so that their influence is primarily one of reducing the efficiency with which the beam being corrected is transformed into a plane wave. The amplitudes of these waves are small if the lattices P_{12} and P_{13} are three-dimensional:

$$\frac{\Delta\varepsilon\sqrt{\beta'^2+\beta''^2}}{2\sin^2 2\theta}\ll 1, \qquad (15)$$

a condition which is analogous to condition (20) in ref. 2. We note that the satisfaction of condition (14) implies the satisfaction of condition (15) when $\delta \ll \theta$.

Waves of the fourth type can grow as a result of the decomposition of the beam being corrected into several thin filaments,[9,10] which prevent the transformation of the given beam into a plane wave. The effect of the self-focusing of the beam being corrected can be reduced by increasing the angle δ to a value satisfying the condition that the lattice P_{23} be three-dimensional:

$$\frac{\Delta\varepsilon\alpha}{2\sin^2\delta}\ll 1. \qquad (16)$$

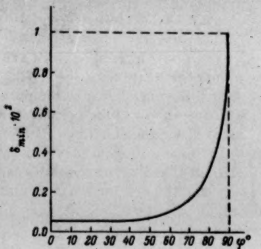

Fig. 2. Angular selectivity of a dynamic hologram as a function of the angle φ, the angle through which the plane of the wave vectors of the beam being corrected is rotated with respect to the incidence plane, XoZ, in the case $\sqrt{(\Delta\varepsilon_{\alpha+\beta''})^2+(\Delta\varepsilon_{\beta'})^2} = 10^{-4}$, $\theta = 0.1$ rad.

Another method for suppressing the self-focusing, which does not involve restriction (16) on the angle δ, is to terminate the transformation into a plane wave by the traveling lattices before the higher diffraction orders at the lattice P_{23} reach an appreciable level. An estimate of the necessary ratio β'/α for a specified ratio of the intensities of the beam being corrected and of the plane wave at the boundary, $S(0)/J_1(0)$, yields

$$\frac{\beta'}{\alpha} > \ln\frac{S(0)}{J_1(0)}. \tag{17}$$

Condition (17) can be achieved in practice, for example, through the use of resonant scattering of light by traveling acoustic waves produced by electrostriction. In this case β' is usually 20-50 times larger than α (ref. 11), and condition (17) holds at values of $S(0)/J_1(0)$ up to $\sim 10^3$. In this case the resonance condition is $\Omega_R(\Lambda) = 2\pi v_{so}/\Lambda$, where v_{so} is the sound velocity in the medium and Λ is the period of the interference pattern of the two plane waves; this condition can hold exactly only for one of the lattices formed as a result of the interference of the plane wave of the beam being corrected and the correcting wave. Since this condition does not hold for the other lattice, the modulation depth of the dielectric constant in this lattice is reduced. There is a corresponding reduction in the efficiency with which that wave being corrected is transformed into the correcting wave. To suppress this effect we must set an upper limit on the angle between the plane waves in the correcting beam: $\delta_{\max} = \Delta\Omega/v_{so}k_0$ where $\Delta\Omega$ is the width of the Brillouin line,[11] and k_0 is the average wave number of the interfering waves. The ratio of this quantity to the angle $\delta_{\min}$, defined by (14), is a measure of the number of plane waves which can be transformed into a plane wave without loss of energy. An estimate of this ratio for a medium with parameters $\Delta\varepsilon_{\beta'} \sim 10^{-5}$ ($\Delta\varepsilon_{\beta'} \gg \Delta\varepsilon_{\alpha+\beta''}$) and $\Omega_R/\Delta\Omega \simeq 20$, characteristic of organic liquids with an electrorestrictive nonlinearity mechanism, and $2\theta = 0.2$ in the case $\varphi = 90°$ yields a value $\delta_{\max}/\delta_{\min} \simeq 40$ and, in the case $\varphi = 0$, a value $\delta_{\max}/\delta_{\min} \sim 2$.

5. It has been shown above that if inequality (17) holds the beam being corrected must have parameters satisfying condition (14) if this beam is to be completely transformed into a plane wave. In practice, however, this condition may not always hold, so that it is worthwhile to analyze the correction possibilities in the opposite limiting case:

$$\frac{\sqrt{(\Delta\varepsilon_{\alpha+\beta''})^2+(\Delta\varepsilon_{\beta'})^2}}{4\sin\delta\sin 2\theta\cos\varphi+2\sin^2\delta} \gg 1. \tag{18}$$

For this analysis we partition the cross section of the beam being corrected into several small regions, within each of which we can assume the beam intensity to be essentially constant and the wave front to be planar. Using condition (18) we can treat the transformation of the beam being corrected into a plane wave independently within each of these small regions, using the procedure of ref. 2. In general, this independence of the transformation processes in the different regions leads to a modulation of the intensity over the cross section and to a distortion of the front. This distortion is not important when (17) holds, since the difference between the phase advances in different regions of the transformed wave is small [it must be kept in mind that in this case the satisfaction of condition (17) corresponds to an essentially complete transformation of the beam being corrected only in those regions where its intensity is a maximum]. The intensity modulation in the cross section of the transformed wave leads to the appearance of waves propagating at angles with respect to the original direction of the correcting wave. In a first approximation the energy expended on these waves can be estimated on the basis of the theory of static plane amplitude holograms.[12] A more rigorous calculation incorporating the functional dependence of the transformation efficiency of the beam being corrected on its intensity in the corresponding part of the cross section shows that the total energy of the waves propagating in directions different from that of the correcting wave does not exceed 20% if the hologram thickness corresponds to complete transformation of the beam in regions of maximum intensity.

Accordingly, the use of media with resonant nonlinearity mechanisms in dynamic correctors in the case in which condition (14) does not hold at least eliminates the distortions of the shape of the wave front, so that the divergence of the wave transformed by the corrector can be reduced to nearly diffraction value.

In conclusion we should point out that the general features of this analysis of holographic correctors using media with resonant nonlinearity mechanisms can apparently be extended to the case in which lithium niobate crystals are used as the medium for recording the dynamic holograms. According to the data of refs. 1 and 13, the modulation depth of the dielectric constant, $\Delta\varepsilon_\chi$, produced in such a medium for a certain exposure time for beams making an angle χ increases with increasing χ. Accordingly, if we use a large angle θ we can satisfy the inequality $\Delta\varepsilon_\theta/\Delta\varepsilon_\delta \simeq \sin 2\theta/\sin\delta > \ln S(0)/J_1(0)$, which is equivalent to (17).

The authors thank Yu. N. Denisyuk for useful discussion.

---

1) In Eq. (1) we have neglected a second-order term in δ, which is the projection of the vector $[\mathbf{E}\ \mathrm{grad}\ (\ln\varepsilon)]$ on the oY axis.

2) We assume below that $\varepsilon_0 = 1$, so that we can neglect reflection and refraction of light at the boundary of the medium.

3) These coefficients are related to the phase shift between the traveling interference patterns and the lattice they produce, ψ, by $\tan\psi = \beta'/\beta''$.

[4] Inequality (14) can also be interpreted as the condition for selectivity of the dynamic hologram with respect to all the waves incident on it.

(Submitted December 7, 1973)
Zh. Tekh. Fiz., 44, 2580-2584 (December 1974)

Red heterostructure luminescent diodes consisting of $Al_xGa_{1-x}As$ solid solutions with a zinc-doped active region have been studied. The electroluminescence spectra are studied as a function of the impurity concentration and as a function of the aluminum concentration in the active region. It has been found that injected electrons traversè the entire active region into the p-GaAs substrate if the active region is thin.

Preliminary results of a study of the properties of the heterostructure luminescent diodes $p\text{-}Al_xGa_{1-x}As-n\text{-}Al_yGa_{1-y}As$ $(y > x)$ are reported in refs. 1 and 2. As suggested in ref. 3, the use of zinc-doped p-type $Al_xGa_{1-x}As$ solid solutions as the active regions of these diodes makes it possible to produce injection light sources emitting efficiently at 300°K in the red region up to $\lambda \simeq 6400$ Å.

We reported here a more detailed study of the electroluminescence spectra of these diodes. The synthesis procedure and conditions are similar to those described in ref. 2. The heterostructure luminescent diodes are produced by liquid epitaxy in which the substrate is zinc-doped p-GaAs. The radiation is observed in the direction normal to the plane of the p − n junction through a $n\text{-}Al_yGa_{1-y}As$ wide-band emitter. The diode area is about 0.5 mm^2.

At 300°K these samples display an external quantum efficiency at $\lambda = 6900$ Å of 1-1.5%; that at $\lambda = 6700$ Å is 0.4-0.5%; and that at $\lambda = 6500\text{-}6400$ Å is 0.1-0.2%.

The electroluminescence spectra are recorded by a standard synthronous-detection procedure. The radiation is detected by an FÉU-62 photomultiplier or a germanium photodiode. The measurements are carried out over the temperature range 77-300°K.

We turn first to the nature of the electroluminescence spectra of these diodes as a function of the doping level of the p-type and n-type regions. The acceptor and donor concentrations (N_A and N_D, respectively) for some of these samples are shown in Table 1. The acceptor (zinc) concentration in the n-type region is lower than the donor (tellurium) concentration in the n-type region for all the diodes, and the value of N_A can be determined from the voltage−capacitance measurements. The donor concentration in the n-type region is determined from data in the literature on the tellurium segregation coefficient for the case in which solid solutions are doped during growth by the liquid method.[4] The Al concentration in the active region and that in the wide-band emitter are determined by microscopic x-ray spectral analysis.

TABLE 1

Sample	N_D (Fe)	N_A (Zn)	hν, eV; $T = 300°$ K
92 P 2	$2 \cdot 10^{17}$	$2 \cdot 10^{16}$	1.816
88 P 2	$2 \cdot 10^{17}$	$2 \cdot 10^{16}$	1.810
N 28	10^{18}	$4 \cdot 10^{17}$	1.874
145 P 2	$5 \cdot 10^{18}$	$1.7 \cdot 10^{17}$	1.865

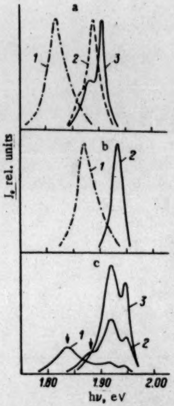

Fig. 1. Electroluminescence spectra of heterostructure luminescent diodes having various doping levels for the p-type and n-type regions. a: 92P2 structure. 1) T = 300; 3) 155; 3) 85°K. b: N28 structure. 1) T = 300; 2) 77°K. c: 145P2 structure. 1) $j = 3 \cdot 10^{-2}$; 2) 0.7; 3) $1.5 \cdot 10^2$ A/cm^2, T = 77°K. The arrows show the emission band due to diagonal tunneling.

Let us consider the structures with weakly doped p-type and n-type regions (samples 92P2 and 88P2; Table 1). The red spectrum of such structures at 77°K (Fig. 1a, curve 3) has the shape characteristic of weakly doped p-GaAs samples[5] and $p\text{-}Al_xGa_{1-x}As$ samples.[6,7] The short-wavelength emission band in this case is apparently of an excitonic nature, and the long-wavelength band 25 MeV away from it is due to transitions between the conduction band and acceptor level of zinc.[7] According to data obtained earlier in a study of the photoluminescence spectra of zinc-doped $Al_xGa_{1-x}As$ samples,[6] the energy gap between the exciton and "zinc" emission bands in the electroluminescence spectra of heterostructure luminescent diodes is not governed by the Al concentration in the active region for direct compositions of the solid solutions. As the excitation level is raised, the intensity of the short-wavelength band increases more rapidly. Increasing the temperature from 77 to 300°K leads to a continuous decrease in the relative intensity of the longer-wavelength zinc band (Fig. 1a, curves 1-3). At the same time, the short-wavelength band broadens and becomes asymmetric. The extended short-wavelength decay of this band at 300°K (curve 1 in Fig. 1a) implies that free electron−hole pairs participate in the recombination.[5,8] The characteristic radiative-transition times in these diodes at 300°K are about 50 nsec (ref. 2).

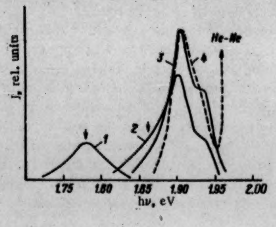

Fig. 2. Electroluminescence and photoluminescence spectra of the 148P1 structure with heavily doped p-type and n-type regions. 1-3) Electroluminescence spectrum. j (A/cm²): 1) 10^{-2}; 2) 20; 3) 120; 4) photoluminescence spectrum, T = 77°K. The arrows show the emission band due to diagonal tunneling.

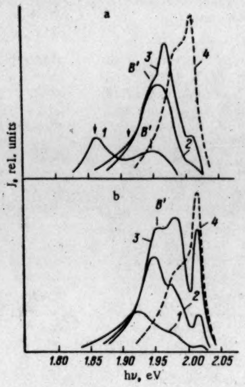

Fig. 3. Electroluminescence spectra of heterostructure luminescence diodes having a high Al−As concentration in the active region. a: 153P2 structure. 1) $j = 7 \cdot 10^{-2}$; 2) 20; 3) 80; 4) $2 \cdot 10^3$ A/cm² (pulsed excitation). b: 144P2 structure. 1) $j = 4 \cdot 10^{-2}$; 2) 10; 3) 120; 4) $1.6 \cdot 10^3$ A/cm² (pulsed excitation), T = 77°K. The arrows show the emission band due to diagonal tunneling.

As the zinc concentration in the active region is increased (sample N28; Table 1), the longer-wavelength band, due to transitions to acceptor levels becomes predominant in the emission spectrum of the diodes at 77°K (Fig. 1b, curve 2). Furthermore, as expected, the radiative-transition times at 300°K decrease to 10-15 nsec.

Increasing the tellurium concentration in the n-type region of the diodes (samples 148P1 and 145P2; Table 1) leads to the appearance in the electroluminescence spectra at 77°K of a broad long-wavelength emission band in addition to the edge bands. As the voltage applied to the diode is increased, the position of this band shifts in the short-wavelength direction (Fig. 1c, curves 1 and 2, and Fig. 2, curves 1 and 2). To determine the nature of this band we have studied the photoluminescence spectra of the active region of the corresponding structures when they are excited by a He−Ne laser on the side of the wide-band n-type emitter. Although the excitation level in the photoluminescence is chosen to be low, the long-wavelength emission band is not found in the photoluminescence spectrum (Fig. 2, curve 4). This result implies that the moving long-wavelength band in the electroluminescence spectra of the diodes is due to diagonal tunneling analogous to that which occurs in heavily doped p−n GaAs junctions[9-11] and GaAs−$Al_xGa_{1-x}As$ heterojunctions.[10,11]

These electroluminescence spectra are typical of heterostructure luminescent diodes in which the Al−As concentration in the active region is lower than 32%. As the Al concentration in the active region is increased, and the transition compositions are approached ($X_n = 0.37$; ref. 3), the nature of the electroluminescence spectra changes. At low and medium current densities the predominant feature in the electroluminescence spectrum of these samples at 77°K is the broad B' band (Fig. 3, a and b, curves 1 and 2).

The maximum of this band shifts considerably in the short-wavelength direction as the excitation level is raised; in contrast with the emission band considered above (due to diagonal tunneling), the rate at which the maximum of the B' band shifts is much lower, and its position does not correspond to the magnitude of the applied voltage. The B' band is observed in the electroluminescence spectra even at bias values considerably higher than the voltage corresponding to the height of the barrier at the heterojunction. The narrow edge emission bands characteristic of luminescent diodes with a narrower band-active region (Fig. 3, a and b, curves 3 and 4) are found in the electroluminescence spectra of these structures only at high current densities. Comparison of Figs. 3a and 3b shows that the energetic separation of B' and the edge bands increases with increasing aluminum concentration in the active region of the diodes.

The electroluminescence spectra in Fig. 3 are generally analogous to the photoluminescence spectra of solid $Al_xGa_{1-x}As$ solutions having the corresponding compositions.[12] Here, the B band is evidently due to indirect transitions between acceptor states and donor levels corresponding to the minimum X_1, which lie at a lower energy than the minimum[12] Γ_1. Increasing the aluminum concentration leads to a further displacement of this indirect donor level with respect to the direct minimum of the conduction band, causing the observed increase in the separation of B' and the edge emission bands, which are still due to direct transitions. With a further increase in the AlAs concentration in the active region the edge transitions also undergo a change in nature, becoming indirect.

Up to this point we have only considered the short-wavelength part of the emission spectra, due to recombination in the active region of the diodes. However, in addition to the short-wavelength bands, the emission spectra of all the diodes contain long-wavelength bands whose shape and position correspond to radiative transitions in the p-GaAs substrate. For samples with a thick active region (d = 20-25 μ) the intensity of the long-wavelength "gallium arsenide" band is no more than 5% of the intensity of the red band at 300°K, and the ratio of the intensities of these bands is independent of the current density over the range 10-10^4 A/cm². The long-wavelength band in this case is evidently due to optical excitation of the p-GaAs substrate by the short-wavelength emission band.

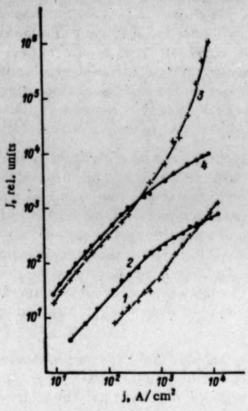

Fig. 4. Intensities of the short-wavelength and long-wavelength emission bands as a function of the current density for the N28 structure (the active region is d = 7 μ thick). 1, 3) Long-wavelength band at 300 and 77°K, respectively; 2, 4) short-wavelength band at 300 and 77°K, respectively.

For samples with a thin active region (d ≃ 4-7 μ) the relative intensity of the gallium arsenide band, even at low current densities, is much higher than that for structures with a thick active region. As the current density is increased we generally observe a faster-than-linear increase in the intensity of the long-wavelength band (Fig. 4, curve 1); at the same time, the increase in the intensity of the red band slows (Fig. 4, curve 2). As the temperature is reduced to 77°K these effects are displayed even more clearly (Fig. 4, curves 3 and 4). The intensity ratio of the red and long-wavelength bands changes at current densities lower than at 300°K, and the intensification of the gallium arsenide band is accompanied by a transition to stimulated emission.[1)] The observed intensification of the gallium arsenide accompanying an increase in the current density in the structures having thin active regions is evidently due to the complete traversal of the active region by the injected electrons, which reach the p-GaAs substrate.

The increase in the effective length of the diffusion-drift displacement for the minority carriers (electrons) as the current density is increased is apparently due to a strengthening of the electric field in the active region. On the one hand, a temperature reduction from 300 to 77°K strengthens the electric field because of the reduction in the free-hole concentration in the active region; on the other hand, it increases the electron mobility. These effects are probably responsible for the observed increase in the flow of carriers across the active region as the temperature is reduced from 300 to 77°K.

In conclusion the authors thank V. M. Tuchkevich and Zh. I. Alferov for their interest, and T. B. Godlinnik for a microscopic x-ray spectral analysis.

[1)] The ratio of the red and gallium arsenide bands was studied in diodes having solid contacts, with the emission observed parallel to the plane of the p–n junction. The spectral sensitivity of the pickup is taken into account in plotting the curves.

Gas temperature in the positive column of a medium-β helium discharge

Yu. M. Kagan and K. K. Paskalev
A. A. Zhdanov Leningrad State University

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 2585-2588 (December 1974)

We compare various approximate methods for calculating the radial distribution and the values of atomic temperatures on the axis in the positive column in helium at medium pressures.

1. In a previous paper we described a method for determining the parameters of a positive column discharge in helium at medium pressures using measurements of the continuum radiation arising from deceleration of electrons by atoms.[1] The expression was used for spectral radiative power per unit volume:

$$\varepsilon_\omega = 4\cdot 10^{-28}\, n\frac{p}{T}T_e e^{-\frac{\hbar\omega}{kT_e}}\int_0^\infty\left[x^{3/2}+\left(x+\frac{\hbar\omega}{kT_e}\right)^{3/2}\right]e^{-x}dx. \tag{1}$$

It follows from Eq. (1) that by measuring the ratio of the continuum intensities at two different frequencies we can determine the electron temperature T_e directly.

To determine the electron density n from the absolute intensity of the continuum at frequency ω we must know the "hot pressure" p and the gas temperature T.

When one can assume that the electrons lose their energy mainly in elastic collisions with the atoms, the relation

$$kT_e = \frac{1}{3}\frac{M}{m^2}\left(\frac{eET}{p\nu_0}\right)^2 \tag{2}$$

holds, where the collision frequency (independent of the electron velocity for helium) is

$$\nu = \nu_0\frac{p}{T};\quad \nu_0 = 6.3\cdot 10^{11}. \tag{2a}$$

Then Eq. (1) can easily be converted to the form

$$\varepsilon_\omega = 1.4\cdot 10^{-26}\, nEF(\tilde{T}_e), \tag{3}$$

where $\tilde{T}_e = T_e\cdot 10^{-4}$°K,

$$F(\tilde{T}_e) = \sqrt{\tilde{T}_e}\, e^{-\frac{\hbar\omega}{kT_e}}\int_0^\infty\left[x^{3/2}+\left(x+\frac{\hbar\omega}{kT_e}\right)^{3/2}\right]e^{-x}dx. \tag{3a}$$

For our wavelengths λ = 7800 Å in the range of $\tilde{T}_e$ from 1 to 3.5 we can assume that

$$F(\tilde{T}_e) \simeq 1.14\tilde{T}_e. \tag{3b}$$

From Eq. (3), knowing E and T_e, we can easily determine n, without measuring the values of p and T. The above method can also be used to determine the radial distribution of n and T_e. In accordance with experiment, we assume that the longitudinal field E does not vary over the radius.

2. In some cases we are interested in the radial variation of the atomic temperature. If we neglect the electron thermal conductivity and assume the electron distribution to be Maxwellian, for medium pressures the heat conduction equation takes the form

$$-\frac{1}{\rho}\frac{d}{d\rho}\left[\rho\varkappa_0\sqrt{T}\frac{dT}{d\rho}\right] = 2\frac{m}{M}\langle\varepsilon\nu\rangle n = 3\frac{m}{M}k\nu_0 T_e\frac{pn}{T}. \tag{4}$$

To solve this equation one must know the radial variation of T_e and pn/T. These can bedetermined from Eq. (1) by measuring the radial variation of the absolute intensity at a single wavelength and the ratio of intensities at two wavelengths. However, it is difficult to measure the radial variation of the intensity ratio with sufficient accuracy. The problem is simplified when Eq. (2) holds. Then, by introducing the variable $x = \rho/R$, we can rewrite Eq. (4) in the form

$$-\frac{1}{x}\frac{d}{dx}\left[x\frac{d}{dx}T^{3/2}\right] = An(x)T(x), \tag{5}$$

$$A = \frac{3}{2\varkappa_0}\frac{e^2}{m\nu_0}\left(\frac{E}{p}\right)^2 pR^2,$$

where $\varkappa_0 = 10^3$. The boundary condition for Eq. (5) has the form $dT/dx = 0$ for $x = 0T(0) = T_0$.

The solution of Eq. (5) will be

$$T^{3/2}(x) - T^{3/2}(1) = A\int_x^1\frac{dy}{y}\int_0^y n(z)T(z)z\,dz, \tag{6}$$

where T(1) is the temperature at the wall. If in the zero-order approximation we substitute

$$n(x)T(x) = n_0T_0, \tag{7}$$

for the integrand, we obtain

$$T^{3/2}(x) - T^{3/2}(1) = \frac{1}{4}An_0T_0(1-x^2). \tag{8}$$

The temperature on the axis is

$$T_0^{3/2} - T^{3/2}(1) = \frac{1}{4}An_0T_0. \tag{9}$$

The temperature T(x) falls off in the radial direction, as does the electron density n(x). Therefore we consider an approximation of the form

$$n(x)T(x) = n_0T_0(1-x^2)^2. \tag{10}$$

Then

$$T^{3/2}(x) - T^{3/2}(1) = \frac{1}{12}An_0T_0\left(\frac{11}{6} - 3x^2 + \frac{3}{2}x^4 - \frac{1}{3}x^6\right), \tag{11}$$

$$T_0^{3/2} - T^{3/2}(1) = \frac{11}{72}An_0T_0. \tag{12}$$

More accurately, we can relate the quantities n(x)T(x) with the experimentally measured behavior of the continuum intensity at a single wavelength. From Eqs. (2), (3), and (3b), we obtain

$$\frac{\varepsilon(x)}{\varepsilon_0} = \frac{n(x)T^2(x)}{n_0T_0^2}, \tag{13}$$

where ε_0 is the value of the continuum intensity on the axis.

TABLE 1. Values of Atomic Temperatures on the Column Axis, in Units of 10^{-2} °K, Obtained by the Various Approximations

i/R, mA/cm	Form of approximation	pR, torr·cm: 20		40		60		80	
		R, cm: 1.0	2.8	1.0	2.8	1.0	2.8	1.0	2.8
25	(7)	3.8	3.5	4.2	4.0	4.6	4.3	4.8	4.7
	(10)	4.0	3.8	4.5	4.4	5.1	4.9	5.4	5.4
	(15)	3.8	3.6	4.3	4.5	4.9	4.7	5.1	5.1
50	(7)	4.0	3.8	4.7	4.7	5.3	5.0	5.7	5.8
	(10)	4.4	4.3	5.3	5.5	6.1	6.1	6.7	7.0
	(15)	4.3	4.1	5.0	5.2	5.5	5.6	6.3	6.0
100	(7)	4.5	4.9	5.5	5.1	6.4	6.4	6.9	7.1
	(10)	5.1	5.7	6.4	7.1	7.1	8.0	8.4	9.0
	(15)	4.9	5.3	6.0	6.0	6.7	7.2	7.7	8.3
200	(7)	5.5	5.8	6.8	7.2	7.7	8.1	8.7	9.1
	(10)	6.5	7.1	8.2	9.0	9.7	10.0	11.1	12
	(15)	6.1	6.5	7.5	8.2	8.7	9.3	9.9	10

It follows from Eq. (6) that

$$T^{3/2}(x) - T^{3/2}(1) = A n_0 T_0^2 \int_x^1 \frac{dy}{y} \int_0^y \frac{\frac{\varepsilon(z)}{\varepsilon_0}}{T(z)} z\,dz. \tag{14}$$

For T(2) in the integrand we adopt the approximation, close to the approximations of Eqs. (8) or (11),

$$T(z) = (T_0 - T_R)(1 - z^2) + T_R, \tag{15}$$

where $T_R \equiv T(1)$.

In the range of values of pR from 20 to 80 torr · cm and of values of i/R from 25 to 200 mA/cm, for tubes of radius from 1 to 3 cm, the experimental variation of the continuum intensities over the radius can be described by an approximation of the form

$$\frac{\varepsilon(z)}{\varepsilon_0} = 1 - z. \tag{15a}$$

with sufficient accuracy [if we take into account that this quantity appears in the integrand of Eq. (14)].

Then Eq. (14) can be written in the form

$$T^{3/2}(x) - T^{3/2}(1) = A n_0 T_0 (1 + \beta) \int_x^1 \frac{dy}{y} \int_0^y \frac{1 - z}{1 + \beta - z^2} z\,dz, \tag{16}$$

where $\beta = T_R/(T_0 - T_R)$. In the further calculation it is more convenient to rewrite Eq. (16) in the equivalent form

$$T_0^{3/2} - T^{3/2}(x) = A n_0 T_0 (1 + \beta) \int_0^x \frac{dy}{y} \int_0^y \frac{1 - z}{1 + \beta - z^2} z\,dz.$$

The double integral can be expressed in terms of the Riemann Zeta function. Tables of this function are given in ref. 2:

$$\zeta(1, 2 \mid z) = -\int_0^z \frac{\ln|1 - t|}{t} dt,$$

$$T_0^{3/2} - T^{3/2}(x) = A n_0 T_0 (1 + \beta) \frac{1}{2}\left[2x - (\sqrt{1+\beta} - 1)\zeta\left(1, 2 \left| \frac{x}{\sqrt{1+\beta}}\right.\right) + (\sqrt{1+\beta} + 1)\zeta\left(1, 2 \left| \frac{-x}{\sqrt{1+\beta}}\right.\right)\right]. \tag{17}$$

$$T_0^{3/2} - T_R^{3/2} = A n_0 T_0 (1 + \beta) \frac{1}{2}\left[2 - (\sqrt{1+\beta} - 1)\zeta\left(1, 2 \left| \frac{1}{\sqrt{1+\beta}}\right.\right) + (\sqrt{1+\beta} + 1)\zeta\left(1, 2 \left| \frac{-1}{\sqrt{1+\beta}}\right.\right)\right]. \tag{18}$$

To find the radial behavior of the temperature from Eqs. (8), (11), and (17), we must know the quantities E, p, and n_0. In order to eliminate n_0 it is convenient to use an expression for the total current through the tube

$$i = 2\pi e E \int_0^R b_e n(\rho) \rho\, d\rho = B \int_0^1 n(x) T(x) x\,dx, \tag{19}$$

where

$$B = 2\pi \frac{e^2}{m v_0} \frac{E}{p} R^2.$$

The electron mobility is

$$b_e = \frac{e}{m v} = \frac{e}{m v_0} \frac{T}{p}.$$

Using the approximation of Eq. (7), we obtain

$$i = \frac{1}{2} n_0 T_0 B. \tag{20}$$

Using the approximation of Eq. (10), we obtain

$$i = \frac{1}{6} n_0 T_0 B. \tag{21}$$

Using the approximations of Eqs. (15) and (15a), we obtain

$$i = \frac{1}{2} B n_0 T_0 (1 + \beta)\left[2 + (\sqrt{1+\beta} - 1)\ln\left(1 - \frac{1}{\sqrt{1+\beta}}\right) - (\sqrt{1+\beta} + 1)\ln\left(1 + \frac{1}{\sqrt{1+\beta}}\right)\right]. \tag{22}$$

Using the corresponding expressions for the temperature on the axis and for the current, for the approximation of Eq. (7) we obtain

$$T_0^{3/2} - T_R^{3/2} = \frac{1}{2} \frac{A}{B} i = 1.19 \frac{i}{R} E R, \tag{23}$$

$$T_0^{3/2} - T_R^{3/2} = \frac{11}{12} \frac{A}{B} i = 2.18 \frac{i}{R} E R \tag{24}$$

for the approximation of Eq. (10), and

$$T_0^{3/2} - T_R^{3/2} = 2.29 I(\beta) \frac{i}{R} E R \tag{25}$$

for the approximation of Eqs. (15) and (15a).

In Eqs. (23)-(25) the current i is expressed in milliamperes and the field E in volts per centimeter,

$$I(\beta)=\frac{2-(\sqrt{1+\beta}-1)\zeta\left(1,2\left|\frac{1}{\sqrt{1+\beta}}\right.\right)+(\sqrt{1+\beta}+1)\zeta\left(1,2\left|\frac{-1}{\sqrt{1+\beta}}\right.\right)}{2+(\sqrt{1+\beta}-1)\ln\left(1-\frac{1}{\sqrt{1+\beta}}\right)-(\sqrt{1+\beta}+1)\ln\left(1+\frac{1}{\sqrt{1+\beta}}\right)}. \quad (26)$$

Table 1 shows calculated values of temperatures on the axis for these approximations. It can be seen from the table that the different approximations give temperature values on the axis which are about the same: The table shows that the similarities hold approximately.

Temperature and electron density in the positive column of a medium-pressure helium discharge.

Yu. M. Kagan and K. K. Paskalev

A. A. Zhdanov Leningrad State University

(Submitted July 23, 1973)
Zh. Tekh. Fiz. 44, 2588-2591 (December 1974)

We have calculated the electron temperature in the positive column of a discharge in helium at medium pressures taking account of inelastic losses; electron density on the axis is also determined.

It is conventional to assume that in the medium pressure region in helium electrons lose energy by elastic collisions with atoms. This leads to the relation

$$kT_e^0 = \frac{1}{3}\frac{M}{m^2}\left(\frac{eET}{p\nu_0}\right)^2, \tag{1}$$

where E is the field; T is the gas temperature; p is the pressure in the hot tube; ν is the collision frequency (independent of the velocity for helium), $\nu = \nu_0 (p/T)$; $\nu_0 = 6.3 \cdot 10^{11}$.

In the derivation of Eq. (1), the energy distribution of slow electrons is assumed to be a Maxwellian, as is valid for helium.

Table 1 compares the electron temperatures measured on the axis in a tube of radius R = 2.8 cm, by the method described in ref. 1, with temperatures calculated from Eq. (1). It can be seen that there is a divergence, particularly for small pressures and large currents. This divergence is associated with the fact that the values of E/p for helium are large and one should analyze the effect of inelastic losses. In the general case, with the electron thermal conductivity neglected, the electron energy balance has the form

$$eb_e E^2 - 2\frac{m}{M}\langle\nu\varepsilon\rangle - \frac{\alpha}{n} eV_1 = 0, \tag{2}$$

where b_e is the electron mobility; α is the total number of inelastic collisions; V_1 is the excitation potential of the first excited level; and n is the electron density.

For helium we have

$$2\frac{m}{M}\langle\nu\varepsilon\rangle = 3\frac{m}{M}kT_e\nu.$$

Introducing the notation $T^* = eV_1/k$, we obtain

$$T_e = T_e^0 - \frac{\alpha}{3\frac{m}{M}\nu n}T^*. \tag{3}$$

We take the expression for α from ref. 2

$$\alpha = \frac{4}{\sqrt{\pi}} n\nu_{ee}\left(1 + \gamma_2 u_1^{5/2}\right) e^{-\eta(u_1)}, \tag{4}$$

where

$$u_1 = \frac{eV_1}{kT_e} = \frac{T^*}{T_e},\quad \gamma_2 = \frac{m}{M}\frac{\nu}{\nu_{ee}},$$

and ν_{ee} is the frequency of electron–electron collisions,

$$\nu_{ee} = \frac{4\pi e^4 n}{m^2\left(\frac{2kT_e}{m}\right)^{3/2}}\ln\Lambda = \nu_{ee}^0\frac{n}{T_e^{3/2}},$$

$$\eta(u_1) = \int_0^{u_1}\frac{1 + \gamma_2 u^{5/2}}{1 + \gamma_2 u^{5/2}}\,du,\quad \gamma_1 = \frac{1}{6}\left[\frac{eE\lambda(T_e)}{kT_e}\right]^2\frac{\nu}{\nu_{ee}}.$$

We introduce the notation

$$\gamma_0 = \frac{m}{M}\frac{\nu_0}{\nu_{ee}^0},\quad x = \frac{nT}{p},\quad x_0 = \gamma_0 (T^*)^{5/2}.$$

The integral $\eta(u_1)$ becomes

$$\eta(u_1) = \frac{T^*}{T_e^0}\left\{1 + \frac{2}{3}\frac{x}{x_0}\left(1 - \frac{T_e}{T_e^0}\right)F(A)\right\}, \tag{5}$$

$$F(A) = -A\left\{\frac{1}{2}\ln\frac{(1+A)^2}{1+A^2A} - \sqrt{3}\,\mathrm{arc\,tg}\,\frac{2A-1}{\sqrt{3}} + \sqrt{3}\,\mathrm{arc\,tg}\,\frac{1}{\sqrt{3}}\right\}, \tag{6}$$

$$A = \left(\frac{x}{x_0}\frac{T^*}{T_e^0}\right)^{-1/3}. \tag{7}$$

Finally, we obtain

$$\left(\frac{\alpha}{3\frac{m}{M}\nu n_e} = \frac{1}{3\sqrt{\pi}}\frac{T^*}{T_e}\right)^{2/3}\left(1 + \frac{x}{x_0}\right)e^{-\eta(u_1)} \equiv \Phi(x, T_e^0, T_e), \tag{8}$$

TABLE 1. Values of Electron Temperature, Calculated without (T_e^0) and with (T_e). Allowing for Inelastic Loss and as Determined from Continuum Measurements

i/R	Method of temp. determ.	pR: 10	15	20	40	60	80

	Current	13	12	19	16	13	20	10	25

and Eq. (2) takes the form

$$T_e^0 - T_e = \Phi(x, T_e^0, T_e)\, T^*. \tag{9}$$

Equation (9) can be used to calculate the electron temperature T_e. Here, x and T_e^0 play the role of parameters which are determined by the values of E, T, p, and n. The quantities E and p can be measured, and the values of T can be calculated by methods described in ref. 3. The different approximations give values of T which are close. To calculate the density on the axis we can use Eq. (19) of ref. 3:

$$i = B \int_0^1 n(x)\, T(x)\, x\, dx,$$

$$B = 2\pi \frac{e^2}{m v_0} \frac{E}{p} R^2. \tag{10}$$

The approximations given there for the functions n(x) and T(x) are not sufficiently accurate for the case of large currents, when there is quite a steep fall in the continuum intensity. Therefore, we adopt a more accurate approximation for the continuum intensity:

$$\frac{\varepsilon(x)}{\varepsilon(0)} = (1 - x^2)\, e^{-\alpha' x^2}, \tag{11}$$

where the parameter α' is chosen in each specific case.

For T(x) we use the approximation given in ref. 3,

$$T(x) = (T_0 - T_R)\,[1 - x^2 + \beta], \tag{12}$$

where

$$\beta = \frac{T_R}{T_0 - T_R}.$$

By means of these approximations and a relation connecting the behavior of the derivative of n(x)T(x) and that of the continuum (ref. 3)

$$n(x)\, T(x) = n_0 T_0^2 \frac{\frac{\varepsilon(x)}{\varepsilon_0}}{T(x)}$$

we finally obtain an expression for the reduced electron density on the axis:

$$\tilde{n}_0 R = 7.1 \frac{\frac{i}{R}}{\frac{E}{p} T_0 \varphi(\alpha', \beta)}, \tag{13}$$

where $\tilde{n}_0 = n_0 \cdot 10^{-11}$, i/R is in mA/cm, E/p is in cm·torr.

For $\varphi(\alpha', \beta)$ we have

$$\varphi(\alpha', \beta) = (1 + \beta)\left\{\frac{1 - e^{-\alpha'}}{\alpha'} - \beta e^{-\alpha'(1+\beta)}\,[E_i(\alpha'(1 + \beta)) - E_i(\alpha', \beta)]\right\}. \tag{14}$$

By means of Eq. (11) we can perform the calculation for all pressures with i/R = 100 and 200. For the values i/R = 25 and 50 we use Eq. (15) of ref. 3.

The results of the calculation are shown in Table 2. Table 2 also shows results of measurements of electron density on the axis, measured by the continuum method described in ref. 1. The agreement is satisfactory.

Using the values of n_0 obtained, and Eq. (9), we can calculate the electron temperature T_e on the axis, allowing for inelastic collisions. For values of pR equal to 10 and 15, we insert the electron density measured in the continuum into Eq. (9) [Eq. (1) of ref. 3].

The calculated values of T_e, allowing for inelastic losses, are given in Table 1. It can be seen that in many cases they do not differ appreciably from the values of T_e^0, and are close to the experimental values.

Direct current in a metal–selenium–metal structure bounded by an rf plasma

A. D. Andreev and S. I. Lubinskii

V. I. Lenin Belorussian State University, Minsk

(Submitted July 6, 1973; resubmitted January 30, 1974)
Zh. Tekh. Fiz., 44, 2591-2594 (December 1974)

The direct component of the current which arises in an Al–Se–Al structure under the influence of the plasma of an rf gas discharge has been measured. This current appears because of rectification at the plasma–selenium contact and because of the penetration of plasma electrons into the selenium film due to the field near the contact and thermal diffusion. The current increases with increasing density of the charged particles in the plasma. The influence of the potential of the control grid on the induced current has been studied.

We report here a study of the direct component of the electric current which arises in a metal–selenium–metal structure subjected to an rf plasma. In contrast with the case of a rectifying circuit using a gas-discharge gap between the working electrodes,[1] the plate of amorphous selenium (on which a metal electrode has been deposited) is in immediate contact with the plasma and is at a floating potential, which is governed by the power supplied to the plasma and the density and temperature of the charged particles in the plasma. In this arrangement it is possible to use a control grid[2] mounted in the discharge region near the surface of the film in order to study the contact layer.

Figure 1 shows the apparatus. An rf discharge is excited in chamber 6, made of molybdenum glass, 150 × 30 mm in size, and subjected to continuous evacuation. The air pressure in the chamber is adjusted by a needle inleakage value to a value of 0.02-10 torr. Metal grid 4, mounted near the Se film, ~ 1 mm from the surface of this film, reduces the effective contact area with the plasma. The film of amorphous selenium 2, having a thickness of ~ 60 μ and a dark resistivity of up to 10^{11} $\Omega \cdot$cm, is deposited by evaporation in vacuum on an aluminum substrate 1, previously coated with bismuth. On top of this selenium film is an aluminum electrode 3, a band 0.8 cm^2 in area, deposited by thermal evaporation in vacuum at a pressure of $5 \cdot 10^{-5}$ torr. The contact area between the rf plasma and the surface of the selenium film is $3 \cdot 10^{-4}$ m^2. Outer electrodes 8 are connected to the output terminals of an oscillator. The oscillator, which operates with pulsed excitation and has a resonant frequency of 400 kHz, uses a GMI-83 vacuum tube. The plate circuit of the oscillator consists of a coil itself consisting of 470 turns of wire 0.7 mm in diameter, mounted tightly on a textolite mount 70 mm in diameter. When the tube of the oscillator is triggered by a positive rectangular pulse rising at a rate of $5 \cdot 10^9$ V/sec, oscillations are excited in the circuit; they decay to 0.1 of their initial amplitude over $5 \cdot 10^{-5}$ sec. The trigger pulses are fed to the control grid of the tube of the oscillator from a pulsed amplifier using a GU-29 tube.[3]

The density and temperature of the charged particles in the plasma are measured with a double electrical probe consisting of two molybdenum wires 5, 0.5 mm in diameter, soldered to the chamber wall. A part of the probes, equal to 12 mm, extends into the plasma; the two wires are 12 mm apart. To suppress the rf interference, the probes are shorted by an 82 pF capacitor (chosen empirically), and each is connected to the measuring circuit through a single-layer coil having an inductance of 50 μH, wound on a cardboard frame. The density is determined on the basis of the average mass of the primary components of air through measurement of the voltage–current characteristics.[3] Table 1 shows the electron temperatures and densities corresponding to various amplitudes of the applied voltage and various pressures in the discharge chamber.

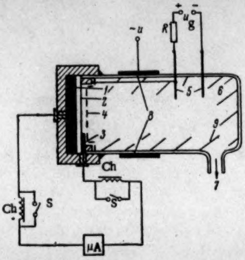

Fig. 1. The experimental apparatus. 1) Aluminum substrate; 2) film of amorphous selenium; 3) measuring electrode; 4) metal grid; 5) probes; 6) gas-discharge chamber; 7) pump; 8) metal electrodes for exciting the plasma; 9) plasma; R) limiting resistance (15 kΩ).

The capacitive method used here to excite the plasma cannot produce a charged-particle density and emission homogeneous throughout the volume in the specified pressure range. As a rule the emission is brighter and the plasma is denser near the electrodes connected to the measuring instruments, particularly at relatively high pressures or in places where the capacitive coupling with the mass is most pronounced. The scatter in the values of the electron temperature could be due to an instability of this type.

Figure 2 shows the induced voltage and the current flowing in the closed circuit of electrodes 1 and 3 (Fig. 1) as functions of the pressure in the chamber for various amplitudes of the rf voltage used to excite the plasma. We see from this figure that the current and voltage increase with increasing pressure and with increasing rf voltage. For the first 10-15 sec after the switch is closed the current in the circuit decays; then it reaches a steady value. The current decay could be due to the capture of charge

carriers at traps in the semiconducting film.[4]

The sample is positioned with respect to the chamber in such a manner that it is at a floating potential, which arises because of the influence of only the part of the rf voltage due to the additional capacitive coupling of the oscillator output and the mass through the plasma and the substrate. Since the plasma–selenium–aluminum combination is a rectifying system,[5] a constant voltage component appears across the selenium film. Since the mobility of the plasma electrons is much higher than that of the ions, and the total current to the surface of the film must vanish over a cycle, we conclude that this surface becomes negatively charged.

This negative charge is a reservoir which can furnish electrons to the interior of the semiconducting film. During thermal diffusion, and under the influence of the alternating electric field, there can be a redistribution of the electron density from the surface to the substrate. The positive plasma ions, which have a higher mass and a lower penetrating ability than do the electrons, are retained at the surface. At a given power of the rf field, which is fed partially into the substrate, a potential difference is maintained between the substrate and the surface of the semiconductor. This potential difference produces a current in the closed circuit of electrode 3; the current consists of this current and the current component due to the rectification at the plasma–selenium junction. When the selenium surface is separated from the plasma by a transparent dielectric film and a grounded grid 4, there is no current in the circuit, and there is no voltage on electrodes 3 and 1.

Figure 3 shows the current and voltage arising in the metal–selenium–metal structure as a function of the voltage applied to metal grid 4. We see from this figure that the current and voltage both increase as the positive bias on this grid is increased in magnitude. As the positive bias on this grid is increased, plasma electrons are attracted to this grid, and an increasing number of these electrons penetrate into the selenium, increasing the induced current and voltage. As a negative bias on this grid is increased, a field is produced in the contact region which prevents electrons from reaching the selenium, and only some of the fast electrons turn out to be capable of penetrating into the film; an increasing number of ions strike the grid, and the ion component of the current increases. The voltage changes correlate with the current changes. The more rapid decay of curve 2 can be attributed to a weakening of the rectifying effect of the plasma–selenium junction as the grid is made negative. Measurements of the voltage–current characteristics show that there is essentially no rectification when the grid is held at −100 V.

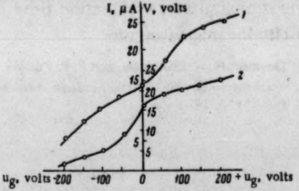

Fig. 3. Induced current (1) and voltage (2) as functions of the grid voltage.

On the basis of these experimental results and their qualitative analysis we can assume that the constant voltage and the direct component of the electric current which arise in the closed circuit containing the contact between an amorphous selenium film and an rf plasma can be due partially to the penetration of electrons into the selenium as a result of their thermal motion and under the influence of the alternating electric field; they can also be due partially to the rectification at the plasma–selenium contact. It can be suggested that in rf deposition during the film growth the impurity ions present in the film collect either at the surface of the film or at the substrate under the influence of the voltage, and the injected plasma electrons are either captured by neutral centers, producing a negative space charge, or neutralized positively charged centers, reducing their density in the film.

Measurement of transverse relaxation time T_2 of optically oriented He^4 with an oscillator magnetometer

N. A. Dovator, R. A. Zhitnikov, and P. P. Kuleshov

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted April 3, 1974)
Zh. Tekh. Fiz., 44, 2594-2595 (December 1974)

The dependence of the frequency of a self-excited oscillator magnetometer on the phase shift in the feedback loop is used to measure the transverse relaxation time T_2 of optically oriented He^4 atoms and to investigate the phase characteristics of the absorption chamber. The measured value of T_2 extrapolated to zero intensity of the pumping light is 0.2 msec for an absorption chamber at 0.2 torr. The frequency dependence of the absorption-chamber phase shift is given.

A method for measuring the transverse relaxation time of optically oriented atoms has been described by Kubo,[1] who has also investigated the phase characteristics of the absorption chamber directly in a cesium-oscillator magnetometer arrangement.

In the present paper a similar method is used to investigate the phase characteristics and to measure the transverse relaxation time T_2 of metastable He^4 atoms in a helium oscillator magnetometer apparatus.

The oscillation frequency ω is given by the equation[2]

$$\varphi(\omega) + \operatorname{arc\,ctg} \Delta\omega S_2 = 0, \qquad (1)$$

where $\varphi(\omega)$ is the phase–frequency characteristic of the feedback loop, $\Delta\omega = \omega - \omega_0$ is the deviation of the oscillation frequency from the Larmor frequency, $1/S_2 = 1/T_2 + 1/T_p$ is the effective transverse relaxation rate ($1/T_p$ is the optical pumping rate, which is proportional to the intensity I).

The phase–frequency characteristic of the feedback loop of the magnetometer can be represented as a linear function of frequency when the deviation of the oscillation frequency from the Larmor frequency lies within the width of the absorption line:

$$\varphi(\omega) = -90^\circ - k\Delta\omega + \Delta\Phi, \qquad (2)$$

where k is the slope of the phase–frequency characteristic of the feedback loop ($k > 0$); and $\Delta\Phi$ is an additional phase shift in the feedback circuit.

Inserting (2) into (1) gives

$$\operatorname{arc\,ctg} \Delta\omega S_2 = 90^\circ - \Delta\Phi + k\Delta\omega, \qquad (3)$$

$$S_2 = \frac{\operatorname{tg}(\Delta\Phi - k\Delta\omega)}{\Delta\omega}. \qquad (4)$$

The coefficient k is usually known, so that by prescribing $\Delta\Phi$ and measuring the frequency deviation $\Delta\omega$ it is possible to calculate S_2. Extrapolating $1/S_2$ to zero intensity gives the inverse relaxation time $1/T_2$.

The phase shift is tuned to a value corresponding to the center of the magnetic resonance line through the minimum of the S_z signal in an oscillator helium magnetometer with automatic phase lock with a sampling servo system.[3] A calibrated SLPZ-0.5 μsec delay line is used for the tuning and for the introduction of a prescribed phase shift. The phase modulation is switched off after tuning to the center of the magnetic resonance line in order to eliminate modulation broadening of the absorption line. A digital frequency meter is used to measure the deviation of the oscillation frequency as a function of the additional phase shift $\Delta\Phi$. The total error in S_2 measured in this manner is 6%.

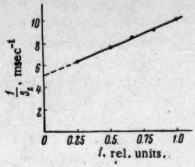

Fig. 1. Plot of $1/S_2$ vs light intensity I.

The absorption chamber of the helium magnetometer consists of a cylinder of diameter 50 mm and length 70 mm filled with spectrally pure He^4 at a pressure of 0.2 torr. The intensity of the discharge in the chamber corresponds to 40% absorption of the pumping light ($\Delta I/I = 40\%$).

Figure 1 shows a plot of $1/S_2$ measured for various intensities of the pumping light. Extrapolation of $1/S_2$ to zero light intensity gives the transverse relaxation time T_2. For the given conditions the value obtained is 0.2 msec, which coincides with the value of T_2 obtained by measuring the linewidth of the S_x signal with subsequent extrapolation to zero light intensity and resonance magnetic field amplitude.

In the determination of T_2 allowance must be made for the effect of inhomogeneity of the magnetic field in the volume of the absorption chamber. In our case this inhomogeneity is 12 γ/cm. An estimate made using Cagnac's formulas[4] shows that the effect is negligible here.

It can be seen from Eq. (3) that the method described above can also be used to measure the phase characteristic of the absorption chamber. This characteristic is shown in Fig. 2 for a chamber with a pressure P = 0.2 torr at an absorption of the pumping light $\Delta I/I = 40\%$. (I = 1

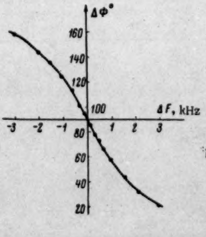

Fig. 2. Phase characteristic of absorption chamber.

in Fig. 1).

Within the limits of measurement error the phase shift of the absorption chamber is observed to be independent of the amplitude of the rf field for increases of the latter such that saturation had still not set in. This agrees with the theory of Bell and Bloom.[5]

Current-convective instability in a three-component plasma

E. Z. Meilikhov

(Submitted April 11, 1974)
Zh. Tekh. Fiz., 44, 2595-2597 (December 1974)

The current-convective instability of a three-component plasma in the positive column of a discharge in a magnetic field is investigated using the semiclassical approximation. Properties related to the existence of two instability modes are noted. The calculations agree qualitatively with experiments in Ne + H_2 gas mixtures.

The Kadomtsev–Nedospasov[1] current-convective instability in a weakly ionized plasma with different ion species has several properties. In the present paper, the qualitative theory of this instability is considered and is used to analyze recent experimental results.[2]

The dispersion relation for the current-convective instability in a gas-discharge plasma with two ion species is obtained in the semiclassical approximation. Expressions for the perturbation of the ion and electron densities n'_1, n'_2, and n'_e are easily obtained (see ref. 3 for example) from the equations of motion. Assuming the electrons to be magnetized by an external magnetic field H_{0z} and nonmagnetized ions, we obtain

$$n'_{1,2} = -\varphi' n_{1,2} \frac{k^2 - i\varkappa k_x}{-\frac{i\omega}{\mu_{1,2}} + k^2 \frac{k_0 T_{1,2}}{e} + i\,(k_z E_{0z} + k_x E_{0x})}, \tag{1}$$

$$n'_e = \varphi' n_e \frac{\frac{k_z^2 + k_\perp^2}{\gamma_e^2} + \frac{i\varkappa k_y}{\gamma_e}}{-\frac{i\omega}{\mu_e} + \frac{k_0 T_e}{e}\left(\frac{k_z^2 + k_\perp^2}{\gamma_e^2}\right) - i\left(\frac{k_z E_{0z} - k_y E_{0x}}{\gamma_e}\right)}. \tag{2}$$

Here, φ' is the perturbation of the potential $n_{1,2,e}$, are the densities of ions of the first and second species and of electrons, respectively ($n_e = n_1 + n_2$); $\mu_{1,2,e}$ are their mobilities; ω and k are the frequency and wave vector; T_e and $T_{1,2}$ are the change temperatures; $\gamma_{1,2,e} = (1/c)\cdot\mu_{1,2,e} H_{0z}$ are parameters characterizing the degree of charge magnetization ($\gamma_e \gg 1$, $\gamma_{1,2} \ll 1$); $\varkappa = \nabla_x n_{1,2,e}$ is the parameter in the semiclassical approximation and characterizes the transverse inhomogeneity of the plasma density (or order $\varkappa \sim 1/a$, where a is the transverse dimension of the plasma column); k_0 is the Boltzmann constant; and E_{0z} and E_{0x} are, respectively, the longitudinal electric field and the transverse ambipolar field, which can be written

$$E_{0x} = -\frac{k_0 T_e}{e} \varkappa \frac{\frac{n_e \mu_e}{\gamma_e^2} - \frac{n_1 \mu_1 T_1}{T_e} - \frac{n_2 \mu_2 T_2}{T_e}}{\frac{n_e \mu_e}{\gamma_e^2} + n_1 \mu_1 + n_2 \mu_2}. \tag{3}$$

The dispersion relation is obtained assuming neutrality $n'_e = n'_1 + n'_2$ by substituting (3) into (1) and (2) and assuming the usually well-satisfied conditions $T_{1,2} \ll T_e$, $k_\perp^2 \gg k_z^2 \gamma_e^2$ (or $L^2 \gg \gamma_e^2 a^2$, where L is the length of the plasma column). We then obtain

$$\begin{aligned} n_1 &\left(\frac{\omega}{\mu_2} + \frac{k_0 T_e}{e} k_x \varkappa - k_z E_{0z}\right)\left[\left(\frac{\omega}{\mu_1} + \frac{k_0 T_e}{e} k_x \varkappa\right)\left(\frac{k_x \varkappa}{\gamma_e} - i\frac{k_\perp^2}{\gamma_e^2}\right)\right. \\ &\quad - \left(\frac{\omega}{\mu_e} + k_z E_{0z} - \frac{k_0 T_e}{e}\frac{k_x \varkappa}{\gamma_e}\right) \\ &\left.\times (k_x \varkappa - ik^2)\right] + n_2\left(\frac{\omega}{\mu_1} + \frac{k_0 T_e}{e} k_x \varkappa - k_z E_{0z}\right)\left[\left(\frac{\omega}{\mu_2} + \frac{k_0 T_e}{e} k_x \varkappa\right)\left(\frac{k_x \varkappa}{\gamma_e} - i\frac{k_\perp^2}{\gamma_e^2}\right)\right. \\ &\quad \left. - \left(\frac{\omega}{\mu_e} + k_z E_{0z} - \frac{k_0 T_e}{e}\frac{k_x \varkappa}{\gamma_e}\right)(k_x \varkappa - ik^2)\right] = 0. \end{aligned} \tag{4}$$

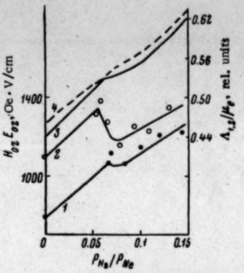

Fig. 1

To determine the threshold values of the frequency and the magnetic field we separate the real and imaginary parts of the dispersion relation (4). Introducing the dimensionless variables

$$\Omega = \frac{\omega}{\mu_e k_x \varkappa \frac{k_0 T_e}{e}}, \quad \Lambda = E_{0z} H_{0z} \frac{k_z \mu_e}{c k_x \varkappa \frac{k_0 T_e}{e}},$$

we obtain

$$\frac{\Omega\,(\gamma_e + \beta_1/\gamma_e) + \Lambda - 1}{\beta_1 \Omega + 1 - \Lambda/\gamma_e} + \alpha \frac{\Omega\,(\gamma_e + \beta_2/\gamma_e) + \Lambda - 1}{\beta_2 \Omega + 1 - \Lambda/\gamma_e} = 0, \tag{5a}$$

$$\frac{\Omega\,(\beta_1 - \gamma_e) - \Lambda + 2}{\beta_1 \Omega + 1 - \Lambda/\gamma_e} + \alpha \frac{\Omega\,(\beta_2 - \gamma_e) - \Lambda + 2}{\beta_2 \Omega + 1 - \Lambda/\gamma_e} = 0, \tag{5b}$$

where $\beta_{1,2} = \mu_e/\mu_{1,2}$; $\alpha = n_2/n_1$. The system of equations (5a) and (5b) has two solutions, which correspond to the two branches of current-convective instability in a plasma with two ion species

$$\Omega_{1,2} \simeq -\frac{1}{\beta_{1,2}}, \quad \Lambda_{1,2} = 1 + \frac{1}{\gamma_e} - \gamma_e \Omega_{1,2} \simeq 1 + \frac{1}{\gamma_e} + \frac{\gamma_e}{\beta_{1,2}}. \tag{6}$$

Since the charge mobilities $\mu_{1,2,e}$ (and thus the values of the parameters γ_e, $\beta_{1,2}$) depend essentially on the composition of the gas mixture (determined by the ratio of the neutral particles of different species), the oscillation frequencies and the values of the threshold field ($\Omega_{1,2}$ and $\Lambda_{1,2}$) also vary when the composition changes. For a certain ratio between the densities of the neutral plasma components, oscillations appear which correspond to one of the oscillation branches, namely, that branch corresponding to the term, either Λ_1 or Λ_2, having the smallest value. For some cases a change in the plasma composition leads to one oscillation branch replacing the other (formally, this means a change from $\Lambda_1 > \Lambda_2$ to $\Lambda_1 < \Lambda_2$, or vice versa) which, in turn, leads to peculiarities in the dependences of the instability frequency and the threshold magnetic field on the plasma composition.

Figure 1 (curves 1 and 2) gives the products of the threshold fields $E_{0z}H_{0z}$ (for the current-convective instability in Ne + H_2 mixtures) obtained from analysis of the experimental data of ref. 2. The partial pressure of Ne is 1) 0.3 and 2) 0.46 mm Hg. Note the features occurring for a certain value of ratio of Ne and H_2 partial pressures: $p_{H_2}/p_{Ne} = 0.06$. Evidently this is the phenomenon, noted above, where one branch replaces the other.

To check this hypothesis we obtain qualitative estimates using (6) and numerical values of charge mobilities in an Ne + H_2 plasma. Using the relation for mobility in a gas mixture:[4] $1/\mu_{1,2,e} = p_{Ne}/\mu_{1,2,e}^{(Ne)} + p_{H_2}/\mu_{1,2,e}^{(H_2)}$ [$\mu_{1,2,e}^{(Ne)}$ and $\mu_{1,2,e}^{(H_2)}$ are, respectively the charge mobilities in Ne and H_2 for a pressure p = 1 mm Hg], we can write the following expressions for γ_e, β_1, β_2:

$$\gamma_e = \frac{1}{c} H_{0z} \frac{\mu_e^{(Ne)}}{1 + \left[\frac{\mu_e^{(Ne)}}{\mu_e^{(H_2)}}\right]\left(\frac{p_{H_2}}{p_{Ne}}\right)}, \tag{7}$$

$$\beta_1 = \frac{\mu_e^{(Ne)}}{\mu_{Ne^+}^{(Ne)}} \frac{1 + \left[\frac{\mu_{Ne^+}^{(Ne)}}{\mu_{Ne^+}^{(H_2)}}\right]\left(\frac{p_{H_2}}{p_{Ne}}\right)}{1 + \left[\frac{\mu_e^{(Ne)}}{\mu_e^{(H_2)}}\right]\left(\frac{p_{H_2}}{p_{Ne}}\right)}, \tag{8}$$

$$\beta_2 = \frac{\mu_e^{(Ne)}}{\mu_{H_2^+}^{(Ne)}} \frac{1 + \left[\frac{\mu_{H_2^+}^{(Ne)}}{\mu_{H_2^+}^{(H_2)}}\right]\left(\frac{p_{H_2}}{p_{Ne}}\right)}{1 + \left[\frac{\mu_e^{(Ne)}}{\mu_e^{(H_2)}}\right]\left(\frac{p_{H_2}}{p_{Ne}}\right)}. \tag{9}$$

Using experimental values of the threshold magnetic field[2] and taking for the mobilities and their ratios:[4] $\mu_e^{(Ne)}/p_{Ne} = 1.2 \cdot 10^6$ cm^2/V · sec · torr, $\mu_e^{(Ne)}/\mu_e^{(H_2)} = 3$, $\mu_e^{(Ne)}/\mu_{Ne^+}^{(Ne)} = 3 \cdot 10^2$, $\mu_e^{(Ne)}/\mu_{H_+^2}^{(Ne)} = 2 \cdot 10^2$, $\mu_{Ne^+}^{(Ne)}/\mu_{Ne}^{H_2} = 1$, $\mu_{H_2^+}^{(Ne)}/\mu_{H_2^+}^{(H_2)} = 10$ we plot from (6)-(9) the curves of the ratio $\Lambda_{1,2}/\mu_e \sim E_{0z}H_{0z}$ vs the gas mixture. This is shown in the figure by curves 3 and 4 for $p_{Ne} = 0.46$ mm Hg, and the solid line is composed of the three parts of curves 3 and 4 corresponding to the smallest value of $E_{0z}H_{0z}$. It can be seen that for $p_{H_2}/p_{Ne} \simeq 0.06$ there is a characteristic point on the solid line corresponding to a change in the oscillation branches. The general nature of this characteristic point is similar to those of the experimental curves 1 and 2. Allowing for the roughness of the computational scheme, we can consider the theory to be in qualitative agreement with experiment.

In conclusion, we note that a detailed explanation of the phenomenon evidently requires that the nonlinear interaction between the two modes be taken into account when their thresholds and frequencies coincide.

The author thanks V. V. Parail for discussion.

The effect of an axial magnetic field on the coupling of the longitudinal modes in a gas laser is investigated experimentally. For magnetic field values at which splitting occurs between the σ components of the gain curve (the gain is equal to the basic separation modes or is a multiple of an odd number of these separations) the laser operates in a stable self-locking type II mode. It is shown that the width of the resonant spontaneous locking region depends on the cavity geometry and the magnitude of the excitation.

The present paper is an investigation of the coupling of the axial modes in a gas laser ($\lambda = 0.63\,\mu$) in a constant axial magnetic field. The magnitude of the coupling essentially determines the different laser operating modes: the free-running mode and the spontaneous locking mode (the pulsed mode). A stable mode must be attained for successful application of lasers to various problems.

Spontaneous locking of modes can be obtained in a gas laser by various methods: placing a modulator inside the optical cavity,[1] scanning by one of the mirrors,[2] choosing a definite operating mode, and spontaneous locking.[3] We will consider stable modes obtained by spontaneous locking of a gas laser.

The effect of a magnetic field on spontaneous mode-locking is noted in refs. 4 and 5. References 6 and 7 reported resonance values of the magnetic field at which dips are observed in the curve of output power vs magnetic field. In ref. 8, variations in the optical spectrum are observed for a resonance magnetic-field value at which the splitting of the σ components of the neon gain profile is equal to the separation between longitudinal modes.

The behavior of a gas laser in a constant magnetic field has been theoretically analyzed in general form in ref. 9. Many papers have considered spontaneous locking of laser modes in zero magnetic field, for example refs. 10 and 11. A rigorous theoretical examination of spontaneous locking of longitudinal modes of a gas laser in an axial magnetic field encounters serious mathematical difficulties. Therefore, an experimental investigation of this mode is of interest.

Tubes with Brewster windows are employed in the experiment. An iris is placed inside the cavity to select the transverse modes. All the results discussed below refer to the basic transverse mode. The intermode beat spectrum is investigated using a C4-5 spectrum analyzer, a wide-band U3-11 amplifier, and an FÉU-36 photomultiplier. The optical spectrum of the output radiation is observed on a Fabry–Perot scanning interferometer with an internal iris. To retune the mode spectrum with respect to the center of the atomic line one of the cavity mirrors is attached to a piezoceramic element. We consider (except for special cases) an He–Ne laser with an optical cavity $L = 1.5^{\mathrm{m}}$ long, a discharge gap $l_1 = 88$ cm, and a tube with an internal diameter $d = 5$ mm which is filled with a natural mixture of neon isotopes at 1.1 mm Hg and located in the center of the cavity. The axial magnetic field is produced by a solenoid $l_2 = 70$ cm in length, with an internal diameter of 8 cm. The investigation of the coupling resonances of longitudinal modes in the magnetic field is carried out by measuring the different parameters of the laser output radiation: intermode beat spectrum, optical mode spectrum, and the constant and variable components of the output radiation. The onset of the spontaneous locking mode is characterized by stabilization of the optical modes, narrowing of the intermode beat spectrum, a substantial decrease in the radiation noise, and the appearance of high-frequency fluctuations.

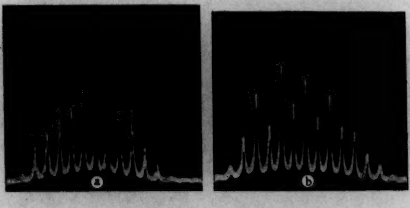

Fig. 1. Laser optical spectra. a) Free-running mode; 2) resonant self-mode-locking.

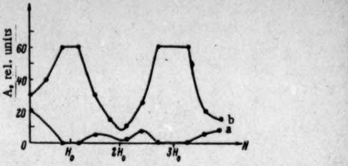

Fig. 2. Amplitude of the components of the intermode beat spectrum vs magnetic field. a) Beats at frequency c/2L; b) at 2c/2L.

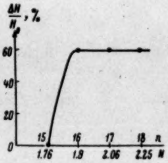

Fig. 3. Width of the resonant self-locking region vs relative excitation. n is the number of excited modes.

Under the experimental conditions the free-running mode of the gas laser is observed with zero magnetic field and maximum pumping. The optical mode amplitudes vary randomly (Fig. 1a), the components of the intermode beat spectrum have a small amplitude (Fig. 2), and strong low-frequency noise is observed in the output radiation. That is, only weak coupling occurs between the modes and they lase independently of each other.

If all the laser parameters remain unchanged, and the axial magnetic field is increased until it reaches the value at which splitting of the σ components of the gain curve is equal to the separation between the longitudinal modes ($H = H_0 = \Delta/2\mu g$, where $\Delta = c/2L$, μ is the Bohr magneton, g is the g factor, and c is the velocity of light), a significant change occurs: The free-running mode is replaced by spontaneous locking. The amplitudes of the modes are stabilized and assume a characteristic form – a regular alternation of modes with small and high amplitudes (Fig. 1b). The component of the intermode beat spectrum at $f_0 = c/2L = 100$ MHz falls off considerably in amplitude (to the noise level of the hf channel), and the component of the spectrum at $f_1 = 2c/2L = 200$ MHz increases greatly (Fig. 2); low-frequency noise is reduced in the output radiation and pulses appear with a repetition frequency $f_1 = 200$ MHz. These features are characteristic of the so-called type-II spontaneous locking.[12] When the modes are detuned with respect to the center of the atomic line, the envelope of the optical spectrum does not change its position and shape (comb), and the modes change their amplitudes smoothly.

Similar phenomena have been observed for magnetic field values $H = (2k + 1)H_0$, where $k = 1, 2, 3 \ldots$ (Fig. 2). No signs of spontaneous locking are observed for H values that are multiples of $2H_0$ when the experimental methods described above are used. Note that dips are formed in the curve of the output power vs magnetic field for all H values that are multiples[6,7] of H_0. The maximum splitting of the σ components of the gain curve at which resonant spontaneous locking is observed is determined by the amount the gain exceeds the losses in the laser – the relative excitation. In our case $H_{max} = 9H_0$.

Spontaneous mode-locking is observed for a range of magnetic fields near $(2k + 1)H_0$. For a given cavity geometry the width of this region depends essentially on the amount by which the gain exceeds the loss. In the experiment the relative excitation is varied by means of the iris or the current in the gas-discharge tube. The width of the spontaneous locking region has a tendency to saturate when the relative excitation is increased (Fig. 3). The maximum width of the region obtained in the experiments is ~ 60% of H_0.

A second factor having a considerable effect on spontaneous locking of longitudinal laser modes in a magnetic field is the cavity geometry, i.e., the dimensions, the ratio of the length of the active medium to the length of the cavity, and the position of the active medium in the cavity. Theoretically, all these parameters are taken into account in the calculation of the Fourier components[9] of the excitation density N_2, N_4, and N_6. The effect of cavity geometry on the width of the spontaneous locking region can be seen more clearly for an equal-isotope composition (50% Ne^{20} and 50% Ne^{22}) and a short tube ($l_1 = 37$ cm). The optimum conditions for obtaining stable resonant spontaneous mode-locking type-II operation are $N_2 = 0$ and $|N_4| = \max$ for $n_4 < 0$.

Obtaining stable spontaneous mode-locking operation of gas lasers in a magnetic field widens the possibilities of using spontaneous locking lasers for practical problems.

Exact solutions of the nonlinear electrodynamic equations

N. G. Puchkova and A. F. Kulish

Kiev Institute of Civil Aviation Engineers

(Submitted January 28, 1974)
Zh. Tekh. Fiz., 44, 2600-2602 (December 1974)

The electrodynamic problem is investigated for the case in which the permeability and permittivity are specified as products of two power functions of the electric and magnetic fields. Two classes of exact solutions characterizing inverse electrodynamic boundary-value problems are found for the nonlinear one-dimensional, nonstationary Maxwell equations.

Two exact solutions have been found for the nonlinear one-dimensional nonstationary system of electrodynamic equations when the permeability and permittivity can be represented as products of two power functions of the electric and magnetic fields. Both solutions make it possible to analyze the inverse boundary-value problems for an inhomogeneous plate with an initial distribution of E_0 and H_0 in the form of specified functions of the coordinate. On one boundary of the plate ($x = 0$) E and H vary as a function of the time according to definite laws. Each solution contains three arbitrary constants, which can be used to approximate the coordinate inhomogeneity for a real plate.

Kolesnikov[1] has investigated the case in which the nonlinear electrodynamic problem can be reduced to a linear problem by an inversion method. One of the present authors[2] has expanded the class of media to which that method is applicable.

Unlike refs. 1 and 2, we assume that the permeability μ and permittivity ε are given or determined experimentally as functions

$$\varepsilon=\varepsilon_0 H^p E^{q-1};\quad \mu=\mu_0 H^{p-1}E^q \tag{1}$$

Here, H and E are the dimensionless magnetic and electric fields, μ_0 and ε_0 are fixed constants of the appropriate dimensions, and p and q are arbitrary numbers.

We write the nonstationary Maxwell equations for the one-dimensional case:[3]

$$\frac{\partial D}{\partial t}=-\frac{\partial H}{\partial x};\ \frac{\partial B}{\partial t}=-\frac{\partial E}{\partial x}. \tag{2}$$

Here, D is the electric induction $D = \varepsilon E$, and B is the magnetic induction $B = \mu H$.

Using Eqs. (1), we find that the system (2) assumes the form

$$\varepsilon_0\frac{\partial}{\partial t}H^pE^q=-\frac{\partial H}{\partial x};\ \mu_0\frac{\partial}{\partial t}H^pE^q=-\frac{\partial E}{\partial x}. \tag{3}$$

Accordingly,

$$\frac{\partial}{\partial t}H^pE^q=-\frac{1}{\varepsilon_0}\frac{\partial H}{\partial x}=-\frac{1}{\mu_0}\frac{\partial E}{\partial x}.$$

Consequently,

$$H=\frac{\varepsilon_0}{\mu_0}E+A(t), \tag{4}$$

where A(t) is an arbitrary integration function.

We therefore replace system (3) by the single equation

$$\left(\frac{\varepsilon_0}{\mu_0}E+A\right)^{p-1}E^{q-1}\left\{\left[(p+q)\frac{\varepsilon_0}{\mu_0}E+qA\right]\frac{\partial E}{\partial t}+pEA'\right\}=-\frac{1}{\mu_0}\frac{\partial E}{\partial x}. \tag{5}$$

We have thus reduced the problem to the solution of the nonlinear first-order partial differential equation (5). As an example we consider the simplest case, in which $p = q = 1$, i.e., the permittivity depends linearly on the magnetic field only, $\varepsilon = \varepsilon_0 H$, and the permeability depends linearly on the electric field, $\mu = \mu_0 E$. In this case Eq. (5) is simplified:

$$\left[\frac{2\varepsilon_0}{\mu_0}E(x,t)+A(t)\right]\frac{\partial E}{\partial t}+A'(t)E(x,t)=-\frac{1}{\mu_0}\frac{\partial E}{\partial x}. \tag{6}$$

We seek a solution of the nonlinear equation (6) in the form

$$E(x,t)=a_0(t)z+a_1(t);\quad (z=x+t). \tag{7}$$

We insert the corresponding deviations from (7) into Eq. (6):

$$\frac{2\varepsilon_0}{\mu_0}a_0a_0'z^2+\left[\left(\frac{2\varepsilon_0}{\mu_0}a_1+A\right)a_0'+\frac{2\varepsilon_0}{\mu_0}(a_0^2+a_0a_1')+a_0A'\right]z$$
$$+\left[\frac{2\varepsilon_0}{\mu_0}(a_1'+a_0)+A'\right]a_1+A(a_1'+a_0)=-\frac{a_0}{\mu_0}.$$

We equate the coefficients of like powers of z. We then obtain the equations

$$\left.\begin{aligned}a_0&=\alpha=\text{const},\\ a_1'+a_0&=-\frac{\mu_0}{2\varepsilon_0}A',\\ \frac{\mu_0}{2\varepsilon_0}AA'&=\frac{a_0}{\mu_0}.\end{aligned}\right\} \tag{8}$$

From the latter we find

$$A=\frac{2}{\mu_0}\sqrt{\alpha\varepsilon_0(t+b)};\quad a_1=-\alpha t-\frac{\mu_0}{2\varepsilon_0}A+a \tag{9}$$

(α, *a*, and b are arbitrary constants of integration).

Equations (4), (7), and (9) allow us to write the following equations, which satisfy (3):

$$\left.\begin{aligned}E&=a+\alpha x-\sqrt{\frac{\alpha}{\varepsilon_0}(t+b)},\\ H&=\frac{\varepsilon_0}{\mu_0}\left[a+\alpha x+\sqrt{\frac{\alpha}{\varepsilon_0}(t+b)}\right].\end{aligned}\right\}$$

These equations characterize the inverse boundary-value problem for an inhomogeneous plate when the electric and magnetic field distributions at the initial time $t = 0$ are given as linear functions of the coordinate x:

$$E_0=a-\sqrt{\frac{\alpha b}{\varepsilon_0}}+\alpha x,$$

$$H_0=\frac{\varepsilon_0}{\mu_0}\left(a+\sqrt{\frac{\alpha b}{\varepsilon_0}}+\alpha x\right)$$

($0 \le x \le l$, where l is the plate thickness). The constants *a*, α, and b are usually known.

On one boundary of the plate (say, $x = 0$) the corresponding fields vary with time according to a special law [Eq. (10) for $x = 0$].

Next we examine the case in which $A(t) = 0$. Equation (5) assumes the form

$$(p+q)\frac{\varepsilon_0^p}{\mu_0^{p-1}}E^{p+q-1}\frac{\partial E}{\partial t}=-\frac{\partial E}{\partial x}. \tag{11}$$

We subject this equation to the separation of variables:

$$E(x, t) = X(x)\,T(t)$$

and obtain the solution

$$T(t) = \left[\frac{p+q-1}{\mu_0(p+q)}\left(\frac{\mu_0}{\varepsilon_0}\right)^p (c_1 - \lambda^2 t)\right]^{\frac{1}{p+q-1}},$$

$$X(x) = \left[-\frac{1}{(p+q-1)(c_2+\lambda^2 x)}\right]^{\frac{1}{p+q-1}}.$$

Consequently,

$$\left.\begin{aligned} E &= \left[\frac{1}{\mu_0(p+q)}\left(\frac{\mu_0}{\varepsilon_0}\right)^p \frac{\lambda^2 t - c_1}{c_2+\lambda^2 x}\right]^{\frac{1}{p+q-1}}, \\ H &= \frac{\varepsilon_0}{\mu_0} E. \end{aligned}\right\} \qquad (12)$$

Here, λ^2 is the separation constant for the variables, and c_1 and c_2 are arbitrary constants of integration.

It is impossible to derive (10) from these equations for $p = q = 1$ in a more specialized case ($A = 0$). This is a feature of the solutions of the nonlinear equations.

Equations (12) can also be interpreted as the solution of the inverse boundary-value problem for an inhomogeneous plate with complex initial distributions of E_0 and H_0 [Eqs. (12) for $t = 0$] and with E and H varying as a function of the time on the boundary $x = 0$. The constants c_1, c_2, and λ can be used to approximate a real inhomogeneity along the coordinate x for a given plate, for example, by analogy with the procedure in gasdynamics[4] (see also Puchkova[5]).

It is readily verified by the direct substitution of (9) and (4) into (12) that these functions satisfy the system of equations (3). The solutions (10) and (12) are not found in the literature. They can be used to check the numerical methods used in nonlinear electrodynamic problems.

Streamer propagation after the voltage termination in a streamer chamber

N. S. Rudenko and V. I. Smetanin

Scientific-Research Institute of Nuclear Physics, Electronics, and Automation, Tomsk

(Submitted June 18, 1973; resubmitted April 5, 1974)
Zh. Tekh. Fiz., 44, 2602-2604 (December 1974)

Streamers are observed to propagate stably in the direction of the electric field after the voltage in a streamer chamber is cut off. An electron-optical method has been used to study the influence of the initial conditions on this "self-propagation" of the streamers.

While working with streamer chambers we have noted a certain discrepancy between the lengths of the streamers observed visually in the streamer chamber and those photographed at corresponding times by means of an electron-optical image converter.[1] In an effort to find the reason for this discrepancy we have studied the processes which occur after the voltage is cut off in the chamber. Figure 1 is a schematic diagram of the experimental apparatus. The operation of the apparatus is described in detail in ref. 2. The apparatus used in the present experiments differs from that described in ref. 2 in that a cutoff switch 4 is installed in an effort to study the processes which occur in the chamber after the voltage is removed from the chamber electrodes. The time at which this switch operates can be accurately adjusted by changing the electrical length of the delay line for the ignition pulse, L_4. Line L_8 is not used in these experiments. The cutoff switch, which operates in a neon atmosphere ($P = 1$–5 atm), provides a stability of ±0.5 nsec in the length of the pulse applied to the chamber over a broad range of pulse lengths. The pulse length (the cutoff time) is chosen so that the streamer stage of the discharge is observed in the chamber at the given electric field.

Using this electron-optics system we photograph the traces in the chamber at various times after the chamber voltage is cut off. The voltage pulse in the chamber displays no oscillations after cutoff because of the damping effect of the resistance of the arc in the neon-filled switch (Fig. 2).

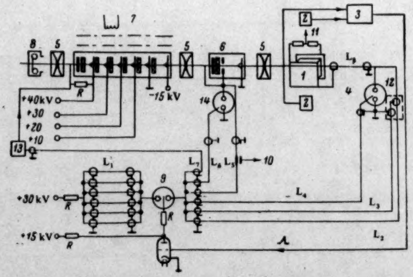

Fig. 1. Schematic diagram of the experimental apparatus. 1) Streamer chamber; 2) scintillators with photomultiplier; 3) coincidence circuit; 4) cutoff switch of the chamber; 5) objective lenses; 6) ZIM-2 high-speed electron-optical shutter; 7) UM-95 light intensifier; 8) camera; 9) switch for the nanosecond-pulse shaper; 10) capacitive voltage divider for observing the exposure pulse; 11) active divider for the voltage on the chamber electrodes; 12) connector; 13) device producing microsecond pulses of +50 kV to supply the fifth stage of the UM-95; 14) cutoff switch of the shutter; L_1) shaping lines; L_2-L_8) transmission lines.

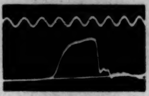

Fig. 2. Voltage pulse across the chamber. The calibration frequency is 100 MHz.

In monitoring the streamer traces in the chamber after the voltage cutoff we observe self-propagation of the streamers: After the voltage cutoff the streamers continue to propagate toward the electrodes of the chamber without any significant expansion for a considerable time, and the shape of the streamers is the same as that shown on the photographs in ref. 2. Figure 3 shows distributions of the average streamer length at various times after the voltage cutoff for an electric field of 14.5 kV/cm. The pulse applied to the chamber is 30 nsec long. The numbers above the peaks in these distributions show the exposure time with respect to the time at which the voltage is applied to the chamber electrodes. The separation of the peaks in Fig. 3 implies that the streamers propagate after the voltage is cut off and that the streamers exist for a considerable time. The streamers continue to propagate at an average velocity ~ $6 \cdot 10^7$ cm/sec. The propagation velocity of the streamers at the end of the development interval is ~ 10^7 cm/sec. After the voltage is cut off and the streamers propagate the average streamer brightness increases to a maximum and then decreases to the sensitivity threshold of the apparatus (Fig. 4). The peaks on the curves in Fig. 4 coincide, within the experimental error, with the end of the streamer-development interval. The distance which the streamers traverse after the voltage cutoff is governed by both the initial electric field in

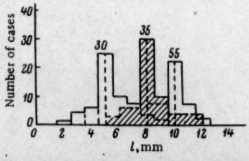

Fig. 3. Distribution of the length of the streamers on the trace at various times.

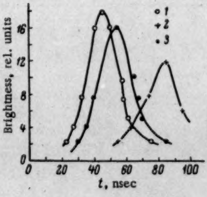

Fig. 4. Change in the brightness of the trace in the chamber after the voltage cutoff. 1) $E_0 = 16$; 2) 8.6; 3) 14.5 kV/cm.

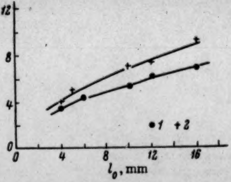

Fig. 5. Self-propagation length of the streamers as a function of the voltage and the initial length. 1) E_0 = 10.4; 2) 16 kV/cm.

the chamber and the length which the streamers acquire before the voltage cutoff (Fig. 5); the effect of the length of the streamers at the cutoff time is much stronger.

We will not discuss these results here, since we have submitted for publication a paper including a detailed discussion of the mechanism for streamer development in neon, including an explanation of the self-propagation of streamers after the voltage cutoff.[1)]

In conclusion we note that this self-propagation of the streamers does not have any significant effect on the working characteristics of streamer chambers,[1] since this effect displaces the streamer-regime working region toward shorter times by only 1-1.5 nsec at fields 10-20 kV/cm.

Electron-optical properties of postdeflection quadrupole lenses

T. Ya. Fishkova

A. F. Ioffe Physicotechnical Institute, Academy of Sciences of the USSR, Leningrad

(Submitted March 29, 1974)
Zh. Tekh. Fiz., 44, 2604-2606 (December 1974)

In an analysis of the electron-optical properties of a quadrupole−octupole lens which receives a previously deflected beam, equations are found for the paraxial trajectory and for the third-order spherical abberation. The aberration coefficients for the deflected beam are expressed in terms of the wide-field geometric-aberration coefficients of the undeflected beam.

Quadrupole lenses are known to be capable of amplifying deflections.[1,2] This property is exploited in several electron-beam devices, in which quadrupole systems replace axisymmetric focusing lenses.[3-5] Certain quadrupole lenses are located beyond deflecting systems, so that the axial trajectory of the beam becomes curvilinear in these systems. It is reasonable that the resolution of the instrument at the edge of the raster will be governed not only by the intrinsic aberrations of the deflecting systems, but also by the aberrations of the postdeflection quadrupole lenses.

Figure 1 shows the trajectory of the charged-particle beam for the case of ideal deflection (in which the deflection angle is the same for all beam trajectories) in the presence of focusing (F) and defocusing (D) postdeflection quadrupole lenses. It is easy to show: first, the vertex angles x'_0 and y'_0 for the deflected and undeflected beams are different; second, the deflected trajectories intersect each other on a line passing through the point determining the position of the real or imaginary image (this point is adopted as the origin, z = 0); third, for small vertex angles (x'_0 and y'_0) and small deflection angles (ξ_0 and φ'_0) the initial conditions at the entrance of the quadrupole lens in the converging (xoz) and diverging (yoz) planes can be written as

$$\left.\begin{aligned} x_{en} &= x_0 + x'_0 a_F + \xi'_0\lambda_F, \quad x'_{en} = x'_0 + \xi'_0, \\ y_{en} &= y_0 + y'_0 a_D + \varphi'_0\lambda_D, \quad y'_{en} = y'_0 + \varphi'_0, \end{aligned}\right\} \tag{1}$$

where x_0 and y_0 are the dimensions of the object in the $z^* = 0$ plane.

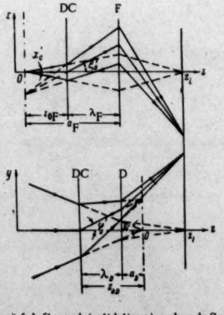

Fig. 1. Trajectories of deflected (solid lines) and undeflected (dashed lines) beams in the converging (xoz) and diverging (yoz) planes of the quadrupole lens. DC) Deflection centers; F and D) principal planes of the lens; O) real or imaginary source; z_i) Gaussian image.

To find the first-order trajectory of the deflected beam in the quadrupole lens we consider (as below) only the converging plane, since we can transform to the diverging plane by simply replacing x by y and y by x (x ⇌ y) and interchanging the deflection angles, $\xi'_0 \rightleftharpoons \varphi'_0$, and the indices F ⇌ D.

We seek a solution of the paraxial equation of the charged-particle trajectory in the quadrupole lens, $x'' + \beta^2 f(z)x = 0$, in the form

$$x_p = x'_0 x_\alpha + x_0 x_\beta + \xi'_0 x_\gamma \tag{2}$$

with the following initial conditions at the entrance to the lens, which satisfy Eq. (1):

$$\left.\begin{aligned} x_\alpha(\text{en}) &= a_F, \quad x_\beta(\text{en}) = 1, \quad x_\gamma(\text{en}) = \lambda_F \\ x'_\alpha(\text{en}) &= 1, \quad x'_\beta(\text{en}) = 0, \quad x'_\gamma(\text{en}) = 1. \end{aligned}\right\} \tag{3}$$

Expressing x_γ in terms of the linearly independent solutions x_α and x_β, we find

$$x_\gamma = x_\alpha + (\lambda_F - a_F)\, x_\beta. \tag{4}$$

For convenience we introduce the quantity z_0 − the distance from the source to the deflection center (Fig. 1). Finally, substituting (4) into (2), we find

$$x_p = (x'_0 + \xi'_0)\, x_\alpha + (x_0 + z_{0_F}\xi'_0)\, x_\beta. \tag{5}$$

To find the third-order aberrations we use successive approximations. It is interesting to consider an octupole lens along with the quadrupole lens; an octupole lens is capable of correcting geometric aberrations.

We substitute the paraxial solution (5) for a point source ($x_0 = y_0 = 0$) into the right-hand side of the equation for the charged-particle trajectory in a quadrupole−octupole lens,[6] taking terms of third order into account. Then we use the familiar equation (see, e.g., ref. 7) for the aberrational divergence in the plane of the Gaussian image, z_i, to find the third-order spherical aberration of a postdeflection quadrupole−octupole lens, Δx_{pd}, in quadrature form.

We write the following relationship between Δx_{pd} and the aberration coefficients:

$$\begin{aligned} \Delta x_{pd} = M_F\,[&(B_1 x'^3_0 + B_2 x'_0 y'^2_0) + A_3 x'^2_0\xi'_0 + A_4 y'^2_0\xi'_0 + A_5 x'_0 y'_0\varphi'_0 \\ &+ A_6 x'_0\xi'^2_0 + A_7 x'_0\varphi'^2_0 + A_8 y'_0\xi'_0\varphi'_0 + A_9\xi'^3_0 + A_{10}\xi'_0\varphi'^2_0]. \end{aligned} \tag{6}$$

The coefficients B_1 and B_2 determine the spherical aberration of the undeflected beam; the coefficients A_3, A_4, . . . , A_{10} determine the additional contribution due to the predeflection.

Comparison of our equations for the coefficients A_j

with the coefficients corresponding to the third-order geometric aberrations of a quadrupole field, B_l, given in ref. 8, with the corresponding modifications due to the octupole lens,[9] gives the relationships among these coefficients:

$$\left.\begin{array}{c} A_3=3B_1+z_{0F}B_3,\quad A_4=B_2+z_{0F}B_4,\quad A_5=2B_2+z_{0D}B_5,\\ A_6=3B_1+2z_{0F}B_3+z_{0F}^2B_6,\quad A_7=B_2+z_{0D}B_5+z_{0D}^2B_7,\\ A_8=2B_2+2z_{0F}B_4+z_{0D}B_5+z_{0F}z_{0D}B_8,\\ A_9=B_1+z_{0F}B_3+z_{0F}^2B_6+z_{0F}^3B_9,\\ A_{10}=B_2+z_{0F}B_4+z_{0D}B_5+z_{0D}^2B_7+z_{0F}z_{0D}B_8+z_{0F}z_{0D}^2B_{10}. \end{array}\right\} \quad (7)$$

Substituting (7) into (6), we find

$$\begin{gathered} \Delta x_{\mathrm{pd}}=M_{\mathrm{F}}[B_1(x_0'+\xi_0')^3+B_2(x_0'+\xi_0')(y_0'+\varphi_0')^2+B_3(z_{0F}\xi_0')(x_0'+\xi_0')^2\\ +B_4(z_{0F}\xi_0')(y_0'+\varphi_0')^2+B_5(z_{0D}\varphi_0')(x_0'+\xi_0')(y_0'+\varphi_0')+B_6(z_{0F}\xi_0')^2(x_0'+\xi_0')\\ +B_7(z_{0D}\varphi_0')^2(x_0'+\xi_0')+B_8(z_{0F}\xi_0')(z_{0D}\varphi_0')(y_0'+\varphi_0')+B_9(z_{0F}\xi_0')^3\\ +B_{10}(z_{0F}\xi_0')(z_{0D}\varphi_0')^2]. \end{gathered} \quad (8)$$

Accordingly, the aberrational divergence caused by the postdeflection quadrupole–octupole lens can be expressed in terms of the wide-field geometric-aberration coefficients.[8,9] The quantities ξ' and φ_0' are associated with the predeflection, while the products $z_{0F}\xi_0'$ and $z_{0D}\varphi_0'$ give the distances from the longitudinal axis to the intersection of the trajectories of the deflected beam in the planes determining the source position.

In the thin-lens approximation the geometric-aberration coefficients are related and are written analytically in terms of the spherical-abberation coefficients.[8,9] Taking this circumstance into account we can simplify (8):

$$\Delta x_{\mathrm{pd}}=M_{\mathrm{F}}\left[B_1\left(x_0'+\frac{\lambda_{\mathrm{F}}}{a_{\mathrm{F}}}\xi_0'\right)^3+B_2\left(x_0'+\frac{\lambda_{\mathrm{F}}}{a_{\mathrm{F}}}\xi_0'\right)\left(y_0'+\frac{\lambda_{\mathrm{D}}}{a_{\mathrm{D}}}\varphi_0'\right)^2\right]. \quad (9)$$

The conditions for correcting the abberations of a postdeflection quadrupole lens by means of an octupole lens are the same as the conditions for correcting the wide-field aberration coefficients.[9] In the thin-lens approximation these conditions reduce to the condition for correcting spherical aberration for an undeflected beam.

Frequency locking in a 3.39μ laser

E. Yu. Andreeva, S. N. Gulyaev, and D. K. Terekhin

M. I. Kalinin Leningrad Polytechnical Institute

(Submitted October 20, 1973)
Zh. Tekh. Fiz., 44, 2607-2609 (December 1974)

An experimental investigation of the synchronization of a laser with linear polarization is described for two cases: 1) the polarization of the laser radiation is linear and orthogonal to the polarization of the input signal, and 2) the laser radiation is circularly polarized. It is shown that the interaction of the radiation with different polarization leads to frequency locking. When the input signal interacts with a laser that exhibits frequency splitting, locking occurs only when the amplitude of the input signal exceeds a certain threshold value.

One of the phenomena which occur in a laser acted upon by an external signal is locking, or synchronization of its frequency when the frequency of the input signal is close to the laser frequency. It follows from theoretical papers[1-3] devoted to this question that in a single-frequency laser the locking band $\Delta\nu_l$ is proportional to the ratio E_{in}/E_c (E_{in} is the amplitude of the input signal, and E_c is the field in the resonator with no input signal). For example, in ref. 3, in the weak-field approximation, the following expression is obtained for the locking band:

$$\Delta\nu_3 = \frac{1}{2\pi}\frac{C\sqrt{T}}{L\sqrt{\varepsilon}}|E_{in}|\sqrt{\frac{\beta}{\alpha}}, \tag{1}$$

where C is the velocity of light, T is the transmittance of the mirrors, L is the length of the active medium, ε is the dielectric constant, and $\sqrt{\beta/\alpha}$, according to ref. 4, defines the value of $1/E_c$. It is assumed that $E_{in} \ll E_c$, and the polarizations of the input and natural radiation are the same. Experimental data for the locking band in a 0.63 μ Brewster laser, obtained in ref. 5, are in qualitative agreement with theory. It is of interest to consider the interaction between two signals with different polarizations, and the possibility of obtaining frequency locking in this case.

In this paper we describe experimental results on the synchronization of the frequency of a laser with linear polarization for two cases.

The experiment is carried out on the 3.39 μ line of neon. A block diagram is shown in Fig. 1. Lasers Nos. 1 and 2 have semiconfocal resonators with mirror transmittances $T_1 = 12$ and $T_2 = 58\%$, and a length L = 30 cm. The spacing between axial modes is 500 MHz. The transverse modes are selected by irises located inside the resonators. The resonator frequency can be scanned using a piezoceramic element. To increase the frequency stability the resonator flanges are tightened with Invar rods, and the arrangement is mounted on a massive plate. The amplifying tubes of lasers Nos. 1 and 2 with lengths $l_1 = 21$ and $l_2 = 10.5$ cm respectively and diameter d = 0.3 cm are sealed with windows perpendicular to their axes. The tube of laser No. 2 is located in a solenoid. The linear polarization of the radiation from laser No. 1 is defined using a quartz plate placed in the resonator at a certain angle. Laser No. 2 generates radiation with circular polarization in an axial magnetic field. In zero field the introduction of the quartz plate into the resonator at a certain angle makes the polarization orthogonal to the polarization of the input signal. Frequency locking of laser No. 2 by the radiation of laser No. 1 is observed as follows: In zero field the axis of the polarizer coincides with the direction of polarization of the characteristic oscillation of the laser. The frequency of resonator No. 2 is scanned, and the frequency of the input signal is maintained constant. On the screen of the oscilloscope we observe the line shape of the emission of laser No. 2 with a dip in the frequency region close to the frequency of the input signal (Fig. 2). The presence of the dip indicates coincidence between the azimuths of the polarizations of the natural radiation and the input signal, i.e., over a certain frequency range "polarization" locking occurs. From the width of this region one can judge the value of the locking band. The frequency interval between the resonator axial modes serves as the reference for determining the locking band. All the measurements are made with the frequency of the input signal tuned to the center of the gain line. Figure 3 shows the relation between the polarization locking band thus obtained $\Delta\nu_{pl}$ and the amplitude of the input signal E_{in} for different levels of the natural emission E_c. The value of the polarization locking range increases linearly with E_{in}. An increase in the level of the natural emission leads to a narrowing of the locking band. The results obtained agree qualitatively with the results given by Eq. (1). This enables us to suggest that the phenomenon of locking with orthogonally polarized modes is subject to the same laws as those considered in ref. 5, in considering the same polarization. A difference can occur in the region of low input signals, where more detailed investigations are required, particularly for a different value of the resonator anisotropy.

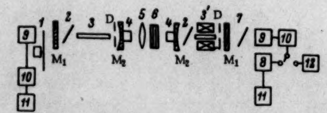

Fig. 1. Block diagram of the experimental arrangement. 1) Mechanical chopper; 2) quartz plate; 3) laser No. 1; 3') laser No. 2; 4) piezoceramic; 5) matching quartz lens; 6) optical wedge; 7) polarizer; 8) detecting circuit; 9) photoreceiver; 10) amplifier; 11) oscilloscope; 12) S4-8 spectrum analyzer; M$_1$ and M$_2$ are mirrors, and D is a diaphragm.

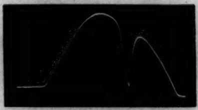

Fig. 2. Oscillogram of the emission line shape when an external signal is present.

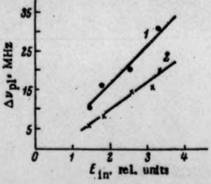

Fig. 3. Width of the polarization locking band as a function of the amplitude of the input signal $\Delta\nu_{pl}(E_{in})$. 1) $E_c = 5.8$; 2) $E_c = 8.6$ relative units.

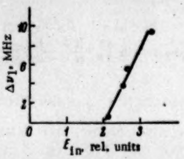

Fig. 4. Locking bandwidth as a function of the amplitude of the input signal when linearly and circularly polarized radiation interacts. $\Omega = 1.3$ MHz, $E_c = 15$ relative units.

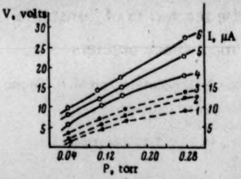

Fig. 5. Maximum splitting as a function of the amplitude of the input signal and the field of the natural oscillations. 1) $\Omega_M(E_{in})$, $E_c = 8.2$ relative units; 2) $\Omega_M(E_c)$, $E_{in} = 3.3$ relative units.

It should be noted that in this experiment the anisotropy of the resonator, set by the quartz plate, is fairly weak (the radiation is circularly polarized in a field H ~ 2 Oe). No polarization locking is observed for a tube with Brewster windows.

We will now consider the interaction between linearly and circularly polarized radiation. When an axial magnetic field is switched on, two circular frequencies appear in the radiation of laser No. 2, corresponding to σ^+ and σ^- polarization modes. The signal, proportional to the amplitude of the low-frequency beat between them, can be separated using a detection circuit placed in the photoreceiver circuit. The value of the splitting of the σ modes Ω is found from the beat frequency using an S4-8 spectrum analyzer. When scanning the frequency of resonator No. 2, one obtains on the screen of the oscilloscope the dependence of the beat amplitude on the detuning, similar to that shown in Fig. 2. The dip in the beat signal envelope is due to frequency locking in laser No. 2. The frequency locking is also recorded on the screen of the spectrum analyzer from the disappearance of the low-frequency beats.

The disappearance of the beat signal between the σ modes of laser No. 2 indicates that over a certain frequency range locking occurs between two circularly polarized oscillations and linearly polarization radiation. In this case the locking band should depend not only on the ratio E_{in}/E_c, but also on the frequency splitting between the σ modes Ω. The maximum splitting Ω_M for which locking occurs will be determined by the levels of E_{in} and E_c. Figure 4 shows $\Delta\nu_l$ as a function of E_{in} for constant Ω. The width of the locking band increases linearly as the amplitude of the input signal E_{in} increases, as in the theory of the interaction of two oscillations. The pronounced threshold of the dependence of $\Delta\nu_l$ on E_{in} is due to frequency splitting of the field E_c. Figure 5 shows the threshold characteristics of $\Omega_M(E_c)$ for E_{in} = const, and $\Omega_M(E_{in})$ for E_c = const. As can be seen from this figure Ω_M is proportional to the amplitude of the input signal and inversely proportional to the amplitude of the field of the natural oscillations. These relations can be written in the following approximate form:

$$\Delta\nu_1 \sim A\frac{E_{in}}{E_c} - B(\Omega). \tag{2}$$

The thereshold conditions correspond to the case $\Delta\nu_l \to 0$, when there is no locking.

Hence, the experimental results obtained in this investigation show that the interaction between radiation with different polarizations leads to frequency locking. The synchronization band depends linearly on the amplitude of the input signal. When the input signal interacts with radiation which is split in frequency, locking only occurs when E_{in} exceeds a certain threshold value.

The authors thank S. A. Fridrikhov for useful discussions.

Efficiency of the scattering of "unstable" charged particles in quadrupole mass spectrometers

E. P. Sheretov, B. I. Kolotilin, and M. P. Safonov

Ryazan' Radiotechnical Institute

(Submitted July 9, 1973)
Zh. Tekh. Fiz., 44, 2609-2613 (December 1974)

The scattering of "unstable" charged particles in a quadrupole mass spectrometer is discussed. Equations are derived for the rate at which the unstable particles leave the analyzer. The relations are found by the method of characteristic solutions of the Hill equation. The accuracy of the resulting relations and the phase characteristics of the scattering are discussed.

One of the important parameters involved in the design of the selector for quadrupole mass spectrometers is the time required to sort the charged particles. Unfortunately, the literature reveals extremely little on this important parameter of analyzers, which governs the size and sensitivity of the selector.[1-3]

In this work we use characteristic solutions of the Hill equation to derive relations required for calculating the efficiency at which unstable charged particles are scattered.[4,5]

We write the Hill equation as[5]

$$\ddot{R} + R\psi(t) = 0, \tag{1}$$

where $\psi(t)$ is a periodic function of the time with period of π or 2π.

With Eq. (1) we can associate two functions (two characteristic solutions) in the region of unstable solutions:[5]

$$R_{02}(n\pi) = A_3 \operatorname{ch} \beta_{02} n\pi + A_4 \operatorname{sh} \beta_{02} n\pi, \tag{2}$$

$$R_{03}(n\pi) = \cos n\pi \, [A_5 \operatorname{ch} \beta_{03} n\pi + A_6 \operatorname{sh} \beta_{03} n\pi]. \tag{3}$$

Characteristic solutions (2) and (3) agree with the general solution of Eq. (1) at times differing from each other by the period of the function $\psi(t)$ or by a time which is a multiple of this period[5] if the constants A_3, A_4, A_5, and A_6 are chosen correctly. Writing two independent particular solutions of Eq. (1) as[6]

$$R_{11}(t) = e^{\mu t} \sum_{-\infty}^{+\infty} C_{2r} e^{j2rt}; \quad R_{12}(t) - e^{-\mu t} \sum_{-\infty}^{+\infty} C_{2r} e^{-j2rt} \tag{4}$$

or

$$R_{21}(t) = e^{\mu t} \sum_{-\infty}^{+\infty} C_{(2r+1)} e^{j(2r+1)t}; \quad R_{22}(t) = e^{-\mu t} \sum_{-\infty}^{+\infty} C_{(2r+1)} e^{-j(2r+1)t}, \tag{5}$$

and following the procedure of ref. 5, we find

$$\beta_{02} = \mu; \quad \beta_{03} = 2\mu. \tag{6}$$

Let us compare characteristic solutions (2) and (3) with the general solution of Eq. (1) at time t_1. If we adopt the general solution in its standard form,[6] we find, e.g., for Eq. (2),

$$R_{02}(n\pi) = 2(AB)^{1/2} [R_{11}(t_1) R_{12}(t_1)]^{1/2} \times \operatorname{ch}\left[\mu\pi n + \operatorname{Arth} \frac{AR_{11}(t_1) - BR_{12}(t_1)}{AR_{11}(t_1) + BR_{12}(t_1)}\right]. \tag{7}$$

Here, A and B are the constants which appear in the general solution of Eq. (1). Now it is easy to show that the condition that the characteristic solution (7) be of an extremal nature corresponds to the equation

$$[\dot{R}_{11}(t_{10}) R_{12}(t_{10}) + R_{11}(t_{10}) \dot{R}_{12}(t_{10})] + \gamma_0 \operatorname{th}\left[\mu\pi n + \operatorname{Arth} \frac{AR_{11}(t_{10}) - BR_{12}(t_{10})}{AR_{11}(t_{10}) + BR_{12}(t_{10})}\right] = 0. \tag{8}$$

In Eq. (8), the quantity γ_0 is the Wronskian for Eq. (1).

If the working point of the particle under consideration is near the boundary of the region of stability on the stability diagram – the typical situation in the design of quadrupole mass spectrometers – then we have $\gamma_0 \to 0$, and condition (8) simplifies, becoming

$$\dot{R}_{11}(t_{10}) R_{12}(t_{10}) + R_{11}(t_{10}) \dot{R}_{12}(t_{10}) = 0. \tag{9}$$

Using (4) and (5), we can show that in this case

$$t_1 = t_{10} = \pi \quad \text{or} \quad \frac{\pi}{2}. \tag{10}$$

In calculating the extremal characteristic solutions for particles whose working points lie well within the instability region of the stability diagram, we find a refined value for the comparison time t_1:

$$t_1 = t_{10} + \Delta t_1, \tag{11}$$

where, in a first approximation, Δt_1 can be determined from

$$\Delta t_1 = (\pm 1) \frac{\gamma_0}{\left.\frac{d^2}{dt^2} [R_{11}(t) R_{12}(t)]\right|_{t=t_{10}}}. \tag{12}$$

These equations are general in nature. At present, sinusoidal signals are used in most cases to feed the selectors in quadrupole mass spectrometry.[7-9] When the analyzers are fed a sinusoidal signal, the motion of the charged particles in the selector volume is described by a system of Mathieu differential equations, which are a particular case of the Hill equation. Accordingly, we turn now to the application of the relations above to the Mathieu equation. In this case it is more convenient to write the two pairs of independent particular solutions as[6]

$$\left.\begin{aligned} R_{11} &= e^{\mu t} \sum_{-\infty}^{+\infty} [C_{u2r} \cos 2rt + C_{v2r} \sin 2rt], \\ R_{12} &= e^{-\mu t} \sum_{-\infty}^{+\infty} [C_{u2r} \cos 2rt - C_{v2r} \sin 2rt], \end{aligned}\right\} \tag{13}$$

$$\left.\begin{aligned} R_{21} &= e^{\mu t} \sum_{-\infty}^{+\infty} [C_{u(2r+1)} \cos (2r+1) t + C_{v(2r+1)} \sin (2r+1) t], \\ R_{22} &= e^{-\mu t} \sum_{-\infty}^{+\infty} [C_{u(2r+1)} \cos (2r+1) t - C_{v(2r+1)} \sin (2r+1) t]. \end{aligned}\right\} \tag{14}$$

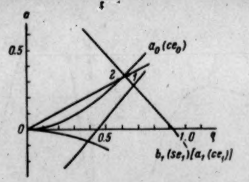

Fig. 1

The first pair of solutions, (13), is more convenient to use in the case in which the working point of the particle lies below the a_0 curve on the stability diagram; the pair in (14) is more convenient if the working point lies above the curve b_1 (se_1) or a_1 (ce_1) (Fig. 1). Now it is easy to show that Eq. (7) can be written as follows for the first pair of solutions, (13):

$$R_{02}(n\pi)=\nu_0\Bigg\{R_0\Bigg[\operatorname{ch}\mu n\pi\sum_{-\infty}^{+\infty}(\mu C_{\alpha 2r}+C_{\nu 2r}2r)\cos 2r\xi + \operatorname{sh}\mu n\pi\sum_{-\infty}^{+\infty}(C_{\alpha 2r}2r-\mu C_{\nu 2r})\sin 2r\xi\Bigg]+\dot{R}_0\Bigg[\operatorname{ch}\mu n\pi\sum_{-\infty}^{+\infty}C_{\nu 2r}\sin 2r\xi + \operatorname{sh}\mu n\pi\sum_{-\infty}^{+\infty}C_{\alpha 2r}\cos 2r\xi\Bigg]\Bigg\}. \tag{15}$$

Here ν_0 can take on two values:

$$\left.\begin{aligned}\nu_{01}&=\frac{\sum\limits_{-\infty}^{+\infty}C_{\alpha 2r}(-1)^r}{\sum\limits_{-\infty}^{+\infty}(\mu C_{\alpha 2r}+C_{\nu 2r}2r)\sum\limits_{-\infty}^{+\infty}C_{\alpha 2r}}\\ &\text{or}\\ \nu_{02}&=\frac{1}{\sum\limits_{-\infty}^{+\infty}(\mu C_{\alpha 2r}+C_{\nu 2r}2r)},\end{aligned}\right\} \tag{16}$$

where ξ is the initial phase of the high-frequency signal, and R_0 and $\dot{R}_0$ are the initial coordinate and velocity of the particle.

In calculating the characteristic solutions from (15) in order to determine the maximum deviation of the particle from the origin for a specified value of n, it is necessary to use (16) to determine the maximum value for ν_0.

For the second pair of particular solutions, (14), it is more convenient to use (3); in this case we find the two characteristic solutions

$$R_{031}(n\pi)=\frac{1}{\sum\limits_{-\infty}^{+\infty}[\mu C_{\alpha(2r+1)}+C_{\nu(2r+1)}(2r+1)]}\times\Bigg\{R_0\Bigg[\operatorname{ch}2\mu\pi n\sum_{-\infty}^{+\infty}[\mu C_{\alpha(2r+1)}+C_{\nu(2r+1)}(2r+1)]\cos(2r+1)\xi + \operatorname{sh}2\mu\pi n\sum_{-\infty}^{+\infty}[C_{\alpha(2r+1)}(2r+1)-\mu C_{\nu(2r+1)}]\sin(2r+1)\xi\Bigg] + \dot{R}_0\Bigg[\operatorname{ch}2\mu\pi n\sum_{-\infty}^{+\infty}C_{\nu(2r+1)}\sin(2r+1)\xi + \operatorname{sh}2\mu\pi n\sum_{-\infty}^{+\infty}C_{\alpha(2r+1)}\cos(2r+1)\xi\Bigg]\Bigg\}, \tag{17}$$

$$R_{032}(n\pi)=\frac{\sum\limits_{-\infty}^{+\infty}C_{\nu(2r+1)}(-1)^r}{\sum\limits_{-\infty}^{+\infty}C_{\alpha(2r+1)}\sum\limits_{-\infty}^{+\infty}[\mu C_{\alpha(2r+1)}+C_{\nu(2r+1)}(2r+1)]}\times\Bigg\{R_0\Bigg[\operatorname{ch}2\mu\pi n\sum_{-\infty}^{+\infty}[C_{\alpha(2r+1)}(2r+1)-\mu C_{\nu(2r+1)}]\sin(2r+1)\xi\Bigg] + \operatorname{sh}2\mu\pi n\sum_{-\infty}^{+\infty}[\mu C_{\alpha(2r+1)}+C_{\nu(2r+1)}(2r+1)]\cos(2r+1)\xi] + \dot{R}_0\Bigg[\operatorname{ch}2\mu\pi n\sum_{-\infty}^{+\infty}C_{\alpha(2r+1)}\cos(2r+1)\xi - \operatorname{sh}2\mu\pi n\sum_{-\infty}^{+\infty}C_{\nu(2r+1)}\sin(2r+1)\xi\Bigg]\Bigg\}. \tag{18}$$

Here, as for R_{02}, we are to choose from (17) and (18) the equation which provides the maximum value of $R_{03}(n\pi)$ for the specified value of n. Figure 2 shows the functional dependences (solid curves) of the r and z coordinates of the particles on the time for the case $a_r = 0.333840$, $q_r = 0.6240$, $R_0 = 1$, $\dot{R}_0 = 0$, $a_z = 0.323038$, $q_z = 0.6000$, $z_0 = 1$, $\dot{z}_0 = 0$, and $\xi = 0$.

The working points of the particles are denoted by 1 and 2, respectively, in Fig. 1. As we see from this figure, these working points lie near the boundaries of the overall stability diagram for a three-dimensional quadrupole mass spectrometer. The dashed curves in Fig. 2 show the corresponding characteristic solutions, calculated from Eqs. (15), (17), and (18). We see from Fig. 2 that there is a good agreement between the extremal excursions of particles from the origin calculated from the characteristic solutions and the actual values.

Figure 3 shows the r and z excursions of unstable particles for a specified value of n as functions of the phase at which the particles enter the high-frequency field, ξ. These functional dependences were calculated from the characteristic solutions given above. Interestingly, these phase functions have a form reminescent of the corresponding functions for the amplitudes of the r and z oscillations of stable particles, given in ref. 5. From this similarity we draw the important conclusion that the maximum sorting time, i.e., the maximum scattering time for the unstable ions, is required when the charged particles enter the selector in a favorable phase (corresponding to the lowest oscillation amplitude of stable particles). For a quadrupole mass filter, e.g., in which there is 100% trans-

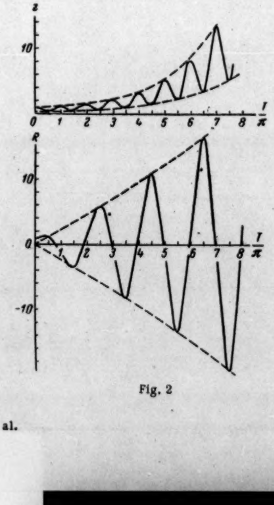

Fig. 2

mission of the ions, this circumstance should lead to the appearance of a functional dependence of the resolution on the time, since the efficiency with which unstable particles entering the selector at a phase of $\pi/4$ are scattered is much higher than that corresponding to a phase of 0 or, especially, $\pi/2$. In this connection we would expect a significant increase in the resolution of a mass filter if we were to modulate the velocity of the ions entering the selector in accordance with the phase of the high-frequency potential fed to the system.

As was mentioned above, the accuracy of Eqs. (15), (17), and (18) is governed by the value of the Wronskian γ_0. As the working point of the particle moves away from the boundary of the stability region the value of δ_0 changes for these particular solutions, and there is a corresponding change in the accuracy of these equations.

As we mentioned above, in calculating the extremal characteristic solutions we can improve the accuracy by refining the comparison time Δt_1. For example, when we use Eqs. (14), we find that Eq. (12) becomes

$$\Delta t_1=(\pm 1)\frac{\sum\limits_{-\infty}^{+\infty} C_{u(2r+1)} \sum\limits_{-\infty}^{+\infty} [\mu C_{u(2r+1)} + C_{v(2r+1)}(2r+1)]}{\sum\limits_{-\infty}^{+\infty} C_{u(2r+1)}(2r+1)^2 \sum\limits_{-\infty}^{+\infty} C_{u(2r+1)} + \sum\limits_{-\infty}^{+\infty} 2C_{v(2r+1)}(2r+1)}$$

or

$$\Delta t_1=(\pm 1)\cdot$$

$$\times\frac{\sum\limits_{-\infty}^{+\infty} C_{u(2r+1)} \sum\limits_{-\infty}^{+\infty} [\mu C_{u(2r+1)} + C_{v(2r+1)}(2r+1)]}{\sum\limits_{-\infty}^{+\infty} C_{v(2r+1)}(-1)^r \sum\limits_{-\infty}^{+\infty} C_{v(2r+1)}(2r+1)^2(-1)^r + \sum\limits_{-\infty}^{+\infty} 2C_{u(2r+1)}(2r+1)(-1)^r}.$$

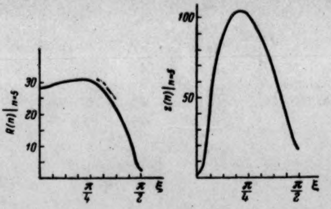

Fig. 3

Our calculations show that it is worthwhile to use these refined equations for Δt_1 only for points lying well within the unstable regions. For regions lying near the boundaries of the stability regions (which are the most important from the standpoint of the design of analyzers having a high resolution) the accuracy provided by Eqs. (15), (17), and (18) is completely adequate.

Reflection of a high-current relativistic electron beam from a conducting surface

A. N. Didenko, A. I. Ryabchikov, V. A. Tuzov, and Yu. P. Usov

Scientific-Research Institute of Nuclear Physics, Electronics, and Automation, Tomsk

(Submitted January 7, 1974; resubmitted April 24, 1974)
Zh. Tekh. Fiz., 44, 2613-2615 (December 1974)

Experiments are reported on the reflection of a high-current beam of relativistic electrons from a conducting surface at an air pressure sufficient for self-focusing of the beam. The reflection occurs with a low loss at a pressure of 0.09 torr and at reflection angles up to 30°. The experiments are carried out at electron energies of 0.6 and 1.0 MeV.

We report here an experimental study of the reflection of a high-current electron beam from a conducting surface at an air pressure sufficient to provide self-focusing of the beam. The experiments are carried out on the Tonus accelerator, which consists of an Arkad'ev–Marx generator with a stored energy of 27 kJ and a maximum output voltage of 2.2 MV, a double shaping line with an output impedance of 24 Ω, and a cold-cathode electron gun.[1]

Figure 1 shows the experimental arrangement. Electron beam 1, from the cathode of the accelerator 2, passes through a titanium foil 3, which is 50 μ thick, and which serves as the anode of the electron gun, into drift chamber 4. The dimensions of this chamber are 500 × 500 × 200 mm. The electron energy is varied from 0.6 to 1.0 MeV in the experiments. At high energies the chamber dimensions are inadequate because the chamber walls affect the reflection. The beam current is measured by Faraday cup 5 with a low-inductance foil shunt having a resistance of $6 \cdot 10^{-3}$ Ω. In the experiments the beam current coming from the accelerator is monitored by reverse-current shunt 6, and the electron energy is monitored by capacitive voltage divider 7. Reflecting plate 8, made of sheet copper 1 mm thick, is mounted on two movable shafts 9, which permit the position of the plate in the drift region to be changed without disrupting the vacuum. The reflecting plate is connected electrically to the drift chamber. In the measurement of the reflected-beam current the Faraday cup is mounted on arc 10, so that the beam reflected from the plate at some angle strikes the cup after traveling a constant distance in the drift chamber (500 mm). The upper wall of the chamber is Plexiglas; its inner side is covered with a metal grid, through which the beam is photographed and monitored by a television system.

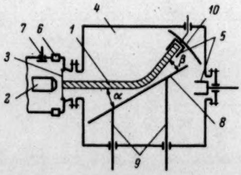

Fig. 1. Experimental arrangement.

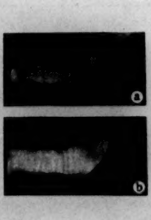

Fig. 2. Air glow as the electron beam passes through the drift chamber near the conducting plate. a) 0.6 MeV, 15 kA, α = 38°, β = 8°; b) 1.0 MeV, 25 kA, α_{cr} = 48°.

	25	50	65	80	95	110
0.09	15	12	10	7.5	5	2.5
1.2	12	10.5	8	5	3.5	1

Figure 2 shows photographs of the beam in the drift chamber. Table 1 shows the angles of incidence α and the corresponding reflection angles β for an air pressure of 0.09 torr, at which we observe the minimum loss in the beam transport. The electron energy is 0.6 MeV, and the current is 15 kA. The functional dependence of β on α shown in Table 1 arises because as the position of the reflecting plate is changed there is a change in the initial distance from the beam axis to the conducting surface along with a change in the angle α. The photograph in ref. 2 of a beam reflected from a conducting surface, with $\alpha \approx \beta$, is the only published experimental result on the reflection of a high-current relativistic electron beam. The angles α and β are equal only for a certain angle of incidence (in our case, α = 15°); in general we have $\alpha \neq \beta$.

Table 2 shows β as a function of the distance between the beam axis and the reflecting plate in the case α = 0°, the distance d. In a time equal to the skin time the beam motion is parallel to the reflecting plate for a distance L without interacting with it. In our experiments, L is varied from 5 to 20 cm. The experimental results show that the interaction of the beam with the conducting surface is weaker than follows from the theoretical model of ref. 3. Measurements of the beam current as a function of the air pressure in the drift chamber show that the current varies only slightly as α is varied from 0 to 30°. Only at α near α_{cr} do we observe a rapid decrease in the current. The critical angle α_{cr}, at which the beam loss occurs

(Fig. 2b), is governed by the air pressure, changing from 40 to 48° as the pressure is reduced from 2 to 0.04 torr. At energies of 0.6 and 1 MeV (Fig. 2, a and b) and at a pressure of 0.09 torr we observe the unusual beam-structure features – bright spikes moving at acute angles with respect to the basic beam – which were first observed in ref. 4 at an electron energy of 300 keV. It should be emphasized that these spikes are not associated with loss of electrons from the beam channel, as in ref. 5. When the beam displays this structure we observe minimum values of the current; this structure is retained at small values of α. Figure 2a shows a photograph of the beam taken in the case in which the spikes disappear upon the reflection of the beam.

These results are important not only in connection with the physics involved, but also in connection with the development of methods for controlling the trajectories of high-current relativistic electron beams in injection, transport, and the shaping of closed configurations without the external electromagnetic fields.

Thermal diffusion in a mixture of cesium vapor and helium

E. S. Bekmukhambetov and V. A. Donov

Institute of Nuclear Physics, Academy of Sciences of the Kazakh SSR, Alma-Ata

(Submitted November 9, 1973)
Zh. Tekh. Fiz., 44, 2615-2617 (December 1974)

The thermal-diffusion ratio in a mixture of cesium vapor and helium has been determined experimentally. It is compared with the value calculated on the basis of the Lennard–Jones model.

Study of thermal diffusion in mixtures of gases with cesium vapor is important for an understanding of transport processes in the cesium thermionic converter. We report on measurements of the thermal diffusion for a mixture of cesium vapor and helium over the temperature range 400-800°K.

Important technical difficulties arise in an experimental determination of the thermal-diffusion ratio k_T or the thermal-diffusion constant α_T in mixtures of gases with cesium vapor when conventional methods are used. Accordingly, we use an atomic-absorption method for these measurements, as discussed in ref. 1.

The lower chamber of the two-chamber apparatus contains metallic cesium; the upper chamber is an optical cell whose volume is much smaller than that of the lower chamber. The change in the concentration of cesium vapor due to thermal diffusion is determined from the change in the optical density. The optical cell is illuminated by the beam from a high-frequency cesium lamp. The measurements are carried out at the cesium line at 455.5 nm by the linear-absorption method.[2]

The idea behind these measurements is as follows: If the temperature maintained in the upper chamber, T_1, is higher than that of the lower chamber, T_2, the cesium vapor becomes distributed in the two chambers according to the ratio $n_1T_1 = n_2T_2$, where n_1 and n_2 are the concentrations of cesium vapor in the upper and lower chambers, respectively. When a foreign gas is admitted into the volume, this ratio changes as a result of thermal diffusion. If, in the absence of this additional component, the concentration of cesium vapor in the optical cell corresponds to an optical density D_0, and if this density changes to D when the foreign gas is admitted, we conclude that the separation in this case is $(1 - \eta)c_1$, where $\eta = D/D_0$ and c_1 is the relative fraction of cesium vapor. Accordingly, knowing the optical density D for a given relative concentration c_1 we can use the equation

$$(1-\eta)\,c_1 = k_T \ln\frac{T_1}{T_2} \qquad (1)$$

to determine the thermal-diffusion ratio k_T for various concentrations of the cesium vapor and the foreign gas.

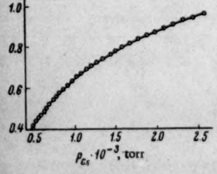

Fig. 1. Optical density as a function of the concentration of cesium vapor.

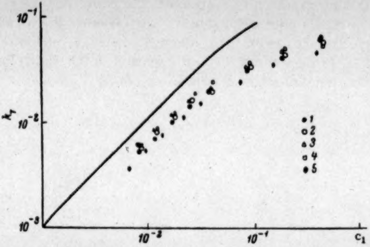

Fig. 2. Thermal-diffusion ratio for a cesium–helium mixture as a function of the relative concentration of cesium vapor. 1) 402-533; 2) 402-596; 3) 401-726; 4) 402-804; 5) 397-873°K.

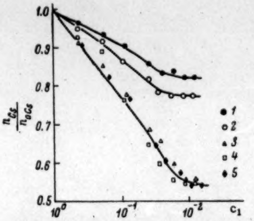

Fig. 3. Relative change in the concentration of cesium vapor due to thermal diffusion as a function of the relative amount of cesium in the mixture. 1) 402-533; 2) 402-596; 3) 401-726; 4) 402-804; 5) 397-873°K.

Equation (1) holds if the optical density of the vapor varies linearly with the concentration. In our measurements, based on the 455.5 nm cesium line, this linearity breaks down, so we use in η the values of the vapor concentrations corresponding to the given optical densities from the experimental functional dependence of D on the concentration n (Fig. 1).

We measure the ratio D/D_0 with added helium for five different temperature gradients. The error in the determination of η is less than 3%. The values of k_T determined from Eq. (1) are shown in Fig. 2 for concentrations $c_1 = 0.4$-0.008.

The curve in this figure is the functional dependence of k_T on the concentration ratio for temperatures 400-1000°K calculated on the basis of the Lennard–Jones model.[3] For these calculations we use[4] the geometric collision parameter $\sigma_{12} = 3.39$ Å and well depth $\varepsilon_{12}/k = 40.8$°K. The calculations show that k_T is a weak function of the temperature, so we have drawn only a single curve. For the temperature range 397-873°K the experimental values of k_T are slightly lower than for narrower temperature ranges. This circumstance should apparently be attributed to an error in the integral form of the equation for the steady state for broad temperature ranges.

Figure 3 shows the relative change in the cesium vapor concentration as a function of its relative concentration in the mixture. We see from this figure that the maximum change in the cesium vapor concentration occurs when there is relatively little of it in the mixture. As the helium concentration is increased, the ratio n^{Gs}/n_{0Gs} tends toward a constant value for each temperature range. A single line is drawn for the ranges 401-726, 402-804, and 387-873°K, since a further increase in the range has essentially no effect on the ratio n_{Gs}/n_{0Gs}.

This measurement procedure gives us a clear idea of the behavior of the cesium vapor concentration in the interelectrode gap of a thermionic converter in the presence of another gaseous component.

Parametric excitation of helicon waves in a plasma by modulated radio frequency waves

V. S. Paverman and D. D. Tskhakaya

Institute of Physics, Academy of Sciences of the Georgian SSR, Tbilisi

(Submitted February 8, 1974)
Zh. Tekh. Fiz., 44, 2617-2620 (December 1974)

The excitation of helicon waves is studied in a magnetoactive plasma in an external weakly modulated high-frequency electric field. The characteristic frequencies of such a system are shown to depend on the amplitude of the external field. Parametric resonance phenomena appear at certain modulation frequencies and the characteristic helicon waves are excited. The growth rate and the threshold amplitude of the external field are determined.

In the present paper we consider helicon waves in a magnetoactive electron plasma in a transverse high-frequency wave with a weakly modulated amplitude. If the carrier frequency of the external wave is much greater than the characteristic frequencies of the plasma, the spectrum of the oscillations depends on the amplitude of the carrier wave. It is well known that the phenomenon of parametric resonance can occur if a parameter characterizing an oscillatory system is varied at a characteristic frequency, and the amplitude of the parametric oscillation increases exponentially. Accordingly, by amplitude modulating the pump wave at an appropriate frequency, it is possible to excite parametrically the natural helicon waves of a magnetoactive plasma.

A similar problem for an isotropic plasma has been considered by Aliev and Zyunder[1] who investigated the parametric excitation of electrostatic waves by a modulated microwave field.

The wavelength of the helicon waves considered in the present paper is assumed to be much smaller than the wavelength of the external wave. The external high-frequency field $E_0(t)$ can thus be represented in the form

$$\mathbf{E}_0(t) = \mathbf{E}_0 \sin \Omega t + \mathbf{E} \sin(\Omega + \Delta\Omega)t + \mathbf{E} \sin(\Omega - \Delta\Omega)t, \tag{1}$$

where E_0, E and the constant magnetic field H_0 (O, O, H_0) are all in the same direction. The carrier frequency Ω is of the order of the electron plasma frequency and is much greater than $\Delta\Omega$, the frequency at which the amplitude of the external high-frequency wave is modulated. The depth of modulation is to be assumed small, i.e., $E \ll E_0$.

The set of equations describing the behavior of an electron plasma in an alternating electric field and a constant magnetic field has the form

$$\left.\begin{aligned} \operatorname{curl} \mathbf{E} &= -\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t}, \\ \operatorname{curl} \mathbf{H} &= \frac{1}{c}\frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi}{c} en\mathbf{V}, \\ \frac{d\mathbf{V}}{dt} &= \frac{e}{m}\mathbf{E} + \frac{e}{mc}[\mathbf{VH}], \\ \frac{\partial n}{\partial t} &+ \operatorname{div}(n\mathbf{V}) = 0. \end{aligned}\right| \tag{2}$$

The equilibrium state is described by the equations

$$\frac{d\mathbf{V}_0(t)}{dt} = \frac{e}{m}\mathbf{E}_0(t); \quad \frac{\partial n_0}{\partial t} = 0. \tag{3}$$

Assuming that the deviations from the unperturbed values of $V_0(t)$, $E_0(t)$, n_0, and H_0 are small, we linearize (2) and write the coordinate dependence of the nonequilibrium quantities as exp(ikr). We consider perturbations propagating along the z axis. It is readily shown that the equations for the longitudinal and transverse waves decouple in this case. The effect of the high-frequency field on the longitudinal waves shows up only as a Doppler shift. For the transverse waves, however, we have

$$\frac{d^2H_\pm(t)}{dt^2} + (\omega_L^2 + c^2k^2)H_\pm(t) \mp i\omega_H\omega_L^2 e^-(t)\, e^{\pm i\omega_H t}\int_{-\infty}^{t} e^+(t_1) H_\pm(t_1)\, e^{\pm i\omega_H t_1} dt_1,$$

$$\left.\begin{aligned} H_\pm(t) &= \frac{H_x(t) \pm iH_y(t)}{\sqrt{2}}, \\ \omega_L^2 = \frac{4\pi e^2 n_0}{m};\quad \omega_H &= \frac{eH_0}{mc};\quad a_0 = \frac{ekE_0}{m\Omega^2};\quad a = \frac{ekE}{m\Omega^2}, \\ e^\pm(t) &= \exp\left\{\pm ik\int_{-\infty}^{t} V_0(t_1)\,dt_1\right\} \\ &= \sum_{n,m,l} J_n(a_0) J_m(a) J_l(a)\, e^{\pm i(m+n+l)\Omega t \pm i(m-l)\Delta\Omega t} \end{aligned}\right\} \tag{5}$$

and $J_n(x)$ is the Bessel function. The condition $\Delta\Omega \ll \Omega$ is used in (5).

We solve Eq. (4) for H_+. By (4) the transition from clockwise helicon waves H_+ to counterclockwise H_- can be effected through the substitution $\omega_H \to -\omega_H$. In what follows we assume everywhere that $a \ll 1$. Retaining first-order terms in a, we obtain the Fourier components $H_p(\omega)$:

$$H_p(\omega) = \int_{-\infty}^{\infty} H_+(t)\, e^{i(\omega + p\Omega)t} dt$$

which are given by the equation

$$\begin{aligned} \{\omega_L^2 + c^2k^2 - (\omega + p\Omega)^2\} H_p(\omega) + \omega_H\omega_L^2 \sum_{n,m} \frac{J_n(a_0) J_m(a_0)}{\omega - \omega_H + (l-n)\Omega} H_{p-n+m}(\omega) \\ = a\omega_H\omega_L^2 \sum_{n,m}\left\{\frac{J_n(a_0) J'_m(a_0)}{\omega_H - \omega - (p-n)\Omega} + \frac{J_m(a_0) J'_n(a_0)}{\omega_H - \omega - \Delta\Omega - (p-n)\Omega}\right\} \\ \times H_{p-n+m}(\omega + \Delta\Omega) + (\Delta\Omega \to -\Delta\Omega). \end{aligned} \tag{6}$$

Here, $J'_n(a_0) = (\partial/\partial a_0)\, J_n(a_0)$, and the second term on the right side of Eq. (6) ($\Delta\Omega \to -\Delta\Omega$) is obtained from the first by replacing $\Delta\Omega$ by $-\Delta\Omega$. Below we restrict the discussion to plasma waves with frequency ω such that

$$|\omega - \omega_l| \ll \Omega.$$

The presence of the small parameter a leads to an equation for $H_0(\omega)$. With p = 0 Eq. (6) contains summations of the form

$$\sum_n J_n(a_0) H_n(\omega) \text{ and } \sum_n J'_n(a_0) H_n(\omega).$$

These summations can be found from the same equation (6) for $p \neq 0$ by multiplying it by $J_p(a_0)$, $J'_p(a_0)$ and then summing over p. Applying the method of successive approximations and retaining terms of first order in a, we obtain the following equation for $H_0(\omega)$:

$$\mathcal{E}(a_0, \omega) H_0(\omega) = \frac{a}{2} \omega_0^2 (a_0, \omega) \frac{\partial}{\partial a_0} \left\{ \frac{\mathcal{E}(a_0, \omega) + \mathcal{E}(a_0, \omega + \Delta\Omega)}{\omega_0 (a_0, \omega)} \right\}$$
$$\times \frac{H_0(\omega + \Delta\Omega)}{\mathcal{E}(a_0, \omega + \Delta\Omega) - \omega_0(a_0, \omega + \Delta\Omega)} + (\Delta\Omega \rightarrow -\Delta\Omega). \tag{7}$$

Here

$$\left.\begin{aligned} \mathcal{E}(a_0, \omega) &= \omega - \omega_H + \sum_n \omega_n (a_0, \omega), \\ \omega_n (a_0, \omega) &= \frac{\omega_H \omega_L^2 J_n^2 (a_0)}{\omega_L^2 + c^2k^2 - (\omega + n\Omega)^2}. \end{aligned}\right\} \tag{8}$$

From Eq. (7), by successive elimination of $H_0(\omega \pm \Delta\Omega)$, $H_0(\omega \pm 2\Delta\Omega)$ etc., on, we can obtain a dispersion relation in the form of an infinite continued fraction.[2] We use the smallness of the parameter a to terminate this fraction; to terms of order a^2 the dispersion relation is

$$\mathcal{E}(a_0, \omega) = a^2 \frac{A(a_0, \omega, \Delta\Omega)}{\mathcal{E}(a_0, \omega) + \Delta\Omega - \omega_0(a_0) + 0(a^2)} + (\Delta\Omega \rightarrow -\Delta\Omega), \tag{9}$$

$$A(a_0, \omega, \Delta\Omega) = \frac{\left\{ \omega_0(a_0) \sum_n \frac{\partial \omega_n(a_0)}{\partial a_0} \left[\mathcal{E}(a_0, \omega) + \frac{\Delta\Omega}{2} \right] \frac{\partial \omega_0(a_0)}{\partial a_0} \right\}^2}{\left(\mathcal{E}(a_0, \omega) - \omega_0(a_0)\right) \left(\mathcal{E}(a_0, \omega) + \Delta\Omega\right)} \tag{10}$$

where $O(a^2)$ denotes terms of order a^2. The derivation of Eq. (9) utilizes the inequality

$$\omega \ll \omega_L. \tag{11}$$

Only if (11) holds can one regard ω_n, defined by expression (8), as independent of ω. For $c^2k^2 \ll \omega_L^2$ this assertion is valid if $c^2k^2 \gg \omega^2$ (it should be remembered that $a_0 \approx (ck/\omega_L)v_0/c$, where $V_0 = eE_0/m\Omega^2 \ll c$). With $a = 0$ we obtain the following solution to the dispersion equation $\mathcal{E}(a_0, \omega^*) = 0$;

$$\omega^* = \omega_H \left\{ 1 - \sum_n \frac{\omega_L^2 J_n^2 (a_0)}{\omega_L^2 + c^2k^2 - n^2\Omega^2} \right\}. \tag{12}$$

The summation in (12) is tabulated in ref. 3.

We seek a solution of Eq. (9) close to ω^*. Let

$$\omega = \omega^* + i\gamma \, (|\gamma| \ll \omega^*); \quad \Delta\Omega = \omega_0(a_0) + \Delta, \tag{13}$$

where the detuning $|\Delta| \ll \omega_0(a_0)$. Under these assumptions the second term on the right side of Eq. (9) is small. We then obtain the growth rate γ:

$$\gamma = \frac{i\Delta}{2} \pm \sqrt{\frac{a^2}{4} \left\{ 2 \sum_n \frac{\partial \omega_n (a_0)}{\partial a_0} - \frac{\partial \omega_0 (a_0)}{\partial a_0} \right\}^2 - \frac{\Delta^2}{4}}. \tag{14}$$

The growth rate is at a maximum when $\Delta = 0$. Recalling the definition of $\omega_n(a_0)$, we find that

$$\gamma_{\max} = \frac{a}{2} \left| \omega_H \sum_n \frac{\omega_L^2}{\omega_L^2 + c^2k^2 - n^2\Omega^2} \frac{\partial}{\partial a_0} \left(2J_n^2(a_0) - \delta_{n0} J_0^2(a_0)\right) \right|, \tag{15}$$

where δ_{n0} is the Kronecker delta.

When $c^2k^2 \lesssim \omega_L^2$ $(a_0 \ll 1)$, we obtain the following expressions for the frequency and the maximum growth rate:

$$\omega^* = \frac{c^2k^2 \omega_H}{\omega_L^2 + c^2k^2}, \tag{16}$$

$$\gamma_{\max} \approx a a_0 \frac{\omega_L^2}{c^2k^2} \left(\frac{1}{2} + \frac{\omega_L^2}{c^2k^2} \right)^2 \omega^*. \tag{17}$$

In order to determine the threshold value of the amplitude of the pump wave at which the instability occurs, it is necessary to take account of dissipative processes. In the cold-plasma limit absorption is determined primarily by particle collisions. In all expressions cited above collisions can be taken into account by making the formal substitution

$$\omega_H \rightarrow \omega_H - i\nu \quad (\nu \ll \omega_H).$$

Here, ν for a fully ionized plasma is the frequency of electron–ion collisions; in the case of a weakly ionized plasma ν is the frequency of electron–neutral collisions.[4]

When $c^2k^2 \lesssim \omega_L^2$, expressions (16) and (17) are valid and we find the threshold amplitude for a nonmonochromatic pump wave

$$\left(\frac{EE_0}{4\pi m n_0 c} \right)_{\text{th}} = 2 \frac{\nu}{\omega_H} \frac{kc \sqrt{\omega_L^2 + c^2k^2}}{2\omega_L^2 + c^2k^2}.$$

We note in conclusion that a corresponding expression for the growth rate can be obtained without imposing condition (11) by starting from Eq. (7) and following a presentation analogous to the above. For example, for $c^2k^2 \gg \omega_L^2$ but $a_0^2 \ll 1$ the frequency $\omega \approx \omega_H$ and can be of the order of ω_L, while the modulation frequency, by (13) and (8), is

$$\Delta\Omega = \frac{\omega_H \omega_L^2}{c^2k^2}$$

and is much smaller than Ω. However, the equations for the determination of the frequency of the natural oscillations and the modulation frequency

$$\mathcal{E}(a_0, \omega^*) = 0 \text{ and } \mathcal{E}(a_0, \omega^* + \Delta\Omega) = \omega_0(a_0, \omega^* + \Delta\Omega)$$

are transcendental in the general case and do not yield analytic expressions for ω^* and $\Delta\Omega$.

Electrical strength of nitrogen and hyrodgen at high pressures

É. A. Avilov and N. V. Belkin

(Submitted June 3, 1973)
Zh. Tekh. Fiz., 44, 2620-2621 (December 1974)

The dependence of the static and pulsed breakdown voltages on pd is investigated in nitrogen and hydrogen in the pressure range 10-90 atm for two-electrode gaps with width up to 1 mm, in homogeneous and inhomogeneous fields. It is shown that the static breakdown voltage is lowered considerably as the field inhomogeneity near the cathode is increased; at lower pressures the breakdown voltage deviates from the linear dependence. When the static voltage is replaced by pulses, the breakdown voltage increases, whereas the departure from Paschen's law appears at higher values of pd. This makes it possible to obtain appreciable overvoltages. For the knife-edge–plane gap the pulse factor is 6.5 in hydrogen at pd ~ 3-6 atm • cm.

Gas-filled, high-pressure discharge tubes have recently become popular in various physical investigations and in the technology of short, high-voltage pulses. Such devices are used for the formation of nanosecond voltage pulses in portable pulsed x-ray generators,[1,2] for laser pumping, for pulsed high-power accelerators, and in other physical apparatus. To reduce inductive losses, the discharge tubes operate at pressures of 50 kg/cm^2 or higher. It is of considerable practical and scientific interest to examine the pulse factor (the ratio of the pulsed to static breakdown voltage) at high pressures and for various electric fields in the interelectrode gap.

In the present work, two-electrode gaps are used; these are plane-parallel electrodes 18 mm in diameter with rounded edges.[3] Knife-edge–plane gaps are also used. In the latter case the edge of a tungsten foil 50 μ thick rolled into a cylinder 8 mm in diameter and 5 mm high serves as cathode. The static breakdown voltage is measured by C-96 and C-100 kilovoltmeters, while the pulses are measured by a C1-26 oscilloscope by means of a capacitive voltage divider connected in parallel with the gap. The rate of rise of the pulse voltage is 100 kV/μsec. The breakdown of the spark gap always takes place on the leading edge of the pulse. The measurements are taken after 100 conditioning switching operations.

Breakdown voltages are measured for a gap width of 0.7-0.9 mm in nitrogen (Fig. 1a) and hydrogen (Fig. 1b). The experimental points are averaged over 30-40 values of the breakdown voltage. The working pressure varies from 10 to 90 atm. Curves 1, 3, 5, of Figs. 1 and 2 correspond to static breakdown voltages. Curves 2, 4, 6 represent pulsed voltages. The electrical strength is obtained for gaps with a smooth cathode (curves 5, 6). When the field inhomogeneity at the cathode is increased, the breakdown voltage diminishes. Gaps with an edge cathode (curves 1, 2) have the lowest electric field; curves 3, 4 correspond to a "ribbed" cathode.[4] When the static voltages are replaced by pulses, the breakdown voltage always increases, independently of the shape of the cathode, while the departure from Paschen's law begins at higher values of pd. For example, for pulsed voltages in nitrogen, the departure from the linear law has not been observed at all (curves 2, 4, 6 on Fig. 1). Thus, in all cases, the pulse factor is larger than unity. Figure 2 shows the dependence of the pulse factor on pd in nitrogen and hydrogen. The value is computed from the data of Fig. 1, a and b. It is seen from Fig. 2 that in nitrogen and hydrogen, in the pressure range of 10-90 atm, the pulse factor for gaps with a smooth cathode does not exceed 1.5, which agrees with the literature.[4] For gaps with an extremely inhomogeneous field of the knife-edge–plane type, the pulse factor attains 6.5.

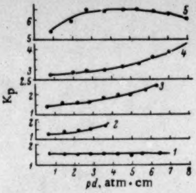

Fig. 2. Dependence of the pulse factor (K_p) on pd, in nitrogen and hydrogen; 1) nitrogen, hydrogen, smooth cathode; 2) nitrogen, "ribbed" cathode; 3) hydrogen "ribbed" cathode; 4) nitrogen, edged cathode; 5) hydrogen, edged cathode.

In this work the high value of the pulse factor is obtained as a result of the substantial lowering of the static breakdown voltage. The low static breakdown voltage can be explained by the action of the prebreakdown currents, which give rise to ionization and the formation of space charge in the gap. The lowest electrical strength appears in the knife-edge–plane gap. For an interelectrode gap of 0.9 mm and static voltage of 60 kV, the prebreakdown cur-

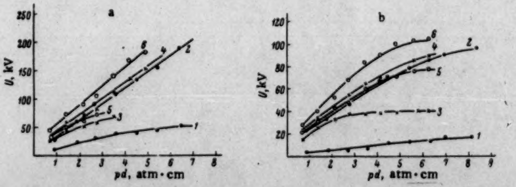

Fig. 1. Dependence of the static and pulsed breakdown voltage on the product of pressure and gap width, in nitrogen (a), hydrogen (b).

rent reaches 450 μA. When pulsed voltages are used the influence of the prebreakdown currents is reduced. Therefore, a higher voltage is required to complete the discharge processes in a short time. The detailed influence of the prebreakdown current on the breakdown voltages of gases at high pressures is considered in ref. 4.

Coherent phase oscillations of electrons in a synchrotron

M. M. Nikitin
Scientific-Research Institute of Nuclear Physics, Electronics, and Automation, Tomsk

(Submitted April 2, 1973; resubmitted October 19, 1973)
Zh. Tekh. Fiz., 44, 2622-2623 (December 1974)

An experimental study is reported of coherent phase oscillations of the center of gravity of an electron beam in a synchrotron. Differences in the interaction of the accelerated bunches with the accelerating system are indicated. Low-frequency relaxation of the bunches is observed. The particle loss caused by the beam oscillations can be eliminated by adjusting the frequencies of the resonator and the rf source.

Coherent oscillations of a beam have previously been observed and studied in storage systems.[1] Oscillations of the beam in the 1.5 GeV synchrotron of the Scientific-Research Institute of Nuclear Physics are observed in the interaction of the electron beam with the accelerating resonator itself at a beam current ~ 20 mA. The shunt resistance of the resonator is 37.5 kΩ, and its Q is 1500 (ref. 2).

The frequency and the changes in the amplitude of the oscillations of the center of gravity of the beam are studied from the synchrotron emission of the electrons; the simple apparatus used for this purpose has an optical filter of inhomogeneous optical density and a photomultiplier; it operates at frequencies up to hundreds of megahertz.[3]

On the oscillogram of the accelerated electron current taken during the acceleration cycle shown in Fig. 1a we see the overall nature of the growth and decay of the radial phase oscillations of the beam. The center of gravity of the bunches is excited at electron energies between 250 and 350 MeV.

The oscillations grow for several milliseconds and lead to a loss of the stored electrons; then the oscillations are quenched. There is an interesting low-frequency relaxation of the natural phase oscillations of the bunches (Fig. 1, b–d). The frequency of this low-frequency relaxation oscillation is proportional to the current of accelerated electrons and is governed by the properties of the accelerating system.

The mechanism for this relaxation is apparently similar to that described in ref. 1. A bunch splits into two parts: One part oscillates at a high amplitude, while the other oscillates at an extremely low amplitude. If the current of the oscillating part is not sufficient to maintain the natural oscillations, these oscillations cease. The bunch comes together again, leading to a repeated growth of the oscillations. This mechanism is illustrated by the oscillogram in Fig. 1d. In most cases the bunch comes together before the natural oscillations of the rapidly oscillating group of electrons are cut off completely.

The experimental frequencies of the coherent phase oscillations for electrons at 300 MeV ($t/T_c = 0.15$) (the energy at which the observations were made) agree with the theoretical value of 79 kHz.

Using an FÉU-30 photomultiplier with a time resolution ~ 2 nsec (the azimuthal dimension of a bunch at ~ 15 nsec), we are able to observe the interaction of the accelerating resonator with each separate bunch simultaneously. For this purpose we used a stepped optical filter, aligned precisely at the center of the beam and transmitting light from only one half of the beam (in the radial direction). It turns out that each of the four bunches in the synchrotron at a given time interacts with the accelerating system in a distinct manner. The differences apparently result from the nonidentical filling of the four separatrices with electrons, the independence of the interactions of the individual bunches with the resonator (when the center of gravity on one bunch reaches its maximum oscillation amplitude, another bunch splits into two parts), and the fact that the coordinates of a given bunch in the cross section of the vacuum chamber can differ slightly from those of other bunches.

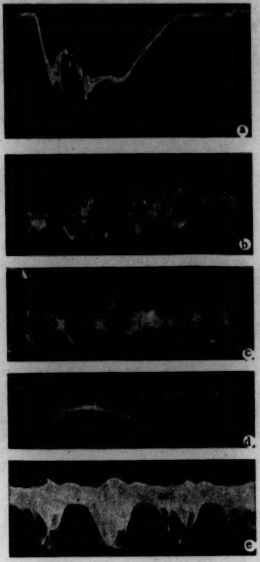

Fig. 1. Oscillograms of the coherent radial phase oscillations of the electrons in the synchrotron. Horizontal scale (msec/div): a) 10; b) 1; c) 0.5; d) 10^{-2}; e) 10^{-3}.

Our experiments showed that the beam oscillations occur primarily on the "unfavorable" slope of the resonance curve of the resonator, i.e., when the resonant frequency of the resonator is higher than the frequency of the rf power source. The natural beam oscillations can also arise on the other slope of the resonance curve, but only if the current of accelerated electrons is several times higher.

Since the accelerator operates unstably under these conditions, we are not able to carry out a detailed study of this case.

Study of the resonance curve of the accelerating resonator shows that there are no parasitic resonances at up to the fourth harmonic of the acceleration frequency. Presumably the bunches also interact with elements of the vacuum chamber and the straight sections of the synchrotron. We have been able to eliminate the particle loss due to natural beam oscillations by tuning the resonator below the frequency of the rf power source, within the range corresponding to nominal conditions for capture of electrons in the acceleration mode.

The author thanks A. N. Didenko for his interest in this work.

Neutral particles from the interaction of laser radiation with a solid target

Yu. A. Bykovskii, N. M. Vasil'ev, I. D. Laptev, and V. N. Nevolin

(Submitted July 23, 1973)
Zh. Tekh. Fiz., 44, 2623-2624 (December 1974)

The characteristics of neutral hydrogen and deuterium atoms formed in the interaction of a single laser pulse with solid targets of zirconium hydride and deuteride are studied. The total number of neutral hydrogen and deuterium atoms is estimated.

Up to the present time investigations of a laser plasma by mass-spectrometer methods have been confined to a study of the ion component. Such important characteristics as the energy and spatial distributions of the ions have been obtained for various flux densities of the laser radiation and for various materials.[1,2] From these studies certain conclusions can be drawn about the processes taking place in a dense high-temperature laser plasma. At the same time the study of the neutrals formed in the interaction of laser radiation with a solid target has not received adequate attention. In our opinion the determination of the velocities, energies, and numbers of these neutrals enables us to draw conclusions about their origin and to supplement the picture of the processes going on in a laser plasma.

Such investigations can also have practical value. Up to the present time mass-spectrometer methods of gas analysis with laser probing of the specimens under study have operated with the lasers in the free running mode.[3] For this reason the amount of material evaporated varies greatly from burst to burst and the results are not reproducible. In the interaction of a giant pulse of radiation the amount of material evaporated depends on the radiation flux density and not on the properties of the irradiated solid. Thus the use of giant pulses for probing specimens significantly increases the reproducibility of the mass-spectrometer analysis of gases.

The neutrals are studied with an MSX-3A time-of-flight mass spectrometer. The ejection pulse of the ion source is delayed relative to the laser pulse up to 2000 μsec. With this experimental arrangement for a single triggering the time of arrival of the neutrals in the mass spectrometer ion source can be determined and their velocity, mass, and energy can be measured. The distance between the irradiated solid and the ion source of the mass spectrometer is ~ 33 cm. The Nd : glass laser has the following parameters: energy per pulse ~ 1 J, $\tau \approx 20$ nsec. The targets are zirconium hydride and deuteride. The radius of the focal spot is $\sim 200\ \mu$. The experiments are performed in a vacuum of $5 \cdot 10^{-6}$ torr.

The results of the experiments with neutral hydrogen atoms formed in the interaction of the laser radiation with the target of zirconium hydride are shown in Fig. 1. The energy of the ionizing electrons in the mass spectrometer source is 50 eV, which corresponds to the maximum of the effective ionization cross section of a hydrogen atom.[4]

The velocity distribution of hydrogen atoms is regular and its maximum corresponds to a velocity of $\sim 3.5 \cdot 10^6$ cm/sec (~ 6.4 eV). The error in determining the amplitude is ± 10%. The distribution of deuterium atoms is similar in character.

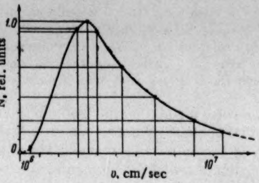

Fig. 1. Velocity distribution of neutral hydrogen atoms.

Using the parameters of our experiment the temperature of the hydrogen plasma formed in the interaction of the laser radiation with the target is estimated with the equations of ref. 5 as ~ 5.6 eV.

The number of detected neutral atoms of hydrogen and deuterium is estimated by admitting helium into the analytic volume through a flow regulator at a rate of $\sim 4.2 \cdot 10^{-5}$ liter/μsec. In doing this the specific form of the dependence of the total effective ionization cross sections of H, D, and He atoms is taken into account. The measured number of hydrogen and deuterium atoms formed by the action of the laser radiation on zirconium hydride and deuteride is $\sim 10^{16}$. This value is in good agreement with the total number of atoms evaporated by laser radiation with our experimental parameters interacting with a solid target.

Our results appear to indicate that the detected neutral hydrogen and deuterium atoms result from recombinations.

Thus a laser plasma can serve as an intense source of high-energy neutrals which can be used to study atomic collision processes.

Certain integral relations in the kinetic theory of gases

S. P. Bakanov

Institute of the Problems of Mechanics, Academy of Sciences of the USSR, Moscow

(Submitted November 19, 1973; resubmitted April 9, 1974)
Zh. Tekh. Fiz., 44, 2625-2529 (December 1974)

In solving a number of problems in the kinetic theory of gases by the moment method it is necessary to evaluate certain moments of the Boltzmann collision integral, a task which many authors regard as the most laborious part of solving the problems. A systematic method for evaluating these moments directly was developed by Uhlenbeck and Wang Chang;[1] in principle this enables one to solve a broad class of kinetic theory problems. The practical application of this method,[1] however, requires very laborious calculations and offers no way of checking the results. The authors[1] themselves have made mistakes in evaluating certain moments. Most important, in a number of cases the use of these moments leads to results which exceed the accuracy of the theory and to the prediction of nonphysical effects.

It is shown in refs. 2 and 3 on the basis of physical considerations that certain relations can be established among the moments of the collision integral. These relations simplify the calculation of the moments, determine the correctness of published calculations, and ensure that the solution corresponds to physical reality.

Without calculating these directly[1] we present another method of evaluating certain moments of the collision integral which has the same three attributes as the relations mentioned above.

1. We consider the Boltzmann equation in the Chapman–Enskog form[4]

$$f^{(0)}\left[\left(c^2-\frac{5}{2}\right)c_i\frac{\partial \ln T}{\partial r_i}+2\left(c_ic_j-\frac{1}{3}\delta_{ij}c^2\right)\frac{\partial c_{0i}}{\partial r_j}\right]=n^2I(\varphi).$$

This equation has a solution of the form

$$\varphi=-\frac{1}{n}\left[A_i\frac{\partial \ln T}{\partial r_i}+B_{ij}\frac{\partial c_{0i}}{\partial r_j}\right], \tag{1}$$

where

$$A_i=\sum_{r=1}^{\infty}a_2a_i^{(r)}=\sum_{r=1}^{\infty}a_2S_{\frac{3}{2}}^{(r)}(c^2)\,c_i, \tag{2'}$$

$$B_{ij}=\sum_{r=0}^{\infty}b_{r+1}b_{ij}^{(r)}=\sum_{r=0}^{\infty}b_{r+1}S_{\frac{5}{2}}^{(r)}(c^2)\,(c_ic_j-\delta_{ij}c^2), \tag{2''}$$

where a_r and b_{r+1} are quantities that depend on the nature of the molecular interaction. Within the framework of a theory which is linear in the derivatives $\partial T/\partial r$ and $\partial c_{0i}\cdot\partial r_j^{-1}$ the method of successive approximations consists of taking account of one, two, etc. terms in expansion (2) in Laguerre–Sonine polynomials. For any model of the molecular interaction, in the single-polynomial approximation solution (1) has the form

$$\varphi=-\frac{1}{n}\left[a_1\left(\frac{5}{2}-c^2\right)c_i\frac{\partial \ln T}{\partial r_i}+b_1\left(c_ic_j-\frac{1}{3}\delta_{ij}c^2\right)\frac{\partial c_{0i}}{\partial r_j}\right], \tag{3}$$

where the coefficients a_1 and b_1 are connected by the relation

$$-4a_1=3b_1. \tag{4}$$

In applications the specification of a molecular interaction leads to the calculation of a_1 and b_1. Thus, for the hard sphere model

$$b_1=\frac{5}{4}\sqrt{\pi}\lambda, \tag{5}$$

λ is the mean free path of the molecules; for Maxwellian molcules

$$b_1=\frac{4}{3}\left(\frac{m}{2k}\right)^{1/2}\frac{1}{\pi A_2(5)},\quad A_2(5)=0.436.$$

We consider the two-dimensional isothermal shear flow of a gas along the z axis ($\partial T/\partial r_i = 0$). Taking account of (3) we write the Boltzmann equation as

$$2c_xc_z=b_1I(c_xc_z).$$

We take the c_x sign $c_{x1}c_xc_{z1}c_zc^2$ sign c_x, and c_xc^2 sign c_x moments[1)] of this equation. On the right-hand side we obtain the moments of the collision integral which we seek:

$$\left.\begin{aligned}I_2&=[c_xc_{z1}c_z\operatorname{sign}c_x],\\ I_3&=[c_xc_{z_1}c_xc_z],\\ I_6&=[c_xc_{z_1}c_x^2c_z\operatorname{sign}c_x],\\ I_{15}&=[c_xc_{z_1}c_zc^2\operatorname{sign}c_x].\end{aligned}\right\} \tag{6}$$

The integrals on the left-hand side can be evaluated by elementary methods. As a result we have

$$\left.\begin{aligned}I_2&=-\frac{\pi}{b_1},\\ I_3&=-\frac{\frac{\pi\sqrt{\pi}}{2}}{b_1},\\ I_6&=-\frac{\pi}{b_1},\\ I_{15}&=-\frac{3\pi}{b_1}.\end{aligned}\right\} \tag{7}$$

We now consider the state of the gas when there is a temperature gradient

$$\frac{\partial T}{\partial r_i}=\frac{\partial T}{\partial z},\quad \frac{\partial c_{0i}}{\partial r_j}=0.$$

We have

$$\left(\frac{5}{2}-c^2\right)c_z=a_1I\left[\left(\frac{5}{2}-c^2\right)c_z\right].$$

We take the c_xc_z sign $c_{x1}c_z(5/2-c^2)$ moments. A simple calculation gives

$$\left.\begin{aligned}I_{11}&=\left[\left(\frac{5}{2}-c^2\right)c_{z_1}c_xc_z\operatorname{sign}c_x\right]=-\frac{\pi}{4a_1},\\ I_{13}&=\left[\left(\frac{5}{2}-c^2\right)c_{z_1}\left(\frac{5}{2}-c^2\right)c_z\right]=\frac{5\pi\sqrt{\pi}}{4a_1}.\end{aligned}\right\} \tag{8}$$

A comparison of Eqs. (7) and (8), taking account of

(4), shows that the following relations hold among the moments of the collision integral, independently of the assumed molecular interaction model:

$$\left.\begin{aligned} I_2 = I_8 = \frac{2}{\sqrt{\pi}} I_3, \\ I_{15} = 3I_2, \\ I_{11} = -\frac{1}{5\sqrt{\pi}} I_{13} = -\frac{1}{3} I_2. \end{aligned}\right\} \quad (9)$$

The moment

$$I_{12} = \left[c_z c_{z_1}, \left(\frac{5}{2} - c^2\right) c_z \operatorname{sign} c_x\right]$$

is also encountered in applications. It is easy to see that it satisfies the equality

$$I_{12} = -\frac{1}{2} I_2. \quad (10)$$

Equations (9) and (10) are a consequence of the single-polynomial approximation in expansion (1), which is satisfied with various degrees of accuracy for various molecular interaction models; for Maxwellian molecules it is satisfied exactly. It should be noted that the method of half-range expansions proposed by Yvon[5] and developed in the kinetic theory of gases by Gross, Jackson, and Ziering,[6] does not really fall outside the limits of the single-polynomial expansion. In higher approximations the method is unjustifiably complicated and no publications of such work are known to the author. Therefore in solving boundary-value problems by the Gross, Jackson, and Ziering (GJZ) method the failure to satisfy Eqs. (9) and (10) must be considered an excess of accuracy (cf. refs. 2, 3, 7, 8).

Thus the values of certain moments of the linearized Boltzmann collision integral can be established without a direct rather cumbersome calculation. These values are exact for Maxwellian molecules. For other molecules the accuracy depends on the limits of applicability of the single-polynomial approximation in the expansion by the Chapman–Enskog method. It should be emphasized, however, that in a number of cases the more accurate values used in numerous publications lead to the prediction of effects which really do not exist. As a rule this is a result of simply exceeding the accuracy of the theory.

Let us point out, finally, that the scheme we have described satisfies the following physical requirement:[2] In solving kinetic theory boundary-value problems the correct limiting transition is ensured in the body of the gas far from the walls.

2. By using Eqs. (9) and (10) we can simplify considerably the procedure for solving kinetic theory boundary-value problems by the GJZ method. We demonstrate the practical realization of the proposed procedure by the example of a Couette flow.

We consider the symmetric Couette problem. The distance between the plates is 2L. The upper plate moves along the z axis with a velocity −u/2, and the lower plate with a velocity + u/2. The x axis is normal to the plates.

The linearized Boltzmann equation has the form

$$c_x \frac{\partial \varphi}{\partial x} = I(\varphi). \quad (11)$$

We seek a solution in the form

$$\varphi^{\pm} = c_z (a_0^{\pm} + a_1^{\pm} c_x).$$

Taking the $c_z(1 \pm \operatorname{sign} c_x)$ and $c_x c_z(1 \pm \operatorname{sign} c_x)$ moments of Eq. (11) we obtain a system of linear differential equations for the expansion coefficients $a_i^{\pm}(x)$:

$$\left.\begin{aligned} \pi \frac{\partial}{\partial x}\left(\pm a_0^{\pm} + \frac{\sqrt{\pi}}{2} a_1^{\pm}\right) = \pm (a_0^+ - a_0^-) I_1 \pm (a_1^+ + a_1^-) I_2, \\ \pi \frac{\partial}{\partial x}\left(a_0^{\pm} \frac{\sqrt{\pi}}{2} \pm a_1^{\pm}\right) = (a_0^+ - a_0^-) I_2 + (a_1^+ + a_1^-) I_3 \pm (a_1^+ - a_1^-) I_4. \end{aligned}\right\} \quad (12)$$

The notation is standard (cf., e.g., ref. 2). Adding and subtracting pairs of Eqs. (12) and introducing the notation

$$a_0^+ + a_0^- = x_1, \quad a_1^+ + a_1^- = x_3,$$
$$a_0^+ + a_0^- = x_2, \quad a_1^+ - a_1^- = x_4,$$

we obtain

$$\left.\begin{aligned} \frac{\partial}{\partial x}\left(x_2 + \frac{\sqrt{\pi}}{2} x_3\right) = 0, \\ \frac{\pi}{2} \frac{\partial}{\partial x}\left(x_1 + \frac{\sqrt{\pi}}{2} x_4\right) = I_1 x_2 + I_2 x_3, \\ \frac{\pi\sqrt{\pi}}{4} \frac{\partial}{\partial x}\left(x_1 + \frac{2}{\sqrt{\pi}} x_4\right) = I_2 x_2 + I_3 x_3, \\ \frac{\pi\sqrt{\pi}}{4} \frac{\partial}{\partial x}\left(x_2 + \frac{2}{\sqrt{\pi}} x_3\right) = I_4 x_4, \end{aligned}\right\} \quad (13)$$

where the first of Eqs. (13) expresses the obvious law of the constancy of stress in the space between the plates.

By using (9) system (13) is reduced to a set of two differential equations:

$$\left.\begin{aligned} \frac{\partial}{\partial x} x_4 - a_{31} x_3 = -a_{31} \frac{2}{\sqrt{\pi}} A, \\ \frac{\partial}{\partial x} x_3 = a_{11} x_4; \end{aligned}\right\} \quad (14)$$

the other two can be integrated at once:

$$\left.\begin{aligned} x_2 + \frac{\sqrt{\pi}}{2} x_3 = A, \\ x_1 + \frac{2}{\sqrt{\pi}} x_4 = \frac{4}{\pi\sqrt{\pi}} I_2 A x + B. \end{aligned}\right\} \quad (15)$$

Here, we have introduced the notation

$$a_{11} = -\frac{8}{\pi(\pi - 4)} I_4 \quad a_{31} = -\frac{4\sqrt{\pi}}{\pi(\pi - 4)}\left(I_2 - \frac{\sqrt{\pi}}{2} I_1\right).$$

Finally by making the substitution $x_3^* = x_3 - (2/\sqrt{\pi})A$ we obtain

$$\left.\begin{aligned} \frac{\partial x_4}{\partial x} - a_{31} x_3^* = 0, \\ \frac{\partial x_3^*}{\partial x} - a_{11} x_4 = 0, \end{aligned}\right\} \quad (16)$$

i.e.,

$$x_3^* = \beta_{11} e^{\alpha x} + \beta_{12} e^{-\alpha x},$$
$$x_4 = \beta_{21} e^{\alpha x} + \beta_{22} e^{-\alpha x},$$

where

$$a = -\frac{4}{\pi(\pi-4)}\sqrt{2\sqrt{\pi}\, I_4\left(\frac{\sqrt{\pi}}{2} I_1 - I_2\right)}.$$

Substitution of the particular solution into one of Eqs. (16) gives

$$\beta_{21} = -\frac{a_{31}}{a}\beta_{11}.$$

Using the symmetry conditions

$$a_0^+(x) = -a_0^-(-x),$$
$$a_1^+(x) = a_1^-(-x)$$

and the boundary conditions

$$a_0^-(L) = -\varepsilon u_0 + (1-\varepsilon)\, a_0^+(L),$$
$$a_1^-(L) = -(1-\varepsilon)\, a_1^+(L),$$

we obtain B = 0, $\beta_{11} = \beta_{12}$, $\beta_{21} = -\beta_{22}$,

$$x_3^*(x) = 2\beta_{11}\,\mathrm{ch}\, ax,$$

$$x_4(x) = -2\frac{a_{31}}{a}\beta_{11}\,\mathrm{sh}\, ax,$$

$$x_2(L) = \frac{\varepsilon}{2-\varepsilon}\left[x_1(L) + 2u_0\right],$$

$$x_3^*(L) + \frac{2}{\sqrt{\pi}}A = \frac{\varepsilon}{2-\varepsilon}x_4(L).$$

From the last two equations we find the constants

$$\beta_{11} = -\frac{2}{\sqrt{\pi}}\frac{\varepsilon}{2-\varepsilon}\frac{u_0}{D},$$

$$A = \frac{2}{\sqrt{\pi}}\frac{\varepsilon}{2-\varepsilon}\frac{u_0}{D}\left(\mathrm{ch}\, aL + \frac{\varepsilon}{2-\varepsilon}\frac{a_{31}}{a}\,\mathrm{sh}\, aL\right),$$

where

$$D = -\frac{\varepsilon}{2-\varepsilon}\frac{4I_2L}{\pi^3}\left(\mathrm{ch}\, aL + \frac{\varepsilon}{2-\varepsilon}\frac{a_{31}}{a}\,\mathrm{sh}\, aL\right) + \frac{1}{\sqrt{\pi}}\left(\mathrm{ch}\, aL + \frac{\varepsilon}{2-\varepsilon}\frac{a_{31}}{a}\frac{4}{\pi}\,\mathrm{sh}\, aL\right),$$

$u_0 = u(m/2kT)^{1/2}$ is the dimensionless relative velocity of the plates. Finally the rate of flow of the gas is given by

$$q_x(x) = \frac{1}{8}\sqrt{\frac{8kT}{\pi m}}\left(\sqrt{\pi}x_1 + x_4\right)$$
$$= \frac{1}{2\pi}\sqrt{\frac{8kT}{\pi m}}\frac{\varepsilon}{2-\varepsilon}\frac{u_0}{D}\left[\frac{2I_2x}{\sqrt{\pi}}\left(\mathrm{ch}\, aL + \frac{\varepsilon}{2-\varepsilon}\frac{a_{31}}{a}\,\mathrm{sh}\, aL\right) - \frac{a_{31}}{a}\,\mathrm{sh}\, aL\right],$$

which agrees with the result obtained in ref. 3.

The author thanks V. V. Struminskii for helpful comments.

[1)] By the A(c) moment of the function $\Phi(c)$ we mean the integral $\int A(c)\,\Phi(c)\, e^{-c^2} d^3c$ over all values of the velocities.

The neutral layer in a collisionless plasma is shown experimentally to be unstable against the connection of magnetic lines of force. The characteristic time of the process is consistent with the development of the collisionless tearing mode.

The structure of magnetic force lines in a neutral plasma layer is important in connection with a number of astrophysical phenomena, e.g., solar flares, the interaction of the solar wind with the magnetosphere, the geomagnetic tail of the earth. The same problem is encountered in plasma confinement in the belt-pinch or the tokamak.[1,2]

We present below the results of direct measurements of the vector magnetic field in a collisionless neutral layer. The experiment is performed in the UN-Phoenix device[3,4] (Fig. 1). A hydrogen plasma ($n_0 = 10^{12}$–10^{14} cm^{-3}, T_0 = 1-5 eV) in a cylindrical glass chamber (l = 100 cm, ϕ = 16 cm) is located in a quasistationary homogeneous magnetic field ($H_0 = 10^2$–10^3 Oe, τ = 1500 μsec) directed along the axis of the system and is compressed by a cylindrical magnetic piston $H^{\sim}$ produced by means of a shock loop 30 cm long. The field of the piston increases sinusoidally ($H^{\sim}_{\max}$ = 1300 Oe, τ = 1.3 μsec) and is opposite to H_0. The initial parameters of the plasma, its density and temperature, are monitored by means of a triple Langmuir probe.

The disturbance of the magnetic field in the plasma accompanying the compression of the latter is recorded by magnetic probes (3 mm diameter). Figure 2 shows the axial magnetic field distribution H_z at times after the start of the process. In the initial stage, when $|H^{\sim}| \leqslant |H_0|$, a rarefaction wave propagates into the plasma. Compression of the plasma occurs when $|H^{\sim}| > |H_0|$, at which point a neutral layer is found; it consists of a cylindrical current layer within which the magnetic field H_z changes sign. When the value of the magnetic piston becomes greater than $2H_0$ a compression shock is formed in front of the neutral layer.[4]

Measurements show that the neutral layer tends towards a state in which the magnetic pressures on the boundaries of the layer are equal, the radial dimension of the layer amounting to (6-10)c/ω_0 for the entire range of initial plasma densities (ω_0 is the electron plasma frequency, c is the velocity of light). The measurements, made with local magnetic probes described in ref. 5, show that the electron temperature T_e in front of the neutral layer reaches 20-40 eV. This temperature is achieved by the dissipation of the energy of the azimuthal current in the anomalous resistance of the plasma in the rarefaction wave[3] and, in the succeeding stage, in the shock wave.[4,5] The Coulomb mean free path for $T_e \geqslant$ 20 eV is greater than the diameter of the plasma volume, so that the plasma can be regarded as collisionless as far as the processes occurring in the layer are concerned.

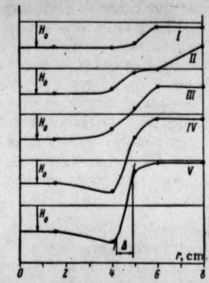

Fig. 2. Formation of neutral layer in plasma. H_0 = 430 Oe, $n_0 = 10^{13}$ cm^{-3}, t (nsec): I) 50; II) 150; III) 250; IV) 350; V) 450.

The axial structure of the magnetic field is investigated using a system of magnetic probes parallel to the axis of the plasma volume and 4 cm from it. The probes

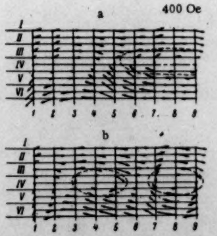

Fig. 3. Axial structure of magnetic field at different times. The origin is taken to be the time at which the region with H_z = 0 passes the probes. Numerals 1-9 denote the positions of the magnetic probes. The first probe is located at the edge of the shock loop. a) H_0 = 300 Oe, $n_0 = 1.8 \cdot 10^{12}$ cm^{-3}, layer velocity $u \doteq 3.3 \cdot 10^7$ cm/sec; b) H_0 = 300 Oe, $n_0 = 2.4 \cdot 10^{13}$ cm^{-3}, u = $1.3 \cdot 10^7$ cm/sec. Time t (nsec): I) –100; II) –60; III) –20; IV) 20; V) 60; VI) 100.

are spaced 2 cm from each other. The radial H_r and axial H_z components at each point are recorded. It is found that in the vicinity of the neutral layer, where $H_z = 0$, a radial field H_r appears which reaches a value of $(0.2\text{–}0.3) \cdot H_b$ (where H_b is the magnetic field at the boundary of the current layer). The behavior of the vector magnetic field as the neutral layer passes the probes is shown in Fig. 3 for two different plasma densities. The structure of the layer is symmetric about the midplane of the shock loop; accordingly, we show in Fig. 3 only the region from the edge of the shock loop to its midplane. The variation in magnitude and direction of the vector magnetic field along the layer can be regarded as being due to the connection of lines of force, which leads to the disintegration of the neutral layer into ring currents. Regions with these currents are indicated in Fig. 3 by the dashed lines. The number, dimensions, and relative location of these ring currents within the layer depend on the initial parameters of the plasma. Thus, a decrease in the initial density n_0 is accompanied by an increase in the width of the layer Δ and by an increase in the axial dimension of the regions with ring currents.

The initial stage of the process is studied using balanced magnetic H_z probes (similar to those used by Green[6]) located outside the plasma volume. It is found with the aid of these probes that the initially monotonic axial magnetic field at the boundary of the plasma volume exhibits a spatial modulation after the appearance of the neutral layer, the amplitude of these modulations reaching $\sim 0.1H^{\sim}$. The growth time of these oscillations $\tau = 30\text{–}50$ nsec. As the appearance of this modulation is associated with the formation of the neutral layer and as the spatial location of the maxima correlates with the position of the above-described current rings, it is reasonable to relate the modulation with the connection of lines of force in the plasma.

Our experimental data are consistent with the results of theoretical calculations on the tearing instability, which show that the lines can link up because of the violation of trapping within the layer due to the finite conductivity of the plasma or the finite Larmor radius of the particles.

The growth rate γ_r of the resistive tearing instability has been obtained by Furth et al.[7] An estimate of the conductivity σ in the neutral layer from the time delay of the signals from a local diamagnetic probe by the method described in ref. 5 gives a value $\sigma \sim 10^{13}$ sec^{-1}. Then $\gamma_r \lesssim 1/\tau$. We note that σ is much smaller than the Coulomb conductivity, which indicates its anomalous nature.

The growth rate of the collisionless tearing instability is obtained by Laval et al.[8] For our conditions, taking for T_e the estimate $T_e \simeq H_b^2/8\pi n$ (which is supported by the readings of local diamagnetic probes) we find that $1/\gamma \lesssim 5$ nsec. Accordingly, $\tau \sim 10/\gamma$, which makes the collisionless tearing instability the more likely mechanism.

In conclusion we should like to thank R. Z. Sagdeev for suggesting the problem, and R. Kh. Kurtmullaev and A. M. Fridman for their interest.

A further analysis of the results obtained in ref. 1 reveals that we have made an error: A surface integral was unjustifiably omitted from integral equation (10). When this surface integral is taken into account the original integral equation becomes

$$
\begin{aligned}
\mathbf{E} = {}& \mathbf{E}_0 + \frac{\varepsilon-1}{4\pi}\left(\operatorname{grad}\operatorname{div} - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)\frac{\partial^2}{\partial t^2} \\
& \times\Bigg[\int\limits_{-\infty}^{\infty} dt' \int\limits_{V(t')} \frac{\tau-\frac{1}{c}R}{R}\, h \Bigg\{\mathbf{E} - c\mathbf{E}\int\limits_{-\infty}^{t'} \nabla\beta\, dt'' \\
& - c\left[\operatorname{curl}\beta \int\limits_{-\infty}^{t'} \mathbf{E}\,dt\right] - c\nabla\beta \int\limits_{-\infty}^{t'} \mathbf{E}\,dt'' + 2c\left(\int\limits_{-\infty}^{t'} \mathbf{E}\,dt''\nabla\right)\beta\Bigg\} d\mathbf{r}' \\
& - \operatorname{grad}\int\limits_{-\infty}^{\infty} dt' \int\limits_{V(t')} \frac{\tau-\frac{1}{c}R}{R}\, hc\beta \int\limits_{-\infty}^{t'} \mathbf{E}\,dt''\,d\mathbf{r}' \\
& + \operatorname{curl}\int\limits_{-\infty}^{\infty} dt' \int\limits_{V(t')} \frac{\tau-\frac{1}{c}R}{R}\, h \Bigg\{\left[c\beta \int\limits_{-\infty}^{t'} \mathbf{E}\,dt''\right] \\
& + c\int\limits_{-\infty}^{t'} [\beta\mathbf{E}]\,dt''\Bigg\} d\mathbf{r}''\Bigg] - \frac{\varepsilon-1}{4\pi}\left(\operatorname{grad}\operatorname{div} - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)\frac{\partial^2}{\partial t^2} \\
& \times \int\limits_{-\infty}^{\infty} dt' \int\limits_{S(t')} \frac{\tau-\frac{1}{c}R}{R}\, h \Bigg\{\left(c\beta\int\limits_{-\infty}^{t'} \mathbf{E}\,dt''\right)\mathbf{n} + \left[\left[\int\limits_{-\infty}^{t'} \mathbf{E}\,dt\,c\beta\right]\mathbf{n}\right]\Bigg\} ds. \qquad (10)
\end{aligned}
$$

All of the equations which follow from Eq. (10) must be corrected accordingly. In particular, the internal field in the case of the scattering of a wave by a sphere of variable radius in the quasistatic case is described by a revision of Eq. (13):

$$
\mathbf{E} = \left[\frac{\varepsilon+2}{3} - (\varepsilon-1)\,\xi(t)\right]^{-1}\mathbf{E}_0(t). \qquad (13)
$$

The resonant properties of the pulsating sphere are manifested in the behavior of the field amplitude averaged over a period. However, the resonant increase in the amplitude of the internal field obtained in the quasistatic approximation in ref. 1 does not occur.
